Motivated by applications in online marketplaces such as ridesharing, we study dynamic pricing and matching in two-sided queues with strategic servers. We consider a discrete-time process in which, heterogeneous customers and servers arrive. Each customer joins their type’s queue, while servers might join a different type’s queue depending on the prices posted by the system operator and an inconvenience cost. Then the system operator, constrained by a compatibility graph, decides the matching. The objective is to maximize the profit minus the expected waiting times. We develop a general framework that enables us to analyze a broad range of strategic behaviors. In particular, we encode servers’ behavior in a properly defined cost function that can be tailored to various settings. Using this general cost function, we introduce a novel probabilistic fluid problem as an infinite dimensional optimization program. The probabilistic fluid model provides an upper bound on the achievable profit. We then study the system under a large market regime in which the arrival rates are scaled by $\eta$ and present a probabilistic two-price policy and a max-weight matching policy which results in $O(\eta^{1/3})$ profit-loss. In addition, under a broad class of customer pricing policies, we show that any matching policy has profit-loss $\Omega(\eta^{1/3})$. Conditional on a given expected waiting time, we also establish scale-free lower and upper bounds for the profit. Our asymptotic analysis provides insights into near-optimal pricing and matching decisions, and our scale-free bounds provide insights into how different service levels impact the firm’s profit.

Additional Key Words and Phrases: queueing games, max-weight matching, dynamic pricing, two-sided queues, ridesharing

ACM Reference Format:

1 INTRODUCTION
The rise of the gig economy has brought dynamic pricing and matching to the foreground of two-sided markets. Ridesharing and meal delivery platforms such as Uber, Lyft, or Doordash adjust these levers so as to maintain a reliable system operation and manage their revenue. Dynamic pricing and matching are essential for these markets as they determine not only the demand response but also the behavior of strategic heterogeneous supply agents. A fundamental issue that emerges in this context, however, is the misalignment of supply and demand preferences (or types). At any given time, a supply unit might not be compatible with a specific type of demand request. To mitigate this, in addition to implementing dynamic pricing and matching, some platforms have

designed their market to give supply units the option of reporting their type. In ridesharing, for example, drivers have the ability to set a specific destination (such as their home or their children’s school)—effectively filtering the trips they are willing to serve—and the platform will match them with riders going in that direction. However, this can lead to undesirable outcomes because supply agents might misreport their types in order to boost their earnings. Indeed, highly profitable destinations such as airports or concert venues are widely preferred by drivers in the ridesharing market. This can negatively impact the performance of such systems by reducing the availability of agents that are willing to serve other trips. The goal of this paper is to provide a framework to analyze and characterize the optimal dynamic pricing and matching decisions in a two-sided market in which supply units strategically report their type to the system operator.

We consider a general two-sided queueing system with strategic servers and customers arriving stochastically in a discrete time setting. Servers and customers have different types and their compatibility is captured by a bipartite graph. In each time period, the system operator posts a price for each type of customer and server. This leads to a fraction of customers and servers accepting the price and joining the system. Each customer entering the system pays the price posted by the system operator. Meanwhile, servers can misreport their type in order to maximize their utility, which is given by the price of the reported type minus a type-specific inconvenience cost. At the end of a time period, the system operator, constrained by the compatibility graph, decides which server-customer pairs to match, and the matched pairs depart from the system.

The system operator’s objective is to formulate a pricing and matching policy so that the difference of the long-run profit obtained by the system operator and the long-run cost incurred due to waiting times is maximized. To analyze the system, for a given policy, we consider a large market regime in which all the arrival rates are scaled by $\eta \to \infty$. Under this asymptotic regime, any policy that is $o(1)$ within the optimal objective is optimal.

1.1 Main Contributions

We develop a general discrete-time, game-theoretical, stochastic framework to study pricing and matching decisions in two-sided markets. In line with our ridesharing motivation, supply agents can strategically misreport their type while demand agents report their type truthfully. The main challenge in this problem is that the selfish behavior of servers leads to correlated arrival rates across different types of servers. In particular, if the price for one type of server changes, the arrival rates of all types of servers are affected. In turn, we show that the inherent game-theoretical nature of the problem leads to a combinatorial problem formulation.

To tackle this challenge, we synthesize the strategic behavior of servers via a judiciously defined cost function that corresponds to the total price paid to the servers by the system operator. We formulate this function as an optimization problem with equilibrium constraints for a broad range of strategic behaviors that servers might exhibit. Indeed, the generality of this formulation enables us to encompass different scenarios: 1) selfish servers maximizing their own utility, 2) a system in which incentive compatibility (truthful) constraints must be satisfied, 3) a partially incentive-compatible system such that at least a fraction of servers are truthful, and 4) a non-game theoretic model in which servers always report truthfully (c.f. [28]). We present relations between these models using simulations and theoretical results.

Under a general cost function, we present the first-order approximation of the system as a probabilistic fluid problem. Our fluid problem is novel in that it allows for probabilistic pricing policies given by probability measures defined over the set of feasible prices. In turn, our fluid problem is an infinite dimensional optimization problem. We begin the analysis by providing structural properties for the probabilistic fluid problem. First, we establish that its optimal value provides an upper bound on the profit obtained under any policy. We then present conditions under which
the probabilistic fluid problem is equivalent to a standard fluid problem, that is, conditions under which the optimal probability measure is a Dirac measure. We compare the optimal fluid objective with different cost function models using simulations.

Finally, we develop a simple probabilistic two-price policy and max-weight matching policy which attains the fluid upper bound asymptotically with $O(\eta^{1/3})$ rate of convergence. An interesting feature of the matching policy is that it doesn’t use the solution of the fluid problem. Instead, it follows state-dependent matching decisions. The pricing policy is an $\epsilon$ perturbation of the one prescribed by the fluid problem. It is probabilistic and state-independent for servers, and a dynamic two-price policy for customers. We also show that under a broad class of customer pricing policies, any matching policy will result in $\Omega(\eta^{1/3})$ profit loss. In addition, under the probabilistic two-price policy, given a desired expected queue length, we present scale-free bounds on the achievable profit. This provides insights on the attainable profit for a firm given a desired service level.

1.2 Literature Review

![Fig. 1. Overview: Literature Review.](image)

In this paper, we consider dynamic pricing and matching for two-sided queues with servers as individual decision makers. We discuss each of these separately.

1.2.1 Two-Sided Queues. Different variants of two-sided queues were studied in the literature. [6] pointed out that a two-sided queue is fundamentally unstable. They analyzed a two-sided queueing model given by a bipartite graph and deduced necessary conditions on the arrival rates for stability. The results were extended by [1]. [9] considered a more general model of two-sided queues: matching queues, which is a multi-sided queue. They presented a matching policy and proved that it is asymptotically optimal with rate of convergence $O(\eta^{1/2})$ where arrival rates are scaled by $\eta$. [19] considered a two-sided queueing model with server arrivals by invitation and also allowed customers and servers to abandon the system. There are numerous applications of two-sided queues, such as routing cryptocurrency in payment processing networks [29], ridesharing systems [4] and [5], general setting of dynamic matching markets [2], and dynamic barter exchange [3].

1.2.2 Dynamic Pricing. Dynamic pricing is a fundamental problem in the revenue management literature [27]. In the context of queueing theory, different models have been considered in [17], [16], [7], and [23]. The main results in these paper present different structural properties of the optimal pricing policy by studying the underlying control problem. Some of the papers involving dynamic pricing which are closely related to our work are presented in detail below.

[22] consider the joint problem of dynamic pricing and matching in a general setting. Their objective is to maximize the total number of matches in a finite time. They consider the same asymptotic regime as ours and provide asymptotically optimal policy but do not provide the rate
of convergence to the optimum. The setting of joint optimization of pricing and matching decisions was also considered in [21] and they also allowed the servers to be strategic.

[14] consider the fundamental problem of dynamic pricing on an M/M/1 queue. They consider customers joining the system depending on the offered price and their waiting times. The objective is to maximize the profit of the system operator. They present an asymptotically optimal pricing policy and also provide the rate of convergence.

1.2.3 Dynamic Matching. Dynamic Matching is a fundamental problem in two-sided queues with heterogeneous customer and server arrivals. A FCFS matching discipline was studied by [6] and [1]. In a related context, [9] considered a multi-sided matching queue and provided an asymptotically optimal matching policy. Delayed matching (batching) in the hope that better matching opportunities will arrive in the future was analyzed by [3] and [2]. In both these papers, they concluded that delayed matching does not provide significant benefits. Some of the papers involving dynamic matching that are close to our work are presented in detail below.

[12] consider a two sided market given by a bipartite graph with associated penalties depending on the type of demand and supply matched. Their objective is to find a matching policy which maximizes the discounted reward in finite time. They present multiple structural properties of the optimal matching policy and also present an asymptotically optimal matching policy.

Our paper is an extension of the work by [28], where a similar model was considered. There are two key differences. They did not consider the game theoretic behavior of servers. This addition to the model results in fundamentally different problem and optimal policy. In addition, unlike this paper, we consider a discrete time model and a more realistic general arrival process. This generalization results in technical difficulties and more involved proofs.

1.2.4 Queueing Games. The book by [11] provides a complete overview on game theory applied to queueing systems. In the present paper, with a large number of servers arriving in the system, we are dealing with non atomic games. [8] deal with non atomic games and show that equilibrium constraints can be equivalently written as a fixed point equation. [18] provides a comprehensive theory of solving and reformulation of the optimization problem with equilibrium constraint which is known to be NP-hard. A comprehensive background on algorithmic game theory can be found in [20].

We combine all these aspects that has been studied in the literature. In particular, we combine dynamic pricing, dynamic matching in a strategic setting and carry out fluid as well as stochastic analysis. Allowing probabilistic policies is a novel approach of formulating the fluid model. These leads to a probabilistic optimal pricing policy and it seems to be fundamental to the systems with strategic behavior and is novel in the literature.

1.3 Notation

We denote the set of real numbers, the set of non negative real numbers, the set of integers and the set of non negative integers by \( \mathbb{R}, \mathbb{R}_+, \mathbb{Z} \) and \( \mathbb{Z}_+ \) respectively. In addition, we denote the extended real line \( \mathbb{R} \cup \{\infty, -\infty\} \) by \( \bar{\mathbb{R}} \). We denote the set of natural numbers from 1 to \( n \) by \( [n] \). In the entire paper, we use \( i, j \) and \( n \) for parameters concerning servers and 2, \( j \) and \( m \) for customers. We refer to servers by she/her/her and to customers by he/his/him. In the entire paper, vectors are boldfaced. We denote a vector of zeros of dimension \( n \) by \( 0_n \) and a vector of ones of size \( m \) by \( 1_m \). We omit the subscript if the dimension of the vector is clear from the context. For two vectors \( x \in \mathbb{R}^n \) and \( y \in \mathbb{R}^m \), we denote the concatenated vector \( z \in \mathbb{R}^{n+m} \) by \( z = (x, y) \). The dot product of two vectors is denoted by \( \langle ., . \rangle \). For functions \( F_j : \mathbb{R} \to \mathbb{R} \) with \( j \in [m] \) and a vector \( \lambda \in \mathbb{R}^m \), we write \( F(\lambda) \) to denote \( (F_1(\lambda_1), \ldots, F_m(\lambda_m)) \). For two matrices \( A \) and \( B \) of size \( m \times n \), the sum of the entries of their Hadamard product is denoted by \( A \circ B \), that is, \( A \circ B = \sum_{i=1}^m \sum_{j=1}^n A_{ij} B_{ij} \). Expectation of a
random variable $\mu$ with probability measure $\alpha$ is denoted as $\mathbb{E}_\alpha[\mu]$. Variance of a random variable is denoted by $\text{Var}[\cdot]$ and co-variance is denoted by $\text{Cov}[\cdot, \cdot]$. For two random variables $X$ and $Y$, if $P[X \leq a] \leq P[Y \leq a]$ for all $a \in \mathbb{R}$, then we say that $X$ stochastically dominates $Y$ and denote it by $X \geq_{s.t.} Y$. Quantities pertaining to the fluid model are denoted with a 'tilde' on top and quantities pertaining to the steady state of the stochastic model are denoted with a 'bar' on top.

2 MODEL

We consider a general two-sided, discrete time queueing system modeled as a bipartite graph $G(N_1 \cup N_2, E)$. We refer to $G(N_1 \cup N_2, E)$ as the compatibility graph, where $N_1 = [n]$ is the set of server types, $N_2 = [m]$ is the set of customer types, and $E$ is the set of compatible edges that represent the feasible matches between customers and servers. Each node in the graph denotes a queue of a customer/server waiting to be matched. In each time slot, first, the system operator determines prices for each customer and server queue. Then, agents arrive to the system and, given the prices, make joining decisions. Customers always join their type’s queue, while servers can strategically choose which queue to join. After this, the system operator matches (possibly) the compatible pairs of customers and servers waiting in the system. Next, we present each component of the model in detail.

We denote the state of the system at time $k$ by $\{q(k) \in \mathbb{Z}_+^{n+m} : k \in \mathbb{Z}_+\}$, where the vector is defined as $q = (q_1(1), \ldots, q_1(n), q_2(1), \ldots, q_m(2))$ and $q_i(1)(k)$ is the number of servers in the $i$ type queue waiting in the system at time $k$, and $q_j(2)(k)$ is the number of $j$ type customers waiting in the system at time $k$. The state space of the system is denoted by $S \subseteq \mathbb{Z}_+^{n+m}$.

**Customers.** We denote the arrival of customers of type $j$ by a sequence of independent random variables $\{a_j(2)(k) : k \in \mathbb{Z}_+\}$ for all $j \in [m]$ with mean $\mathbb{E}[a_j(2)(k)] = \lambda_j(k)$. We assume $|a_j(2)(k)| \leq A_{\text{max}}$ with probability 1 for all $j \in [m]$ and for all $k \in \mathbb{Z}_+$. We allow the arrivals to be correlated across types but they are independent across time. We denote the co-variance matrix of the arrival vector $a(2)(k)$ by $\Sigma(2)(k)$. The mean arrival rate $\lambda(k)$ is determined by the price posted by the system operator and the demand curve for the respective type of customer. Mathematically, we have $F_j(\lambda_j(k)) = p_j(2)(k)$ for all $j \in [m]$, where $F_j : \mathbb{R}_+ \to \mathbb{R}_+$ is the inverse demand curve for $j$ type of customer and $p_j(2)(k)$ is the price posted for $j$ type of customer. We do not make any assumption on the dependence of distribution of the arrival process on the price posted and thus, the co-variance matrix can vary arbitrarily with the price posted. Although, as $|a_j(2)(k)| \leq A_{\text{max}}$, there exists $\Sigma_{\text{max}}(2)$ and $\Sigma_{\text{min}}(2)$ such that $\Sigma_{\text{min}}(2) \leq \Sigma(2)(k) \leq \Sigma_{\text{max}}(2)$. We make the following assumptions on the inverse demand curve which are standard in the economic literature.

![Fig. 2. A tripartite graph for two-sided queues with strategic servers.](image-url)
Assumption 1. The inverse demand curve \( F_j(.) \) is strictly decreasing and twice continuously differentiable for all \( j \in [m] \).

In words, if the posted price for customers is higher, then less customers would be willing to avail that service and vice versa. In addition, we assume that the inverse demand curve is twice continuously differentiable which is a technical assumption required for our analysis.

Assumption 2. The function \( \lambda_j F_j(\lambda_j) \) is concave for all \( j \in [m] \).

By the law of diminishing marginal utility, if the arrival rate increases, then the marginal utility derived from each new customer \((\frac{d}{d\lambda_j} \lambda_j F(\lambda_j))\) decreases. This condition is equivalent to requiring that the demand curve comes from a regular distribution.

Servers. Now, we define the arrival process of servers. We identify servers as decision makers that make strategic joining decisions. A type \( i \) server arriving to the system can join the \( l \) type queue for some \( l \in [m] \) or leave the system depending on its personal utility \( u_{il} \) which, in turn, depends on the price set by the system operator \( p^{(1)}_l \in \mathbb{R}^n \) and the detour penalties \( c \in \mathbb{R}^{nxn} \). In particular, a server of type \( i \) who joins the \( l \) type queue earns \( u_{il} = f_i(p^{(1)}_l) \) for some function \( f_i : \mathbb{R}^n_+ \rightarrow \mathbb{R} \). One typical example of utility function which we will use later for simulations is given by

\[
u_{il} = p^{(1)}_l - c_{il} \quad \forall i \in [n], \forall l \in [n],
\]

where \( p^{(1)}_l \) is the price set by the system operator for servers that join the \( l \) type queue, and \( c_{il} \) is the penalty due to lying incurred by a server of type \( i \) when she joins the \( l \) type server queue. In our ridesharing application, \( c_{il} \) represents a detour cost experienced by a driver when she is assigned a non compatible trip. A type \( i \) driver entering the system will compare her utilities \( u_{il} \forall l \in [n] \) with her outside option. If the maximum possible utility \( u_i = \max_{l \in [n]} u_{il} \) is greater than her outside option, then the driver will join the queue which maximizes her utility. Otherwise, the driver will not join the system at all. Note that all our results holds for general utility function given by \( f(\cdot) \).

Formally, a server of type \( i \) who joins the system at time \( k \) uses the strategy \( \nu_l(k) \in [0,1]^n \), where, for each \( l \in [n] \), \( \nu_l(k) \) is the probability with which a type \( i \) server joins queue \( l \). We say that the strategy profile \( \nu \triangleq (\nu_1(k), \ldots, \nu_n(k)) \in \mathbb{R}^{nxn} \) is an equilibrium if and only if

\[
\forall i, l' \in [n], \text{ and } \sum_{i=1}^{n} \nu_i(k) = 1, \nu_i(k) \geq 0 \quad \forall i, l \in [n]. \quad (EQ)
\]

Given the definition above, we are ready to introduce the arrival processes of servers. Let \( \bar{\mu}(k) \in \mathbb{R}^n_+ \) be the vector of arrival rates of servers to the system, where \( \bar{\mu}_i(k) \) represents the arrival rate of type \( i \) servers. Note that the above constraint only enforces that if the server joins the system, then which queue it will join. To consider the fact that the server may not join the system at all, we will introduce an inverse supply curve denoted by \( G_l : \mathbb{R}_+ \rightarrow \mathbb{R} \) for all \( l \in [n] \). Then, the arrival rate of type \( i \) servers to the system satisfies \( G_i(\bar{\mu}_i(k)) = u_i(k) \). In turn, we define the effective arrival process of servers to queue \( i \) as a sequence of independent random variables \( \{a_i^{(1)}(k) : k \in \mathbb{Z}_+\} \) with mean \( \mathbb{E} \left[ a_i^{(1)}(k) \right] = \mu_i(k) \) for all \( i \in [n] \), where \( \mu_i(k) = \sum_{l=1}^{n} \bar{\mu}_l(k) \nu_l(k) \). Observe that because a given queue may receive servers of different type, the arrival processes to different queues can be correlated. We use \( \Sigma^{(1)}(k) \) to denote the co-variance matrix of the arrival vector \( a^{(1)}(k) \). We assume that \( |a_i^{(1)}(k)| \leq \text{A}_{\max} \) with probability 1 for all \( i \in [n] \) and for all \( k \in \mathbb{Z}_+ \). Similar to the customers, the distribution of the arrival process of servers can vary arbitrarily with respect to the price posted by the system operator and thus, the co-variance matrix \( \Sigma^{(1)}(k) \) is price dependent. We do not specify this dependence as our results are valid in general.
Policies. The system operator uses a stationary policy and makes both pricing and matching decisions. We describe the pricing policy first. Given the state of the system \((\mathbf{q}) \in \mathbb{Z}_{+}^{n+m}\), a stationary pricing policy is a vector \((\mathbf{p}^{(1)}(\mathbf{q}), \mathbf{p}^{(2)}(\mathbf{q})) \in \mathbb{R}_{+}^{n} \times \mathbb{R}_{+}^{m}\) where \(\mathbf{p}^{(1)}(\mathbf{q})\) is the payment to servers in queue \(i \in [n]\), and \(\mathbf{p}^{(2)}(\mathbf{q})\) is the price charged to customers in queue \(j \in [m]\). In order to simplify the analysis, we work in a general space of feasible rates instead of prices. For any stationary rates, we identify a corresponding stationary pricing policy, hence, with some abuse of language, to simplify the analysis, we work in a general space of feasible rates instead of prices. For any stationary rates, we identify a corresponding stationary pricing policy, hence, with some abuse of language, we refer to the stationary rates as stationary pricing policies. Note that, we are only interested in stationary, Markovian, state dependent pricing policies and thus, we omit the dependence of \(\lambda\) and \(\mu\) on the time index \(k\).

On the customer side, there is a one to one mapping between prices and the arrival rate of customers to the customer queues. Hence, we define a customer stationary pricing policy by the arrival rate vector \(\lambda(\mathbf{q}) \in \mathbb{R}_{+}^{n}\). In addition, as the co-variance matrix only depends on the price posted by the system operator, we can re-write it as \(\Sigma^{(2)}(\lambda(\mathbf{q}))\).

On the server side, observe that we do not have a one-to-one correspondence between prices and the arrival rate of servers to the server queues—for a given rate \(\mu\) there could be many price vectors that are consistent with \(\mu\). To address this, we define the set of prices that are consistent with \(\mu\) by

\[
\mathcal{M}(\mu) \triangleq \left\{ \mathbf{p}^{(1)}(\mathbf{q}) \in \mathbb{R}_{+}^{n} : \exists \mathbf{v} \in \mathbb{R}_{+}^{n \times n} \text{ satisfying } (EQ), G_{i}(\bar{\mu}_{i}) = u_{i}, \mu_{i} = \sum_{l=1}^{n} \bar{\mu}_{i} v_{i l} \quad \forall i \in [n] \right\}.
\]

The set \(\mathcal{M}(\mu)\) is composed by those prices for which there exists an equilibrium that leads to the arrival rates \(\mu\) in the servers queues. We further define \(\Omega\) to be the set of rates \(\mu\) such that \(\mathcal{M}(\mu) \neq \emptyset\). In turn, for any state of the system \(\mathbf{q}\), we define a server stationary pricing policy as a probability measure \(\alpha(\mathbf{q})\) defined on the Borel sigma-algebra generated by \(\Omega\). That is, when the system state is \(\mathbf{q}\), the arrival rate of servers into each queue is randomized over \(\mu \in \Omega\) with probability measure \(\alpha(\mathbf{q})\). We use \(\mathcal{P}_{EQ}\) to denote the set of such probability measures. The corresponding price \(\mathbf{p}^{(1)}\) is then selected among the consistent prices so that it minimizes the cost \(\langle \mu, \mathbf{p}^{(1)} \rangle\) for the service provider. The optimal cost function \(c : \Omega \rightarrow \mathbb{R}_{+}\) is defined by

\[
c(\mu) \triangleq \min \left\{ \langle \mu, \mathbf{p}^{(1)} \rangle \right\} \quad \text{subject to } \mathbf{p}^{(1)} \in \mathcal{M}(\mu).
\]  

(1)

Given a price vector \(\mathbf{p}^{(1)}\), there may be more than one set of Nash equilibrium rate vectors \(\mu\). Thus, by minimizing the system operator’s cost over the set of Nash equilibria, we are assuming that the servers will choose the equilibrium that is best for the system operator. This is the optimistic scenario where the implicit assumption favors the system operator’s objective. Assumptions like this are popular in the literature (e.g. see [15] [25] and the references therein) as it simplifies the model and analyzes a policy under the best case scenario. Even though, in practice, the system operator has all the information and can use it to nudge the servers in the right direction, it is important to study the possibility where the servers are free to choose any equilibrium. To do this, we analyze the ‘pessimistic model’ wherein we maximize the minimum possible profit obtained by the system operator over all possible Nash equilibria. The reader should refer to Appendix H for the detailed analysis.

Note that the co-variance matrix of servers will only depend on the price posted by the system operator or equivalently, the probability measure \(\alpha(\mathbf{q})\). Thus, we denote it by \(\Sigma^{(1)}(\alpha(\mathbf{q}))\).

We make two important remarks about the server side policy. First, the reason we allow randomized policies for servers is because they result in a richer class of pricing policies; but also they enable us to tackle the inherent combinatorial structure and non convexity of the service
provider’s objective. The latter, materializes through the cost function \( c(\cdot) \) and the strategic behavior of servers.

Second, in this paper, we are interested in different types of equilibrium behavior depicting different objectives, for example, servers do not lie (incentive compatible model) or the overall profit of the system is maximized. Thus, to keep the model general enough, we will work with a general cost function \( c(\mu) \) throughout the paper and discuss the behavior of each different equilibria or objective by specializing the definition of \( c(\mu) \) in later sections.

Now we specify the matching policy. We denote by \( \{ \bar{x}(k) \in \mathbb{Z}^{nXm} : k \in \mathbb{Z}_+ \} \) the decision of matching customer-servers pairs at time \( k \). Here, \( \bar{x}_{ij}(k) \) is the number of servers in the \( i \) type queue that are matched with customers of type \( j \) at time \( k \). For the matching decisions to be feasible, the following conditions must be satisfied

\[
 x_i^{(1)}(k) \overset{\Delta}{=} \sum_{j=1}^{m} \bar{x}_{ij}(k) \leq q_i^{(1)}(k) + a_i^{(1)}(k) \quad \forall i \in [n], \quad (2a)
\]

\[
 x_j^{(2)}(k) \overset{\Delta}{=} \sum_{i=1}^{n} \bar{x}_{ij}(k) \leq q_j^{(2)}(k) + a_j^{(2)}(k) \quad \forall j \in [m], \quad (2b)
\]

\[
 \bar{x}_{ij}(k) = 0 \quad \forall (i, j) \notin E, \quad \bar{x}_{ij}(k) \geq 0 \quad \forall (i, j) \in E, \quad (2c)
\]

where \( x(k) = (x^{(1)}(k), x^{(2)}(k)) \) for all \( k \in \mathbb{Z}_+ \) denote the total amount of servers and customers matched in each queue at a given time period. The set of constraints (2) ensure that the number of servers in the \( i \) queue that are matched cannot be larger than the total number of servers in that queue plus the arrivals. Similarly, the number of customers in the \( j \) queue that are matched are at most equal to the total number of customers in that queue plus the arrivals. Moreover, the only matches allowed are those given by the compatibility graph \( G(N_1 \cup N_2, E) \). In turn, given the state of the system after arrivals \((q + a)\), a stationary matching policy is defined as the decision of choosing \( \bar{x}(q + a) \) or, equivalently, \( x(q + a) \) subject to (2).

Note that we implicitly assume that the current pricing and matching decisions do not impact the future server arrivals. This is a reasonable assumption as the trips are sufficiently long to diminish the correlation across time. In addition, this model is motivated by drivers choosing to go to a specific destination by declaring their type and they usually tend to spend some time there. Thus, they can be treated as a new independent arrival. In practice, the assumption may not be completely true. Thus, to partially relax this modeling assumption, we have generalized the utility function to depend on the long run rates of matching a customer-server pair \((E(x))\). This means that the current utility of the drivers depends on the matching decisions in all the decision epochs (depends on the matching policy) which in turn influences the arrival process. The reader should refer to Appendix G for details.

**System dynamic.** Given the pricing and matching policy, the system evolves as a discrete time Markov chain. The queue evolution equation is given by:

\[
 q(k + 1) = q(k) + a(k) - x(k),
\]

where \( x \) satisfies (2). We consider policies that render the system stable.

**Definition 1 (Stability).** The discrete time Markov chain is stable if under a given pricing and matching policy, the communicating class containing the state \( 0_{n+m} \) is positive recurrent and all the other states (if any) are transient. We use \( \mathcal{E} \) to denote the set of stationary Markovian pricing and matching policies that make the system stable.

For a stable system, we denote the steady state parameters with a bar on top. In particular, \( \bar{q}(k) \) converges in distribution as \( k \to \infty \) to a random vector denoted by \( \bar{q} \). The arrival rate vector given
the queue length $\bar{q}$, is denoted by $\bar{a}$ such that $\mathbb{E}[\bar{a}] = (\lambda(\bar{q}), \mathbb{E}_{\alpha}(\bar{q}) [\mu])$ and the co-variance matrix of $\bar{a}^{(2)}$ is $\Sigma^{(2)}(\bar{q})$ and that of $\bar{a}^{(1)}$ is $\Sigma^{(1)}(\bar{q})$. The matching decision given the queue length $(\bar{q})$ and arrival rate vector $(\bar{a})$ is denoted by $\bar{x}$.

**Objective.** Each customer entering the system pays the posted price and each server receives the posted price. In addition, the system operator incurs a type specific penalty $s \in \mathbb{R}_{+A}+B$ due to the waiting of customers and servers. The objective of the system operator is to design the pricing and matching policies such that the difference of average profit obtained and the average penalty incurred due to waiting—the net average profit—is maximized. Mathematically,

$$
R^* \triangleq \sup_{(\lambda(\cdot),\alpha(\cdot),x(\cdot)) \in \mathcal{E}} \mathbb{E}_q \left[ \langle F(\lambda(\bar{q})), \lambda(\bar{q}) \rangle - \mathbb{E}_{\alpha(\bar{q})} [c(\mu)] - \langle s, \bar{q} \rangle \right]
$$

subject to,

$$
\lambda(q) \in \mathbb{R}_+^m, \quad \forall q \in S
$$

$$
\alpha(q) \in \mathcal{P}_{EQ}, \quad \forall q \in S
$$

$$
x(\cdot) \text{ satisfies (2).}
$$

We will use $\pi$ to refer to a policy $(\lambda, \alpha, x)$ and denote by $R(\pi)$ the expected net profit associated to that policy. Moreover, $P^*$ and $P(\pi)$ will denote the the optimal profit (when $s = 0_{m+n}$) and the profit evaluated at $\pi$, respectively.

In practice, the customers and servers are delay sensitive and for simplicity of the analysis, we model it by introducing a queueing penalty incurred by the system operator proportional to the queue lengths in the system. This penalty provides an incentive to the system operator to minimize the delay incurred by the customers and servers. In addition, our model can be extended to explicitly model delay sensitive agents by generalizing the utility function to include the expected waiting times. In addition, the price incurred by the customers can be adjusted to include the expected waiting times. This is analogous to having a queueing system where agents balk if waiting times are too long. This is a possible future direction.

For a given pricing and matching policy, computing the objective function of the above optimization problem is itself challenging as the state space of the DTMC can be very large. In addition, the optimization problem becomes a non-convex, integer optimization problem due to the equilibrium constraints captured in $\mathcal{P}_{EQ}$.

Moreover, if the price of one type of the server is changed, it will lead to a change of arrival rates of all types of servers. Due to this, the system operator will be required to adjust the customer prices as well to compensate for the server arrival rates. This dependence of server arrival rates and its influence on the customer arrival rates makes the analysis of the pricing policy non trivial.

To tackle these challenging problem, we start by introducing a novel probabilistic fluid model. Intuitively, we ignore the stochasticity of the system which makes the optimization problem tractable and, in addition, we relax the stability constraint. In further sections, based on the solution to the fluid model, we propose “near-optimal” pricing and matching policies.

### 3 A PROBABILISTIC FLUID MODEL

In this section, we will introduce a fluid counterpart of the optimization problem (3). A novel feature in our fluid optimization problem is that, to determine the pricing policy, we must optimize over the space of probability measures. We provide conditions under which this can be reduced to an optimization problem over the real space and also discuss the implications of the solution to the optimal pricing policy.
3.1 Bounds and Structural Properties

Firstly, we present the probabilistic fluid optimization problem:

\[ \hat{R}^* = \max_{(\hat{\lambda}, \tilde{\alpha}, \tilde{\chi}) \in \mathcal{P}} \left( F(\hat{\lambda}), \tilde{\lambda} \right) - \mathbb{E}_{\tilde{\alpha}} [c(\tilde{\mu})] \]  

subject to \[ \hat{\lambda}_j = \sum_{i=1}^{n} \tilde{\chi}_{ij} \quad \forall j \in [m] \]  
\[ \mathbb{E}_{\tilde{\alpha}} [\tilde{\mu}_i] = \sum_{j=1}^{m} \tilde{\chi}_{ij} \quad \forall i \in [n] \]  
\[ \tilde{\chi}_{ij} = 0 \quad \forall (i, j) \notin E, \quad \tilde{\chi}_{ij} \geq 0 \quad \forall (i, j) \in E, \]  

where \( c(\cdot) \) is the cost function given in (1), \( \hat{\lambda} \) is the ‘average’ flow of customers in the system, \( \tilde{\alpha} \) is the ‘average’ distribution governing the probabilistic server pricing policy and \( \tilde{\chi}_{ij} \) is the ‘average’ flow of \( i \) type of servers matched to \( j \) type of customer. The objective function is the profit obtained by the system operator. Equations (4b), (4c) are flow conserving constraints and (4d) is the compatibility constraint. The major distinction of our proposed fluid problem and others in the literature is that we allow probabilistic pricing policies. This richer space of policies not only obtains a larger profit with respect to the deterministic space of policies, but it also makes the optimization problem more amenable to analysis by turning the objective function into a convex function. Indeed, it is possible that the optimal cost function \( c(\tilde{\mu}) \) is not a convex function of \( \tilde{\mu} \); however, \( \mathbb{E}_{\tilde{\alpha}} [\tilde{\mu}] \) is linear in \( \tilde{\alpha} \). In the next proposition, we leverage this fact to draw a connection between the probabilistic fluid problem (4) and the stochastic problem (3).

**Proposition 1.** Let \( \pi = (\lambda(\cdot), \alpha(\cdot), x(\cdot)) \) be a feasible solution of (3) then

\[ R(\pi) \leq P(\pi) \leq \hat{R}^*. \]

That is, the fluid profit is an upper bound for the stochastic profit and net profit.

Thus, this proposition provides us with an upper bound on the net average profit achievable under any policy. Note that, if we naively try to use the optimal solution of the probabilistic fluid model as the pricing policy for all \( q \in S \), then in each time slot, we will receive fluid profit in expectation. Although, the system becomes unstable as argued in [6] and thus, the stationary distribution doesn’t exist. To see why the system is unstable, consider the case of single link two sided queue operating under the pricing policy given by the fluid solution. It will just be a random walk on \( \mathbb{R} \) which is known to be null recurrent. This provides us with the intuition that we need to operate close to the fluid solution but we need to perturb the arrival rates for customers and/or the probability measure for servers such that the system becomes stable. We now present the following lemma which is a crucial step in the proof of the proposition.

**Lemma 1.** For a given stationary Markovian pricing and matching policy \( (\lambda(\cdot), \alpha(\cdot), x(\cdot)) \), let \( \hat{\lambda} = \mathbb{E} [\lambda(q)], \tilde{\alpha} = \mathbb{E}_q [\alpha(q)] \) and \( \tilde{\chi} = \mathbb{E} [x(q)] \). If \( (\lambda(\cdot), \alpha(\cdot), x(\cdot)) \in \mathcal{E}, \mathbb{E} [\{1_{n+m}, q\}] < \infty \) and \( x(\cdot) \) satisfies (2), then \( (\hat{\lambda}, \tilde{\alpha}, \tilde{\chi}) \) if feasible in the probabilistic fluid problem (4).

Intuitively, the above lemma is enforcing that the ‘average’ arrival rates over the states must be balanced, otherwise, in the long run, some of the queues will keep accumulating the arrivals and that will lead to an unstable system. Thus, the constraints of the fluid model are necessary for stability. This implies that the set \( \mathcal{E} \) is a subset of the feasible region of the fluid model. In addition, as the objective (3a) is convex in its parameters, we can use Jensen’s inequality to obtain the objective of the fluid solution. These two key steps together will give us Proposition 1.
Next, we identify a condition for the optimal cost function $c(\cdot)$ such that the optimal value of the probabilistic fluid optimization problem (4) coincides with that of a non-probabilistic fluid problem. Moreover, we establish that, under this condition, the optimal fluid server pricing policy is a Dirac probability measure. Intuitively, if the optimal cost function is not convex then, under a probabilistic policy $\tilde{\alpha}$, Jensen’s inequality might be violated, that is, $E_{\tilde{\alpha}}[c(\tilde{\mu})] < c(E_{\tilde{\alpha}}[\tilde{\mu}])$. This will lead to lower cost under the probabilistic policy compared to the corresponding deterministic policy, $E_{\tilde{\alpha}}[\tilde{\mu}]$. In turn, when the optimal cost function is convex, we expect that a deterministic server pricing policy will be optimal. In particular, we establish that the probabilistic fluid model can be reduced to the following optimization problem over the real vector space.

$$
\tilde{R}^*_\text{co} \triangleq \max_{(\lambda, \tilde{\mu}, \tilde{\lambda}) \in \Omega} \left( F(\tilde{\lambda}), \tilde{\lambda} \right) - c(\tilde{\mu})
$$

subject to, $\tilde{\lambda}_j = \sum_{i=1}^n \tilde{\lambda}_{ij} \forall j \in [m]$, $\tilde{\mu}_i = \sum_{j=1}^m \tilde{\lambda}_{ij} \forall i \in [n]$ $\tilde{\lambda}_{ij} = 0 \forall (i, j) \notin E$, $\tilde{\lambda}_{ij} \geq 0 \forall (i, j) \in E$.

**Proposition 2.** If $c(\cdot)$ is convex, then $\tilde{R}^* = \tilde{R}^*_\text{co}$ and there exists an optimal solution of (4) $(\tilde{\lambda}^*, \tilde{\alpha}^*, \tilde{\chi}^*)$ such that $\tilde{\alpha}^*$ is a Dirac probability measure.

The proof follows by using Jensen’s inequality in the objective function of (4) and then redefining $E_{\tilde{\alpha}}[\tilde{\mu}]$. This proposition simplifies the fluid model and also provides sufficient conditions under which the optimal fluid pricing policy is deterministic. The proof of the proposition is deferred to the appendix.

In the next sections, we will consider pricing policies which are a small perturbation of the fluid solution and show that the net profit and profit under that policy is ‘sufficiently’ close to $\tilde{R}^*$. Before that, we expound on the cost function $c(\cdot)$ and the equilibrium condition (EQ) which will provide further insights on the server pricing policy which, in turn, will further impact the customer pricing policy.

### 3.2 Cost Function Reformulation

The results in this subsection are for the specific cost function defined in (1). Although, the results in the rest of the paper, in particular the fluid and stochastic analysis are valid for any cost function. We begin by reformulating the constraint (EQ) as a variational inequality. This will allow us to apply KKT conditions on the optimization problem that defines the optimal cost function to equivalently reformulate it as standard inequality and equality constraints optimization problem as done in [18]. The lemma is presented below.

**Lemma 2.** Let $\mathcal{C} = \{ \nu \in \mathbb{R}^{n \times n}_+ : \sum_{i=1}^n \nu_{il} = 1 \forall i \in [n] \}$ and let $\nu \in \mathcal{C}$, the following are equivalent:

1. $\nu$ satisfies (EQ).
2. $\nu$ satisfies $\sum_{i=1}^n \sum_{l=1}^n u_{il}(\nu_{il} - \tilde{v}_{il}) \geq 0$ for all $\tilde{\nu} \in \mathcal{C}$.
3. There exists $\kappa \in \mathbb{R}^n$ and $\xi \in \mathbb{R}_+^{n \times n}$ such that $u_{il} = \kappa_i - \xi_{il}$ and $\xi_{il}v_{ik} = 0$ for all $i, l \in [n]$.

Recall from the definition of $\mathcal{M}(\mu)$, besides the equilibrium constraint, according to the definition of the optimal cost function in (1), we must enforce the following relation between the total rate of $i$ type of server joining the system and their maximum utility with $\tilde{\mu}_{ik} \overset{\Delta}{=} \tilde{\mu}_i v_{ik}$,

$$
G_l \left( \sum_{k=1}^n \tilde{\mu}_{ik} \right) = \max_{i \in [n]} \{ u_{il} \}, \forall i \in [n].
$$
We can write the constraint (6) in terms of standard inequality constraints and binary variables $b \in \{0, 1\}^{n \times n}$ by using the following lemma.

**Lemma 3.** There exists an $M > 0$ such that the following constraints are equivalent:

1. $G_i \left( \sum_{k=1}^{n} \mu_{ik} \right) = \max_{i \in [n]} \{ u_{iI} \}$ for all $i \in [n]$.
2. $G_i \left( \sum_{k=1}^{n} \mu_{ik} \right) \geq u_{iI}, \ G_i \left( \sum_{k=1}^{n} \mu_{ik} \right) \leq u_{iI} + (1 - b_{iI})M, \ b_{iI} \in \{0, 1\}$ for all $i, l \in [n]$ and $\sum_{i=1}^{n} b_{iI} = 1$ for all $i \in [n]$.

The first inequality in 2 enforces $G_i(.)$ to be greater than each of the $u_{iI}$ and the second inequality along with the constraint $\sum_{i=1}^{n} b_{iI}$ enforces $G_i(.)$ to be less than or equal to the maximum of $u_{iI}$. In addition, we can take $M = \sum_{i=1}^{n} (G_i(\langle 1, \mu \rangle))$. Thus, by Lemma 2 and Lemma 3, we obtain a reformulation of $c(.)$ as a value function of a mixed-integer non linear program. If the inverse supply curve is a linear function, then it becomes a mixed-integer linear program.

### 4 ASYMPTOTIC OPTIMALITY OF TWO PRICE POLICY

In this section, we will analyze the stochastic system and show that the net profit obtained is ‘sufficiently’ close to the upper bound $\bar{R}^*$. To show this, we will consider the large market asymptotic regime indexed by $\eta$. In this regime, we propose a dynamic two-price policy and show that its corresponding net profit converges to that of the scaled optimal fluid solution. As we consider a DTMC, let the time between two transition be a finite constant $w$. We define our asymptotic regime below.

**Definition 2 (Asymptotic Regime).** We study the system in the large market regime, wherein for the $\eta^{th}$ system, the time between two decision epochs is scaled by $1/\eta$ and the arrivals between two decision epochs remains the same in the stochastic sense. Mathematically,

$$w_\eta = \frac{w}{\eta}, \quad a_\eta(k) = a(k), \ q_\eta(k) = q(k) \ \forall k \in \mathbb{Z}_+$$

Our convention is to subscript by $\eta$ all the parameters which are associated with the $\eta^{th}$ system. For example, the steady state queue length vector is denoted as $\bar{q}_\eta$ and the corresponding arrival and matching random variables by $\bar{a}_\eta$ and $\bar{x}_\eta$ respectively. The time scaling leads to a large volume of arrivals per unit time and more frequent matching decisions. This is desirable as the inflow of customers and servers are increasing, it is advantageous to make the matching decision more frequently.

Note that, under the asymptotic regime, the optimal fluid solution will be $\tilde{R}_\eta^* = \eta \tilde{R}^*$. This is because the time is scaled by $\eta$ which leads to the profit per unit time to be scaled by $\eta$. Now, motivated by Proposition 1, we will define ‘net profit-loss’, a metric to analyze various policies.

**Definition 3 (Net Profit-Loss).** For a given pricing and matching policy $\pi_\eta$, the net profit-loss, $L_\eta(\pi_\eta)$, for the $\eta^{th}$ system is defined as the difference of the optimal profit $R_\eta^*$ and the long run average net profit obtained under that policy

$$L_\eta(\pi_\eta) \triangleq R_\eta^* - R_\eta(\pi_\eta).$$

In addition, we define the profit-loss as $L_\eta^0(\pi_\eta) \triangleq R_\eta^* - P_\eta(\pi_\eta)$.

We say that a sequence of policies $\{\pi_\eta\}$ is optimal if

$$\lim_{\eta \to \infty} \sup_{\eta} \frac{L_\eta(\pi_\eta)}{\eta} = 0. \quad (7)$$

Thus, any policy which leads to $o(\eta)$ net profit-loss is optimal.
Now that we have defined a criterion to analyze a given policy, we introduce a sequence of policies which are asymptotically optimal. The idea is to design a policy that operates as close to the fluid solution as possible because that will result in fluid optimal profit. Denote the optimal solution of the probabilistic fluid problem as $(\tilde{\lambda}^*, \tilde{\alpha}^*, \tilde{x}^*)$. Note that, without loss of generality, we can assume $\tilde{\lambda}^* > 0_m$, $\mathbb{E}\tilde{\alpha}^* \left[ \mu \right] > 0_a$ and $\tilde{\lambda}_{ij}^* > 0$ for all $(i,j) \in E$, otherwise, we can remove that vertex/edge from the graph and work with a smaller graph such that the above conditions are satisfied. Now, we introduce the two price policy:

$$
\lambda_{\eta,j}(q) = \begin{cases} 
\tilde{\lambda}_{j}^* + \epsilon_\eta & \text{if } q_{j}^{(2)} = 0; \\
\tilde{\lambda}_{j}^* - \epsilon_\eta & \text{otherwise},
\end{cases}
$$

$$
\alpha_\eta(q) = \tilde{\alpha}^*, \forall q \in S. \tag{8}
$$

We assume that $\epsilon_\eta \to 0$ as $\eta \to \infty$ as we want to approach the fluid optimal pricing policy. Without loss of generality, we can assume $\epsilon_\eta \leq 1$ for all $\eta$. We highlight the simplicity of this pricing policy in which we use two different rates only on the customer side and on the server side, we use a fixed probabilistic policy. In addition, the threshold at which we change the rate is at $q_{j}^{(2)} = 0$. This captures how the service provider needs to adjust its pricing policy to maintain a stable system and, in turn, sustain the proper balance of supply and demand.

The matching policy we use is the max-weight matching policy which is defined as:

$$
\tilde{x}_{\eta}(k) = \arg \max_{y \in \mathbb{Z}^{\left| E \right|}} \sum_{(i,j) \in E} y_{ij}(q_{j}^{(1)}(k) + q_{j}^{(2)}(k)) \text{ subject to } (2). \tag{9}
$$

Note that $y$ can be relaxed to be a continuous variable due to the following: the constraint set we have is a polyhedron of the form $\{Ay \leq b\}$ where $b \in \mathbb{Z}^{n+m}$ and $A \in \{0,1\}^{(m+n) \times mn}$. Note that $A$ is the incidence matrix of the bipartite graph $G(N_1 \cup N_2, E)$ and thus, the polyhedron is integral.

We use $\pi_\eta$ to refer to the policy defined in (8) and (9). Now, we will present the main theorem of this paper.

**Theorem 4.** Consider a sequence of DTMCs parametrized by $\eta$ operating under the pricing and matching policy $\pi_\eta$. Then the net profit-loss $L_\eta(\pi_\eta)$ is $O(\eta^{1/3})$ for the choice $\epsilon_\eta = \eta^{-1/3}$.

The main reason we obtain an $\eta^{1/3}$ net profit loss is due to the trade off between the expected queue length and profit-loss. Consider a pricing policy which deviates from the fluid optimal pricing policy by at-most $\epsilon$, that is, for all $q \in S$, we have $|\lambda_j(q) - \tilde{\lambda}^*_j| \leq \epsilon$ for all $j \in [m]$ and $|\mathbb{E}_a(q) \left[ \mu_i \right] - \mathbb{E}\tilde{\alpha}^* \left[ \mu_i \right]| \leq \epsilon$ for all $i \in [n]$. Then, the expected queue length is of the order $\frac{1}{\epsilon}$ and profit loss is of the order $\epsilon^2$. Considering the trade off between expected queue length and profit loss, the best $\epsilon$ is $\eta^{-1/3}$ which results in $\eta^{1/3}$ net profit loss. In particular, the expected queue length is of the order $1/\epsilon$ as $\epsilon$ characterizes the drift of the DTMC towards zero and that is analogous to the traffic intensity in a single sided queue. It is well known that expected queue length scales as $1/\epsilon$ for a single sided queue operating in heavy traffic ($\epsilon \to 0$). In addition, the expression of profit-loss can be expanded using Taylor’s series expansion. The first order term can be shown to be zero by using the optimality of $(\tilde{\lambda}^*, \tilde{\alpha}^*)$. The second order term results in order $\epsilon^3$ loss.

**Proof sketch.** There are two major steps in proving this theorem. First, we need to bound the expected sum of queue lengths under the given policy and second, we need to bound the loss in average profit $(R^*_\eta - P^*_\eta)$. Both the steps require special treatment because of the strategic behaviour of the servers. In addition, analyzing the queueing system is more complicated than [28] as the arrival process is general. Here, we present multiple lemmas which assists us in proving the theorem and outline the major steps in the proof. Firstly, under the given pricing and matching policy, we show that the system is stable and we upper bound the expected sum of queue lengths.
Lemma 4. There exists an \( \eta_0 > 0 \) such that for all \( \eta > \eta_0 \), the discrete time Markov chain operating under the pricing and matching policy \( \pi_\eta \) is positive recurrent and there exists a constant \( B > 0 \) such that \( \mathbb{E} \left[ \langle s, \tilde{q}_\eta \rangle \right] \leq B \frac{1}{\epsilon_\eta} \).

We use the Foster-Lyapunov theorem [26, Theorem 3.3.7] to prove positive recurrence. In particular, we considered a quadratic Lyapunov function and analyzed its drift. Then we use the moment bound theorem [10] to get bounds on the sum of expected queue lengths. Due to the strategic behaviors of the servers, the arrivals to different queues are co-related and the co-variance of the arrival process appears in the constant \( B_1 \).

After we proved that the system is positive recurrent, by Lemma 1, we know that the arrival rates under the two price policy satisfy the constraints of the fluid optimization problem (4). We will use this idea to show the following equality which, in turn, will be useful to obtain the profit-loss bound.

Lemma 5. For all \( \eta > 0 \), the DTMC operating under the pricing and matching policy \( \pi_\eta \), such that \( \mathbb{E} \left[ \langle 1_{n+m}, \tilde{q}_\eta \rangle \right] < \infty \) the following holds:

\[
\sum_{j=1}^{m} \left( \tilde{\lambda}_j^* F'(\tilde{\lambda}_j^*) + F_j(\tilde{\lambda}_j^*) \right) \left( \mathbb{P} \left[ q_{\eta,j}^{(2)} > 0 \right] - \mathbb{P} \left[ q_{\eta,j}^{(2)} = 0 \right] \right) = 0.
\]

In this Lemma, we use the fact that \((\tilde{\lambda}^*, \tilde{\alpha}^*, \tilde{x}^*)\) is the optimal solution of the probabilistic fluid model. Although, we cannot apply the KKT conditions directly as the optimization is over infinite dimensional vector space. Thus, we first construct a finite dimensional optimization problem by eliminating the probability measure \( \tilde{\alpha} \) from the fluid optimization problem (4). We are able to eliminate the probability measure by adding the constraint \( \tilde{\alpha} = \tilde{\alpha}^* \) to the probabilistic fluid model.

To apply KKT conditions, we find a feasible direction at the optimal point. A feasible point of the optimization problem is the ‘average’ arrival rates of the two price policy (8) as the DTMC is stable under two price policy and \( \mathcal{E} \) is a subset of the feasible region of the fluid model.

Now, we use the above lemma to find the profit loss \( L_\eta^P \).

Lemma 6. For all \( \eta > 0 \), the profit loss of the DTMC operating under the pricing and matching policy \( \pi_\eta \) is

\[
\frac{L_\eta^P}{\eta} = -\epsilon_\eta^2 \sum_{j=1}^{m} \left( \frac{\tilde{\lambda}_j^* F''(\tilde{\lambda}_j^*)}{2} + F_j(\tilde{\lambda}_j^*) \right) + O(\epsilon_\eta^2) \quad \text{where}, \quad \sum_{j=1}^{m} \left( \frac{\tilde{\lambda}_j^* F''(\tilde{\lambda}_j^*)}{2} + F_j(\tilde{\lambda}_j^*) \right) < 0.
\]

We use Assumption 1 and Taylor’s series expansion up to second order of the demand curve \( F_j(.) \) for all \( j \in [m] \). We then apply Lemma 5 to eliminate the first order term of the expansion which, in turn, delivers the desired result.

5 LOWER BOUNDS

In this section, we will make the intuition provided for \( \eta^{1/3} \) rigours by showing that, under a broad class of policies, this is the best possible trade off between expected queue length and profit loss. We first establish that the expected queue length is bounded by a term of order \( \frac{1}{\epsilon} \). Then, we consider a broad class of policies and show that the profit loss is exactly of order \( \eta \epsilon^2 \). In turn, by choosing \( \epsilon = 1/\eta^{1/3} \), we deduce that the profit loss is of order \( \eta^{1/3} \).

For the remainder of this section, we make the following mild additional assumptions on the arrival process. For a given \( j \), if we have \( \lambda_j(k) \geq \lambda_j(k') \) for some \( k, k' \in \mathbb{Z}_+ \), we assume that
Consider a single link two sided queue \((q^{(1)}, q^{(2)})\) with Bernoulli arrivals, that is \(a^{(1)}(q) \sim \text{Bernoulli}(\mathbb{E}_{\alpha} [\mu])\) and \(a^{(2)}(q) \sim \text{Bernoulli}(\lambda(q))\). Note that for the case of single link two sided queue, there is no selfish behaviour of servers as there is only a single type of server. Now, let us analyze the imbalance given by \(z(k) = q^{(1)}(k) - q^{(2)}(k)\). Note that, as there is no incentive to keep the customers or servers waiting in the system, we will immediately match any pair of customer-server waiting in the system. Thus, \(q^{(1)}(k)q^{(2)}(k) = 0\) for all \(k \in \mathbb{Z}_+\) with probability 1. So, \(z\) completely describes the state of the system and so, \(z\) is a Markov chain. In fact, it is a birth and death process as shown in Figure 3 where \(l_z = \lambda(z)(1 - \mathbb{E}_{\alpha}(\mu))\), \(m_z = \mathbb{E}_{\alpha}(\mu)(1 - \lambda(z))\) and \(p_z = 1 - l_z - m_z\) for all \(z \in \mathbb{Z}\).

Now, consider a general pricing policy such that we are at most \(\epsilon\) away from the optimal fluid solution, that is, for all \(z \in S\), we have \(|\lambda(z) - \lambda^*| \leq \epsilon\) for all \(j \in [m]\) and \(|\mathbb{E}_{\alpha}(\mu) - \mathbb{E}_{\alpha^*}(\mu)| \leq \epsilon\) for all \(i \in [n]\). Thus,

\[
|l_z - \tilde{l}^*(1 - \mathbb{E}_{\alpha^*}(\mu))| \leq \epsilon - \epsilon^2, \quad l_{\min} \geq (\tilde{l}^* - \epsilon)(1 - \mathbb{E}_{\alpha^*}(\mu) - \epsilon),
\]

\[
|m_z - \mathbb{E}_{\alpha^*}(\mu)(1 - \tilde{l}^*)| \leq \epsilon - \epsilon^2, \quad m_{\max} \leq (\mathbb{E}_{\alpha^*}(\mu) + \epsilon)(1 - \tilde{l}^* + \epsilon).
\]

We can couple this birth and death process with an M/M/1 queue, \(q^\dagger\), with Bernoulli \((\tilde{l}^* - \epsilon)\) arrival and Bernoulli \((\mathbb{E}_{\alpha^*}(\mu) + \epsilon)\) service. The coupling is such that \(q^\dagger(k) \leq |z(k)|\) for all \(k \in \mathbb{Z}_+\) with probability 1. By Kingman’s bound, we know that \(\mathbb{E} [q^\dagger] \sim \frac{1}{\epsilon}\). Thus, by the above defined coupling, \(\mathbb{E} [z]\) is at least \(\frac{\epsilon}{4}\). In short, if we perturb the arrival rates of a two sided queue by at most \(\epsilon\) then it behaves like a single server queue in heavy traffic.

In the next theorem, we exploit the intuition for the single link case to show a related lower bound for the more general system of multiple link two sided queue with arbitrary arrival process.

**Theorem 5.** Consider a DTMC operating under any matching policy and pricing policy such that for all \(q \in S\), we have \(|\lambda_i(q) - \lambda_i^*| \leq \epsilon\) for all \(j \in [m]\) and \(|\mathbb{E}_{\alpha}(\mu) - \mathbb{E}_{\alpha^*}(\mu)| \leq \epsilon\) for all \(i \in [n]\), then there exists \(\epsilon_0 > 0\) such that for all \(\epsilon < \epsilon_0\),

\[
\mathbb{E} \left[\langle 1_{n+m}, \tilde{q}\rangle\right] \geq \frac{1_{n \times n} \circ \Sigma^{(1)}(\tilde{\lambda}^*) + 1_{m \times m} \circ \Sigma^{(2)}_{\min} - 1}{4 \max\{m, n\} \epsilon}.
\]

**5.2 (Net) Profit-Loss**

In this section, we will restrict ourselves to a broad class of pricing policies and show that the profit-loss is \(R^*_n - P_n \sim \epsilon n^2\). We fix the server pricing policy to the optimal fluid pricing policy and
consider a broad class of pricing policies for customers. In particular, we consider the following:

$$\lambda_j, \eta(q) = \lambda_j^* + \phi_j \left( \frac{q}{\eta^\alpha} \right) \eta^\beta, \quad \forall q \in S, \eta > 0, j \in [m].$$

The first component is the optimal fluid rate and the second component is a queue length dependent adjustment (c.f., [14, 28]). The adjustment is decomposed into a scaled queue length dependent adjustment $\phi_j(\cdot)$ and a factor that depends on the scaling parameter $\eta$. We take $\beta < 0$ as we want to approach the optimal fluid solution as $\eta \to \infty$. We impose some technical conditions on the functions $\phi_j(\cdot)$ for all $j \in [m]$.

**Assumption 3.** For all $j \in [m]$, $\phi_j(\cdot)$ satisfies the following.

(a) There exists $M_j < \infty$ such that $\sup_{q \in S} (\phi_j(q)) \leq M_j$ for $j \in [m].$

(b) We have $\alpha + \beta \leq 0$.

(c) There exists $K > 0$ and $\sigma > 0$ such that for all $j \in [m]$, if $q_j^{(2)} / \eta^\alpha > K$ or there exists an $i$ such that $(i, j) \in E$ and $q_i^{(1)} / \eta^\alpha > K$, then $|\phi_j\left(\frac{q}{\eta^\alpha}\right)| > \sigma$.

These conditions are identical to the conditions given in [28]. Condition (a) is a technical assumption which is required for our analysis. Condition (b) states that the scaling of the system state should be less than the scaling of the pricing policy converging to the fluid optimal. Condition (c) establishes the intuitive condition that as the queue length of a customer (or any of its compatible counterparts) is very large, the system operator should decrease (or increase) the arrival rate of the customer. We now present the lower bound on profit-loss.

**Theorem 6.** Consider a sequence of DTMCs parametrized by $\eta$ operating under any pricing policy satisfying 3 and any matching policy. There exists a constant $K > 0$, that depends on $(\phi_j)_{j \in [m]}$, $F$ and $c$, and $\eta_1 > 0$ such that for all $\eta > \eta_1$ we have $R_\eta^* - P_\eta \geq K\eta^{2\beta + 1}$.

The proof involves using Taylor’s Theorem to expand the profit-loss and then using Lemma 8 to drop the first order term. The proof is concluded by showing that the coefficient of the second order term is non zero. Now, from Theorem 5 we have $\mathbb{E}[q] \geq 1/\eta^\beta$. In turn, from Theorem 6, we deduce $R_\eta^* - P_\eta \geq K\eta^{2\beta + 1}$. To make the best use of the trade off, we should pick $\beta = -1/3$ which will give us $\eta^{1/3}$ net profit-loss. This shows that there exists a broad class of policies under which the upper bound given by Theorem 4 is tight. We present the result formally in the following corollary.

**Corollary 7.** Under the hypothesis of Theorem 6, there exists a constant $K'$, that depends on $(\phi_j)_{j \in [m]}$, $F$ and $c$, and $\eta_2 > 0$ such that for all $\eta > \eta_2$, we have $L_\eta \geq K'\eta^{1/3}$.

**Proof.** For the sequence of DTMCs parametrized by $\eta$, by using Theorem 5 with $\epsilon(\eta) = M\eta^\beta$ we have

$$\mathbb{E}\left[\mathbf{1}_{n+m, \mathbf{q}_\eta}\right] \geq \frac{1_{n \times n} \circ \Sigma^{(1)} + 1_{m \times m} \circ \Sigma^{(2)} - 1}{4 \max\{m, n\} M\eta^\beta}.$$ 

Now, the net profit-loss is given by

$$L_\eta = R_\eta^* - P_\eta - \mathbb{E}\left[\langle \mathbf{s}, \mathbf{q}_\eta \rangle\right] \geq K\eta^{2\beta + 1} + \min_{i,j} \{s_i^{(1)}, s_j^{(2)}\} \frac{1_{n \times n} \circ \Sigma^{(1)} + 1_{m \times m} \circ \Sigma^{(2)} - 1}{4 \max\{m, n\} M\eta^\beta} \quad \forall \eta > \eta_1$$

$$\geq \inf_{\beta < 0} \left\{ K\eta^{2\beta + 1} + \min_{i,j} \{s_i^{(1)}, s_j^{(2)}\} \frac{1_{n \times n} \circ \Sigma^{(1)} + 1_{m \times m} \circ \Sigma^{(2)} - 1}{4 \max\{m, n\} M\eta^\beta} \right\} = K'\eta^{1/3}.$$

\[\square\]
6 A QUALITY DRIVEN VIEW OF THE NEAR OPTIMAL POLICY

We present an alternate view of the sequence of policies we considered in the previous sections.

In particular, instead of considering an asymptotic regime, we analyze the system under a near optimal policy and, critically, impose a given service quality.

To gain intuition, let us consider the two price policy given by (8) and (9). From Lemma 4 and Lemma 6, we know that \( \mathbb{E} [\langle 1_{n+m}, \hat{\mathbf{q}} \rangle] \sim \frac{1}{\epsilon} \) and \( R_e - P \sim \epsilon^2 \) with \( \epsilon_\eta = \epsilon \). Now, for the profit to approach the fluid solution, we need to let \( \epsilon \to 0 \). However, this causes the expected sum of queue length to go to infinity and, therefore, there could be an arbitrary large loss of service quality impacting both servers and customers.

In this section, we maximize the profit (or equivalently, minimize the profit-loss) given a target service level of the system. Specifically, we consider the additional constraint that \( \mathbb{E} [\langle 1_{n+m}, \tilde{\mathbf{q}} \rangle] = C \) for some constant \( C > 0 \). In this case, we need to pick \( \epsilon \) to be of the order \( \frac{1}{\sqrt{C}} \). This will lead to an \( O(\frac{1}{\epsilon}) \) profit-loss as \( R_e - P \sim \epsilon^2 \). If \( C \) is large, then the system is allowed to keep customers and servers waiting for a longer period of time. This allows the system operator to use the policy which is closer to the fluid optimal policy and thus, the profit-loss is lower; but, at the same time, the service quality is hurt. We make this discussion rigorous in the following theorem.

**Theorem 8.** Consider a DTMC operating under the pricing and matching policy given by (8) (9) and \( \epsilon = \epsilon_\eta \) is such that \( \mathbb{E} [\langle 1_{n+m}, \tilde{\mathbf{q}} \rangle] = C \), then

\[
R_e - \frac{B_3}{C^2} + O\left(\frac{1}{C^2}\right) \leq R \leq R_e - \frac{B_4}{C^2} + O\left(\frac{1}{C^2}\right),
\]

where

\[
B_3 = -\sum_{j=1}^{m} \left( \frac{\hat{\lambda}_j^* F''(\hat{\lambda}_j^*)}{2} + F'(\hat{\lambda}_j^*) \right) \left( \frac{B_1 + 2B_2}{2\min_{i \in [n]} \left\{ \sum_{j:(i,j) \in E} \bar{\tilde{q}}_j^* \right\}} \right)^2 > 0,
\]

and

\[
B_4 = -\sum_{j=1}^{m} \left( \frac{\hat{\lambda}_j^* F''(\hat{\lambda}_j^*)}{2} + F'(\hat{\lambda}_j^*) \right) \left( \frac{1_{n \times n} \circ \Sigma^{(1)} + 1_{m \times m} \circ \Sigma^{(2)} - 1}{4 \max\{m, n\}} \right)^2 > 0.
\]

This follows directly from Lemma 4, Theorem 5 and Lemma 6 with \( \epsilon_\eta = \epsilon' \). We note that, this result provides bounds on the profit given the expected queue length and it is free of any scaling. Which means, we are able to analyze the original system without relying on any asymptotic regime.

7 VARIATIONS OF COST FUNCTION AND SIMULATIONS

In this section, we demonstrate the generality of our framework by considering four different variations of the cost function. Each variation corresponds to a different model of strategic behavior we impose on servers. We use numerical simulation to compare the different models. We begin by stating the variations of \( c(\cdot) \).

**Selfish Servers (SD):** This corresponds to the cost function defined in Section 2 and given by (1). We denote the optimal objective value of (4) by \( R^0 \) and the optimal solution with \((\ast, 0)\) as the super-script.

**Incentive Compatible (IC):** In this model we enforce the constraint that servers do not lie. This is equivalent to designing an incentive compatible pricing policy. That is, we ensure that \( u_{il} \geq u_{il} \) for all \( l \in [n] \), for all \( i \in [n] \). We make an additional assumption that a server will choose its own queue if possible. Thus, we will have \( \hat{\mu}_{il} = 0 \) for all \( l \neq i \). The cost function with this new
constraint can be re-written as follows:

\[
c^1(\mu) = \min_{p^{(1)}} \left\{ \mu, p^{(1)} \right\}
\]

subject to, \( u_{il} = p_{i}^{(1)} - c_{il} \forall i \in [n], \forall l \in [n], \quad G_{il}(\mu) = u_{il} \forall i \in [n], \quad u_{il} \geq u_{il} \forall i \in [n] \forall l \in [n] \).

By noting that \( c_{il} = 0 \) for all \( i \in [n] \) and eliminating \( u \) and \( p^{(1)} \), we get

\[
c^1(\mu) = \sum_{i=1}^{n} G_{i}(\mu_{i})\mu_{i} \quad \text{if} \quad G_{i}(\mu_{i}) \geq G_{i}(\mu_{i}) - c_{i}, \quad \forall i \in [n], \forall l \in [n],
\]

\[
\quad \text{otherwise.}
\]

Now, if \( G_{i}(\cdot) \) is an affine function, then \( c^1(\cdot) \) is convex so we can reduce (4) to the LP (5).

**Corollary 9.** If \( G_{i}(\cdot) \) is an affine, monotonically increasing function for all \( i \in [n] \), then \( c(\cdot) \) is convex. Thus, by Proposition 2, we have \( R_{*} = R_{*}^{*} \).

**Proof.** We know that \( G_{i}(\mu_{i}) = b_{i}\mu_{i} + b'_{i} \) such that \( b_{i} \geq 0 \). Thus, \( G(\mu, \mu) \) is a quadratic function in \( \mu \) with a positive semi-definite Hessian. Thus, it is convex. In addition, the domain of \( c(\cdot) \) is a polyhedron as it is defined by a finite number of affine inequalities, thus it is convex. \( \square \)

The cost function in this variation is given by (10). We denote the optimal objective value of (4) by \( R_{1}^{\beta} \) and the optimal solution with \((*, 1)\) as the super-script.

**β– Incentive Compatible (β– IC):** In this model we consider a convex combination of the two cases we considered before. That is, we enforce that at least \( 0 < \beta < 1 \) fraction of each type of servers are truthful, that is, they join their own queue. Thus, we add an additional constraint \( v_{ii} \geq \beta \) for all \( i \in [n] \) or equivalently, \( \mu_{ii} \geq \beta \sum_{i=1}^{n} \tilde{\mu}_{il} \) for all \( i \in [n] \). For \( \beta = 0 \), it is equivalent to the first case (SD) and for \( \beta = 1 \), it is equivalent to the second case (IC). The cost function is given by (1) with an additional constraint \( \tilde{\mu}_{ii} \geq \beta \sum_{i=1}^{n} \tilde{\mu}_{il} \) for all \( i \in [n] \). We denote the optimal objective value of (4) by \( R_{1}^{\beta} \) and the optimal solution with \((*, \beta)\) as the super-script.

**First Best, Incentive Compatible (FB–IC):** In this case, all the servers join their own queue irrespective of their utilities. The fluid model is given by [28]. We denote its optimal objective value by \( R_{1}^{**} \) and the optimal solution with super-script \((***, 1)\).

We first present some straightforward relations between the optimal values of (4).

**Proposition 3.** The following statements are true:

(1) \( R_{1}^{**} \geq R_{1}^{*} \) and if \( c_{il} \geq G_{i}(\mu_{i}^{**}) - G_{i}(\mu_{i}^{*}) \) for all \( i, l \in [n] \), then \( R_{1}^{**} = R_{1}^{*} \).

(2) \( R_{1}^{\beta i} \geq R_{1}^{\beta i} \) for all \( 1 \geq \beta_{2} \geq \beta_{1} \geq 0 \).

(3) For \( c_{1} \geq c_{2} \), we have \( R_{1}^{1}(c_{1}) \leq R_{1}^{2}(c_{2}) \).

It is obvious that (2) is true as the feasible region of the optimization problem defining the cost function for \( \beta_{1}-IC \) servers contains the feasible region of \( \beta_{2}-IC \) servers and their objective functions are identical. In addition, (1) follows by noting that the domain of \( c_{i} \) is a subset of the domain of \( c_{i}^{1} \) and they are equal in the domain of \( c_{i}^{1} \).

Now, to solve these fluid models numerically, we present an equivalent reformulation of the probabilistic fluid model as a finite dimensional optimization problem. We first identify that the primal problem (4) is a class of risk averse optimization problem and falls into the category of the problem of moments (Section 6.6, [24]). Thus, by [24, Proposition 6.40 ], we can rewrite the primal
to incentivize the servers and this threshold of penalty depends on the network topology, supply
demand curves given by
It is a finite optimization problem with dimension of the decision variables equal to

equivalently as follows:

subject to, \( \lambda_j = \sum_{j=1}^{n} \chi_{ij} \forall j \in [m], \quad \sum_{l=1}^{n+1} \beta_l \mu_l = \sum_{j=1}^{m} \chi_{ij} \forall i \in [n] \)
\( \chi_{ij} = 0 \forall (i, j) \notin E, \quad \chi_{ij} \geq 0 \forall (i, j) \in E, \quad (1_{n+1}, \beta) = 1, \quad \beta \geq 0_{n+1}. \)
It is a finite optimization problem with dimension of the decision variables equal to \(2m+n^2+3n+1.\)

7.1 N-Network

7.1.1 Cost Function and Fluid Model. We compare the cost functions and the resultant fluid model for the different cases discussed above. In this sub section, we consider an N-network graph and carry out simulations by varying the inverse supply curves and the penalty due to lying. We start by plotting the contour plots of the cost functions with the penalty \( c_{12} = 2 \) and \( c_{21} = 5 \) for all the different cases and for two sets of supply curves. The results are summarized in Fig. 4. It can be observed that for the case of IC and FB: IC, the cost function is convex and for all the other cases, it is non convex. Although, for some choices of supply curves, the cost function is close to convex as in Fig. 4 (e), (f). We will later see that the optimal pricing policy for convex and near convex cost functions is deterministic and for non-convex cost functions, it is probabilistic. We pick linear demand curves given by \( F_1(\lambda_1) = 10 - \lambda_1/2 \) and \( F_2 = 15 - \lambda_2. \) The resultant optimal objective values of (4) is summarized in Table 1. The optimal solution in the case of incentive compatible servers for all the cases is a deterministic pricing policy for the servers as the supply curves are chosen to be linear and thus, the simulation results conform with Corollary 9. In addition, as expected, we have \( R^d \leq R^*_s. \) For the first set of supply curves, by statement one of Proposition 3, for all \( c_{12}, c_{21} \geq 0, \) we have \( R^d = R^*_s \) and for the second set of supply curves, for all \( c_{12} \geq 0.42 \) and \( c_{21} \geq -0.42, \) we have \( R^d = R^*_s. \) In words, if \( c \) is large enough, the system operator doesn’t need to incentivize the servers and this threshold of penalty depends on the network topology, supply and demand curves.
We will consider the same two sets of supply curves as in the fluid model simulations. With perturbation on support \( \{0, 1, 2, 3, 4, 5\} \), the uniform distribution is perturbed to match the mean arrival rate with the two-price policy. We consider binomial distribution for the stochastic system. To analyze the pre-limit behaviour of the policy, we calculate the percentage loss compared to the upper bound \( \eta R^* \). Mathematically,

\[
\%\text{Loss} = \frac{L_\eta}{\eta R^*} \times 100.
\]

We will consider the same two sets of supply curves as in the fluid model simulations.

For the case when \( G_1(\mu_1) = 2\mu_1 \) and \( G_2(\mu_2) = \mu_2 \), all the fluid models have the same optimal solution. We use this optimal fluid arrival rates in the two price policy and simulate the system for different distributions of the arrival rate. We consider binomial distribution \( (n', \rho) \) with \( n' = 5 \) and \( \rho = 0.5 \), and a perturbed uniform distribution with support \( \{0, 1, 2, 3, 4, 5\} \). The success probability of binomial is chosen so that the mean arrival rate matches the two-price policy. Similarly, the uniform distribution is perturbed to match the mean arrival rate with the two-price policy.

For the case when \( G_1(\mu_1) = \mu_1 \) and \( G_2(\mu_2) = 3\mu_2 - 3 \), all the fluid models results in different optimal solutions. Thus, we analyze the stochastic system under all these optimal solutions for the case when \( c_1 = c_2 = 1 \). For this case, the distribution of arrivals we use is uniform distribution with perturbation on support \( \{0, 1, 2, 3, 4, 5\} \).

Fig. 5. N-Network.

The optimal solution in the case of selfish servers for the first and second set of supply curves is a deterministic and probabilistic policy, respectively. By the contour plots of the cost function given in Fig. 4 (a), (d), we can see that in the first case, it is approximately convex and in the second case, it is non convex. This verifies Proposition 2. The optimal solution with \( G_1 = \mu_1, G_2 = 3\mu_2 - 3 \), and \( c = 0_{2 \times 2} \) are as follows:

\[
\begin{align*}
(\bar{\mu}^1)_{0,*} &= \begin{bmatrix} 3.42 \\ 0.12 \\ 0 \\ 0 \end{bmatrix} \\
(\bar{\mu}^2)_{0,*} &= \begin{bmatrix} 0 \\ 0.21 \\ 3.53 \\ 1.97 \end{bmatrix} \\
(\bar{\mu}^3)_{0,*} &= \begin{bmatrix} 0.025 \\ 2.18 \\ 3.52 \\ 0 \end{bmatrix} \\
(\bar{\mu}^1)^{1,*} &= \begin{bmatrix} 3.42 \\ 0 \\ 2.14 \end{bmatrix} \\
(\bar{\mu}^1)^{1,**} &= \begin{bmatrix} 3.33 \\ 0 \\ 2.25 \end{bmatrix} \\
(\bar{\mu}^2)^{1,*} &= \begin{bmatrix} 1 \\ 0 \end{bmatrix} \\
(\bar{\mu}^2)^{1,**} &= \begin{bmatrix} 1 \\ 0 \end{bmatrix} \\
\lambda^{0,*} &= (2.15, 3.58) \\
\lambda^{1,*} &= (3.42, 2.14) \\
\lambda^{1,**} &= (3.33, 2.25)
\end{align*}
\]

One crucial observation is that the optimal solution of IC and FB: IC are close to each other even when \( c \) is small. We analyze this further in the Appendix.

### 7.1.2 Stochastic Simulation

Now, we analyze the proposed two-price policy and max-weight matching policy for the stochastic system. To analyze the pre-limit behaviour of the policy, we calculate the percentage loss compared to the upper bound \( \eta R^* \). Mathematically,

\[
\%\text{Loss} = \frac{L_\eta}{\eta R^*} \times 100.
\]

We will consider the same two sets of supply curves as in the fluid model simulations.

For the case when \( G_1(\mu_1) = 2\mu_1 \) and \( G_2(\mu_2) = \mu_2 \), all the fluid models have the same optimal solution. We use this optimal fluid arrival rates in the two price policy and simulate the system for different distributions of the arrival rate. We consider binomial distribution \( (n', \rho) \) with \( n' = 5 \) and \( \rho = 0.5 \), and a perturbed uniform distribution with support \( \{0, 1, 2, 3, 4, 5\} \). The success probability of binomial is chosen so that the mean arrival rate matches the two-price policy. Similarly, the uniform distribution is perturbed to match the mean arrival rate with the two-price policy.

For the case when \( G_1(\mu_1) = \mu_1 \) and \( G_2(\mu_2) = 3\mu_2 - 3 \), all the fluid models results in different optimal solutions. Thus, we analyze the stochastic system under all these optimal solutions for the case when \( c_1 = c_2 = 1 \). For this case, the distribution of arrivals we use is uniform distribution with perturbation on support \( \{0, 1, 2, 3, 4, 5\} \).
The result for both the cases are summarized in Fig. 6 and Fig. 7. The percentage loss decays very fast and less than 5% error is achieved for $\eta$ as small as 10. This shows the effectiveness of the proposed policy even in the pre-limit system. By Fig. 6 we can observe that the percentage loss is robust to the change of distribution of the arrival rate and by Fig. 6 we conclude that it is robust to different cost functions as well.

In addition, we also study the system free of asymptotic regime and the result for the N-Network is plotted in Fig. 8. Here, we can observe the trade-off between the average sum of queue length and the loss in profit incurred by the system operator. This provides a lot of insight on how to appropriately choose the parameter of two price policy to optimize this trade-off. We can observe that higher variance of the arrival process leads to higher queue lengths for the same loss in profit. This is coherent with Theorem 8.

8 CONCLUSION

In this paper, we considered a very general model of two-sided queues with strategic servers. The cost paid to the servers as a function of their arrival rates is formulated as an optimization problem with equilibrium constraints. We consider multiple different models and present their comparison using theoretical and simulation results. Using a general cost function, we introduced a novel probabilistic fluid model which provides an upper bound on the achievable profit under any policy. Then, we presented a two price policy and max-weight matching policy which achieves this upper bound under the large market regime with $O(\eta^{1/3})$ rate of convergence. We also showed that under a broad class of customer pricing policy, the rate of convergence is lower bounded by $\Omega(\eta^{1/3})$ under any matching policy. Finally, given the service level of the system, we presented the bounds on the achievable profit under the two price policy and max-weight matching policy which is an asymptotic regime free result.
A PROBABILISTIC FLUID MODEL

A.1 Proof of Lemma 1

Proof. In this proof, we denote $\alpha(\mathbf{q})$ as $\alpha(\mathbf{q}, \mathbf{u})$ to be explicit that for all $\mathbf{q} \in S$, $\alpha(\mathbf{q}, \mathbf{u})$ is a probability measure over $\mathbf{u} \in \Omega$. As the DTMC is assumed to be stable, there exists a unique stationary distribution and we denote it by $\pi$. By the hypothesis of the Lemma, we have $\mathbb{E}_\mathbf{q} [\langle 1_{n+m}, \mathbf{q} \rangle] < \infty$. Thus, in steady state, we have $\mathbb{E}_\mathbf{q} [\mathbf{q}] = \mathbb{E}_\mathbf{q} [\mathbf{q}^*] \Rightarrow \mathbb{E}_\mathbf{a} = \mathbb{E}_\mathbf{x},$ where we denote the queue length one time slot after $\mathbf{q}$ by $\mathbf{q}^* = \mathbf{q} + \mathbf{a} - \mathbf{x}$. Now, we will simplify the RHS and LHS separately. We have

$$\mathbb{E}_\mathbf{a} = \mathbb{E} \left[ \mathbb{E}_\mathbf{x} [\mathbf{a}|\mathbf{q}] \right] = \mathbb{E} \left[ \left( \mathbf{\lambda}(\mathbf{q}), \mathbb{E}_\alpha(\mathbf{q}) [\mathbf{u}] \right) \right] = (\mathbb{E}_\mathbf{x} [\mathbf{\lambda}(\mathbf{q})], \mathbb{E}_\alpha(\mathbf{q}) [\mathbf{u}]) \approx (\mathbf{\hat{\lambda}}, \mathbb{E}_\mathbf{\hat{a}} [\mathbf{u}]),$$

(11)

where $(\ast)$ follows as we defined $\lambda_j = \mathbb{E} [\lambda_j]$ for all $j \in [m]$ and

$$\mathbb{E} \left[ \mathbb{E}_\alpha(\mathbf{q}) [\mathbf{u}] \right] = \sum_{\mathbf{q} \in S} \int_\Omega \mu_i \, d\alpha(\mathbf{q}, \mathbf{u}) \, \pi(\mathbf{q}) = \int_\Omega \mu_i \sum_{\mathbf{q} \in S} d\alpha(\mathbf{q}, \mathbf{u}) \, \pi(\mathbf{q}) = \int_\Omega \mu_i \, d\hat{\alpha}(\mathbf{u}) = \mathbb{E}_\mathbf{\hat{a}} [\mathbf{u}],$$

where, $(\ast)$ follows from Tonelli’s Theorem and $(\ast\ast)$ follows as we defined $\sum_{\mathbf{q} \in S} \alpha(\mathbf{q}, \mathbf{u}) \, \pi(\mathbf{q}) = \hat{\alpha}(\mathbf{u})$ and observe that $\hat{\alpha}(\cdot)$ is a probability measure as it is non negative, $\int_\Omega d\hat{\alpha}(\mu_i) = 1$ and it is countably additive. Now, we will simplify the right hand side. First define $\mathbb{E}_\mathbf{\hat{a}} [\hat{\chi}_{1}(\mathbf{q})] = \hat{\chi}_{1j}$ for all $(i, j)$. By (2)(c), we have $\hat{\chi}_{1j} = 0$ for all $(i, j) \notin E$. Next, we have

$$\mathbb{E} \left[ x_{1}^{(1)}(\mathbf{q}) \right] = \sum_{j=1}^{m} \mathbb{E} \left[ \hat{\chi}_{1j}(\mathbf{q}) \right] = \sum_{j=1}^{m} \hat{\chi}_{1j} \forall i \in [n], \quad \mathbb{E} \left[ x_{j}^{(1)}(\mathbf{q}) \right] = \sum_{i=1}^{n} \mathbb{E} \left[ \hat{\chi}_{ij}(\mathbf{q}) \right] = \sum_{i=1}^{n} \hat{\chi}_{ij} \forall j \in [m].$$

(12)

Now, simplifying $\mathbb{E}_\mathbf{a} = \mathbb{E}_\mathbf{x}$ using (11) and (12), we get the constraints of the optimization problem (4).

\square

A.2 Proof of Proposition 1

Proof. Proof It suffices to consider only the set of pricing and matching policies under which $\mathbb{E} [\langle 1_{n+m}, \mathbf{q} \rangle] < \infty$, as, otherwise, the net profit $\mathcal{R}$ will be $-\infty$. We will consider the class of stationary Markovian policies. Note that, by Lemma 1, the constraints of the fluid problem (4), are necessary constraints for stability. Now, under a given pricing and matching policy, we will upper bound the maximum profit and net profit. We have

$$\mathbb{E} [\langle \mathbf{\lambda}(\mathbf{q}), \mathbf{\lambda}(\mathbf{q}) \rangle] - \mathbb{E} [\mathbb{E}_\alpha(\mathbf{q}, \mathbf{u}) \left[ c(\mathbf{u}) \right]] - s \mathbb{E} [\langle 1_{n+m}, \mathbf{q} \rangle] \leq \mathbb{E} [\langle \mathbf{\lambda}(\mathbf{q}), \mathbf{\lambda}(\mathbf{q}) \rangle] - \mathbb{E} [\mathbb{E}_\alpha(\mathbf{q}, \mathbf{u}) \left[ c(\mathbf{u}) \right]]$$

$$\leq \mathbb{E} [\mathbf{\lambda}(\mathbf{q})] - \sum_{\mathbf{q} \in S} \int \mathbb{E} [\mathbf{\lambda}(\mathbf{q})], \mathbb{E} [\mathbf{\lambda}(\mathbf{q})]) - \mathbb{E} [\mathbb{E}_\alpha(\mathbf{q}, \mathbf{u}) \left[ c(\mathbf{u}) \right]]$$

$$\leq \langle \mathbf{\lambda}(\mathbf{q}), \mathbf{\lambda}(\mathbf{q}) \rangle - \mathbb{E}_\mathbf{\hat{a}} [\mathbf{u}] \left[ c(\mathbf{u}) \right] .$$

Thus, the net profit obtained under any stationary pricing and matching policy is upper bounded by the solution of the probabilistic fluid model. This completes the proof.

\square

A.3 Proof of Proposition 2

Proof. We will first show that $R_{\infty}^* \geq R^*$. For a given $\mathbf{\hat{a}}$, let us start by defining $\mathbf{u} \overset{\Delta}{=} \mathbb{E}_\mathbf{\hat{a}} [\mathbf{\hat{u}}]$. Now, the objective function of (4) can be upper bounded by Jensen’s inequality to get

$$\langle \mathbf{\lambda}(\mathbf{q}), \mathbf{\lambda}(\mathbf{q}) \rangle - \mathbb{E}_\mathbf{\hat{a}} [c(\mathbf{u})] \leq \langle \mathbf{\lambda}(\mathbf{q}), \mathbf{\lambda}(\mathbf{q}) \rangle - c (\mathbb{E}_\mathbf{\hat{a}} [\mathbf{\hat{u}}]) = \langle \mathbf{\lambda}(\mathbf{q}), \mathbf{\lambda}(\mathbf{q}) \rangle - c(\mathbf{\hat{u}}).$$

)},
Thus, we have

$$R^* \leq \max_{\hat{\lambda}, \hat{\alpha}, \hat{\beta}} \left\{ F(\hat{\lambda}), \hat{\lambda} \right\} - c(\mu)$$

subject to,

$$\hat{\lambda}_j = \sum_{i=1}^{n} \hat{\chi}_{ij} \quad \forall j \in [m]$$

$$\mu_i = \sum_{j=1}^{m} \hat{\chi}_{ij} \quad \forall i \in [n]$$

$$\hat{\chi}_{ij} = 0 \quad \forall (i, j) \notin E, \quad \hat{\chi}_{ij} \geq 0 \quad \forall (i, j) \in E,$$

Note that we can replace $\hat{\alpha}$ by $\mu$ in the arguments in terms of which we are maximizing as the objective function and constraints only depend on $\hat{\alpha}$ through $\mu$. Thus, by (5), we get $R^* \leq R^*_{co}$. Now, we will show the opposite inequality. Let the optimal solution of (5) be $(\hat{\lambda}^*, \mu^*, \hat{\beta}^*)$. Note that $(\hat{\lambda}^*, \hat{\alpha}^*, \hat{\beta}^*)$ is a feasible solution for (4), with $\hat{\alpha}^* = 1$ if $\hat{\mu} = \mu^*$ and 0 otherwise. Under this feasible solution, the objective function value of (4) is $R^*_{co}$. Thus, we have $R^* \geq R^*_{co}$. This completes the proof.

□

A.4 Cost Function Reformulation

Proof of Lemma 2. We will first show that $2 \Rightarrow 1$.

$$\sum_{i=1}^{n} \sum_{l=1}^{n} u_{il}v_{il} = \sum_{i=1}^{n} \sum_{l \in [n]: v_{il} > 0} u_{il}v_{il}$$

$$\leq \sum_{i=1}^{n} \max_{l \in [n]} \{u_{il}^*\} \sum_{l \in [n]: v_{il} > 0} v_{il}$$

$$\leq \sum_{i=1}^{n} \max_{l \in [n]} \{u_{il}^*\}$$

$$= \sum_{i=1}^{n} \sum_{l=1}^{n} v_{il} \max_{l \in [n]} \{u_{il}^*\}$$

$$\geq \sum_{i=1}^{n} \sum_{l=1}^{n} \tilde{v}_{il}u_{il},$$

where (*) follows as $v_{il} > 0$ only when $u_{il}$ is the maximum among all $u_{il'}$ for $l' \in [n]$ and the maximum is unique. In addition, (***) follows as $\sum_{l \in [n]: v_{il} > 0} v_{il} = 1$ for all $i \in [n]$. Now we will show that $1 \Rightarrow 2$.

Suppose $v_{il} > 0$. For a given $l' \in [n]$, define $\tilde{v}$ as follows:

$$\tilde{v}_{il'} = \begin{cases} v_{il'} & \text{if } i' \neq i \\ v_{il} + v_{il'} & \text{if } i' = i, r = l' \\ 0 & \text{if } i' = i, r = l \\ v_{il} & \text{if } i' = i, r \neq l', r \neq l \end{cases}$$
Note that \( v \in C \) and by 2, we have
\[
\sum_{i=1}^{n} \sum_{l=1}^{n} u_{il} \left( v_{il} - \bar{v}_{il'} \right) \geq 0
\Rightarrow u_{il} \left( v_{il} - \bar{v}_{il'} \right) + u_{il} \left( v_{il} - \bar{v}_{il} \right) \geq 0
\Rightarrow -u_{il} v_{il} + u_{il} v_{il} \geq 0
\Rightarrow u_{il} \geq u_{il'}.
\]
As \( l' \in [n] \) is arbitrary, we deduce \( u_{il} \geq u_{il'} \) for all \( l' \in [n] \). Now, we will prove 3 \( \Rightarrow \) 2. For a given \( i \in [n] \), let \( l \in [n] \) be such that \( v_{il} > 0 \). Then we have, \( \xi_{il} = 0 \) by complementary constraint. This gives us \( u_{il} = \kappa_{l} \leq \xi_{il} = u_{il} \) for all \( l' \in [n] \) as \( \xi_{il} \geq 0 \). This completes the proof.

Now, we will show 2 \( \Rightarrow \) 3. We will show that there exists \( k \in \mathbb{R}^{n} \) and \( \xi \in \mathbb{R}^{n \times n} \) such that 3 is satisfied. Define \( \kappa_{i} = \max_{l' \in [n]} \{ u_{il'} \} \) which gives us \( \xi_{il} - \kappa_{i} = \kappa_{l} \) for all \( i, l \in [n] \). Thus, it is trivially true that \( \xi = 0 \). In addition, if \( v_{il} > 0 \) for some \( i, l \in [n] \), then \( u_{il} \geq u_{il'} \) for all \( l' \in [n] \), which implies that \( \kappa_{i} = u_{il} \) and thus, \( \xi_{il} = 0 \). As \( i, l \) is arbitrary, we have \( \xi_{il} v_{il} = 0 \) for all \( i, l \in [n] \). This completes the proof.

**Proof of Lemma 3.** 1 \( \Rightarrow \) 2. For a given \( i \in [n] \), as \( G_{i}(\sum_{k=1}^{n} \tilde{\mu}_{ik}) = \max_{l \in [n]} \{ u_{il} \} \), we have \( G_{i}(\sum_{k=1}^{n} \tilde{\mu}_{ik}) \geq u_{il} \) for all \( l \in [n] \). In addition, we also have
\[
G_{i} \left( \sum_{k=1}^{n} \tilde{\mu}_{ik} \right) \leq \max_{l \in [n]} \{ u_{il} \} \iff G_{i} \left( \sum_{k=1}^{n} \tilde{\mu}_{ik} \right) \leq u_{il} + M \mathbb{I}_{l = \min_{l' \in [n]} \{ u_{il'} \}} \}
\Rightarrow G_{i} \left( \sum_{k=1}^{n} \tilde{\mu}_{ik} \right) \leq u_{il} + M(1 - b_{il}), \sum_{l=1}^{n} b_{il} = 1. \quad (13)
\]

For (\*) to hold true, we can pick \( M \) to be an upper bound on the left hand side which is \( \sum_{l=1}^{n} G_{i}(\{1, \mu\}) \).

Next, (\**\*) follows by defining \( b_{il} = 1 \{ u_{il} = \max_{l' \in [n]} \{ u_{il'} \} \} \) if the maximizer is unique. In this case, we will have \( \sum_{l=1}^{n} b_{il} = 1. \) If the maximizer is not unique, it suffices to have \( b_{il} = 1 \) for any one of the maximizer (in particular, we pick the smallest \( l \)) and zero for the rest. So \( \sum_{l=1}^{n} b_{il} = 1 \) still holds. This completes the proof. 2 \( \Rightarrow \) 1 follows from (13) along with the inequality \( G_{i}(\sum_{k=1}^{n} \tilde{\mu}_{ik}) \geq u_{il} \) for all \( l \in [n] \).

**B THEOREM 4**

**B.1 Proof of Lemma 4**

**Proof.** For all \( \eta > 0 \), consider the Lyapunov functions \( V(q_{\eta}) = 1_{n+m}, q_{\eta}^2 \) for all \( \eta \). We will calculate the drift of this Lyapunov function and show that it is negative outside a finite set. We have
\[
\mathbb{E} \left[ \Delta V(q_{\eta}(k)) | q_{\eta}(k) \right] = \mathbb{E} \left[ 1_{n+m}, q_{\eta}(k+1)^2 - 1_{n+m}, q_{\eta}(k)^2 \right] | q_{\eta}(k) \]
\[
= \mathbb{E} \left[ 1_{n+m}, (q_{\eta}(k) + a_{\eta}(k) - x_{\eta}(k))^2 \right] \leq \mathbb{E} \left[ 1_{n+m}, q_{\eta}(k)^2 \right] | q_{\eta}(k) \]
\[
= \mathbb{E} \left[ 1_{n+m}, (a_{\eta}(k) - x_{\eta}(k))^2 \right] | q_{\eta}(k) \] + \( 2 \mathbb{E} \left[ (a_{\eta}(k), a_{\eta}(k) - x_{\eta}(k)) | q_{\eta}(k) \right]. \quad \frac{T_{1}}{T_{2}}
\]

Now, we will simplify \( T_{1} \) separately. First note that
\[
0 \leq 1_{n+m}, x_{\eta}(k) \leq 2 \left( 1_{n+m}, a_{\eta}(k) \right) \quad \text{w.p. 1},
\]
as the matching policy is defined such that, at the beginning of each period, there won't be any customer-server compatible pairs waiting in the system. Thus, the maximum possible pairs that can be matched in one time epoch is the total number of arrivals. So, we have

\[
T_1 = \mathbb{E} \left[ \left( \mathbf{1}_{n+m} \cdot (a_{\eta}(k) - x_{\eta}(k))^2 \right) | q_{\eta}(k) \right]
\]

\[
\leq \mathbb{E} \left[ \left( \mathbf{1}_{n+m} \cdot a_{\eta}(k)^2 \right) | q_{\eta}(k) \right] + \mathbb{E} \left[ \left( \mathbf{1}_{n+m} \cdot x_{\eta}(k)^2 \right) | q_{\eta}(k) \right]
\]

\[
= \sum_{i=1}^{n} \left( \Sigma^{(1)}_{i,j} (\alpha(q_{\eta})) + \mathbb{E}_{\alpha_{\eta}(q_{\eta})} [\mu_i]^2 \right) + \sum_{j=1}^{m} \left( \Sigma^{(2)}_{j,j} (\lambda(q_{\eta})) + (\lambda_{i,j}(q_{\eta}))^2 \right) + \mathbb{E} \left[ \left( \mathbf{1}_{n+m} \cdot x_{\eta}(k)^2 \right) | q_{\eta}(k) \right]
\]

\[
\leq \sum_{i=1}^{n} \left( \Sigma^{(1)}_{i,j} (\tilde{\alpha}^*) + \mathbb{E}_{\tilde{\epsilon}^*} [\mu_i]^2 \right) + \sum_{j=1}^{m} \left( \Sigma^{(2)}_{\max} (\tilde{\lambda}^*_j + 1)^2 \right) + \mathbb{E} \left[ \left( \mathbf{1}_{n+m} \cdot x_{\eta}(k)^2 \right) | q_{\eta}(k) \right]
\]

\[
\leq \sum_{i=1}^{n} \left( \Sigma^{(1)}_{i,j} (\tilde{\alpha}^*) + \mathbb{E}_{\tilde{\epsilon}^*} [\mu_i]^2 \right) + \sum_{j=1}^{m} \left( \Sigma^{(2)}_{\max} (\tilde{\lambda}^*_j + 1)^2 \right) + 4 \mathbb{E} \left[ \left( \mathbf{1}_{n+m} \cdot a_{\eta}(k)^2 \right) | q_{\eta}(k) \right]
\]

\[
\leq \sum_{i=1}^{n} \left( \Sigma^{(1)}_{i,j} (\tilde{\alpha}^*) + \mathbb{E}_{\tilde{\epsilon}^*} [\mu_i]^2 \right) + \sum_{j=1}^{m} \left( \Sigma^{(2)}_{\max} (\tilde{\lambda}^*_j + 1)^2 \right) + 4 \mathbf{1}_{n \times n} \circ \Sigma^{(1)}_{\max} (\tilde{\alpha}^*) + 4 \mathbf{1}_{m \times m} \circ \Sigma^{(2)}_{\max}
\]

\[
\Delta \equiv B_1.
\]

Now, we will simplify \(T_2\) below.

\[
T_2 = \mathbb{E} \left[ \left( q_{\eta}(k), a_{\eta}(k) - x_{\eta}(k) \right) | q_{\eta}(k) \right]
\]

\[
= \mathbb{E} \left[ \left( q_{\eta}(k), a_{\eta}(k) \right) | q_{\eta}(k) \right] - \mathbb{E} \left[ \left( x_{\eta}(k), q_{\eta}(k) \right) | q_{\eta}(k) \right]
\]

\[
= \left( q_{\eta}(k), \mathbb{E}_{a_{\eta}(k)} | q_{\eta}(k) \right] - \mathbb{E} \left[ \max_{y \in \mathbb{P}(2)} \left( y, q_{\eta}(k) \right) | q_{\eta}(k) \right]
\]

\[
= \left( q_{\eta}^{(1)}(k), \mathbb{E}_{\tilde{\alpha}^*} [\mu] \right) + \left( q_{\eta}^{(2)}(k), \lambda_{\eta}(q_{\eta}(k)) \right) - \mathbb{E} \left[ \max_{y \in \mathbb{P}(2)} \left( y, q_{\eta}(k) \right) | q_{\eta}(k) \right]
\]

\[
= -\epsilon_{\eta} \left( 1_m, q_{\eta}^{(2)}(k) \right) + \left( q_{\eta}^{(1)}(k), \mathbb{E}_{\tilde{\alpha}^*} [\mu] \right) + \left( q_{\eta}^{(2)}(k), \tilde{\lambda}^* \right) - \mathbb{E} \left[ \max_{y \in \mathbb{P}(2)} \left( y, q_{\eta}(k) \right) | q_{\eta}(k) \right]
\]

\[
= -\epsilon_{\eta} \left( 1_m, q_{\eta}^{(2)}(k) \right) + \sum_{(i,j) \in \mathbb{E}(L) \cup \mathbb{E}(R)} \tilde{\chi}^{(1)}_{i,j} (q_{\eta}^{(1)}(k) + q_{j,i}^{(2)}(k)) - \mathbb{E} \left[ \max_{y \in \mathbb{P}(2)} \left( y, q_{\eta}(k) \right) | q_{\eta}(k) \right]
\]

\[
\text{Lemma 7. For all } \eta > 0, \text{ we have}
\]

\[
\sum_{(i,j) \in \mathbb{E}} \tilde{\chi}^{(1)}_{i,j} (q_{\eta}^{(1)}(k) + q_{j,i}^{(2)}(k)) - \mathbb{E} \left[ \max_{y \in \mathbb{P}(2)} \left( y, q_{\eta}(k) \right) | q_{\eta}(k) \right] \leq -\epsilon_{\eta} \min_{i \in [m]} \left\{ \sum_{j \in (i,j) \in \mathbb{E}} \frac{\tilde{\chi}^{*}_{i,j}}{\lambda^*_j} \right\} \left( 1_n, q_{\eta}^{(1)}(k) \right) + B_2,
\]

where

\[
B_2 = A_{\max} \sum_{(i,j) \in \mathbb{E}} \tilde{\chi}^{(1)}_{i,j} (\mathbb{E}_{\tilde{\alpha}^*} [\mu_i] + \tilde{\lambda}^*_j) + A_{\max} \sum_{i=1}^{n} \left( \sum_{(j,i) \in \mathbb{E}} \frac{\tilde{\chi}^{*}_{i,j}}{\lambda^*_j} \mathbb{E}_{\tilde{\alpha}^*} [\mu_i] \right).
\]

The proof of the Lemma 7 is provided at the end of the proof of the Lemma 4. Now, using the Lemma 7, we have

\[
T_2 \leq -\epsilon_{\eta} \left( 1_m, q_{\eta}^{(2)}(k) \right) - \epsilon_{\eta} \min_{i \in [m]} \left\{ \sum_{j \in (i,j) \in \mathbb{E}} \frac{\tilde{\chi}^{*}_{i,j}}{\lambda^*_j} \right\} \left( 1_n, q_{\eta}^{(1)}(k) \right) + B_2
\]
\[ \leq -\epsilon_\eta \min_{i \in [n]} \left\{ \sum_{j: (i,j) \in E} \frac{\tilde{\lambda}^*_j}{\tilde{\lambda}^*_j} \right\} \langle 1_{n+m}, q^*_\eta(k) \rangle + B_2 \]

Thus, we have
\[ \mathbb{E} \left[ \Delta V(q^*_\eta) | q^*_\eta(k) \right] \leq B_1 + 2B_2 - 2\epsilon_\eta \min_{i \in [n]} \left\{ \sum_{j: (i,j) \in E} \frac{\tilde{\lambda}^*_j}{\tilde{\lambda}^*_j} \right\} \langle 1_{n+m}, q^*_\eta(k) \rangle . \]

So, there exists a finite set \( \mathcal{B}_\eta \) such that for all \( q \not\in \mathcal{B}_\eta \), we have \( \mathbb{E} \left[ \Delta V(q^*_\eta) \right] < 0 \) where \( \mathcal{B}_\eta \) is defined as:
\[ \mathcal{B}_\eta = \left\{ q^*_\eta \in \mathbb{R}^{n+m} : \langle 1_{n+m}, q^*_\eta(k) \rangle \leq \frac{B_1 + 2B_2}{\epsilon_\eta \min_{i \in [n]} \left\{ \sum_{j: (i,j) \in E} \frac{\tilde{\lambda}^*_j}{\tilde{\lambda}^*_j} \right\}} \right\} . \]

Thus, by the Foster-Lyapunov Theorem, the discrete time Markov chain for all \( \eta > 0 \) is positive recurrent. Now, we can use the moment bound theorem, to get a bound on the expected queue length in steady state. We have
\[ \mathbb{E} \left[ \langle s, q^*_\eta \rangle \right] \leq \|s\|_\infty \mathbb{E} \left[ \langle 1_{n+m}, \tilde{q}^*_\eta \rangle \right] \leq \frac{(B_1 + 2B_2)\|s\|_\infty}{2\epsilon_\eta \min_{i \in [n]} \left\{ \sum_{j: (i,j) \in E} \frac{\tilde{\lambda}^*_j}{\tilde{\lambda}^*_j} \right\}} \]

\[ \square \]

**Proof of Lemma.** In this proof, we will omit the \( k \) and \( \eta \) dependence and write \( q, a \) and \( x \) for \( q^*_\eta(k), a^*_\eta(k) \) and \( x^*_\eta(k) \) respectively, for the ease of notation. The max-weight matching policy can be re-written as follows:

\[ \hat{x} = \arg \max_{\tilde{y}} \sum_{(i,j) \in E} \tilde{y}_{ij} (q^{(1)}_i + q^{(2)}_j) \]

subject to \( q^{(2)}_j + a^{(2)}_j - \sum_{i: (i,j) \in E} \tilde{y}_{ij} \geq 0 \quad \forall j \in [m] \)
\[ q^{(1)}_i + a^{(1)}_i - \sum_{j: (i,j) \in E} \tilde{y}_{ij} \geq 0 \quad \forall i \in [n] \]
\[ \tilde{y}_{ij} \geq 0 \quad \forall (i,j) \in E. \]

Recall that, we allow \( \tilde{y} \) to be a continuous variable as the constraint set is an integral polyhedron. Thus, the linear program always have an optimal solution such that \( \tilde{y} \in \mathbb{Z}_+ \). Note that for a given \( q \) and \( a \), a feasible solution to the above problem is
\[ \tilde{y}_{ij} = \min \left\{ \left( q^{(1)}_i + q^{(2)}_j \right) \frac{\tilde{\lambda}^*_j}{\tilde{\lambda}^*_j} \right\} \frac{\tilde{\lambda}^*_j}{\tilde{\lambda}^*_j} \]
\( \forall (i,j) \in E. \)

This can be easily verified as follows:
\[ \sum_{i: (i,j) \in E} \tilde{y}_{ij} \leq \left( q^{(2)}_j + q^{(2)}_j \right) \frac{\sum_{i: (i,j) \in E} \tilde{\lambda}^*_j}{\tilde{\lambda}^*_j} = a^{(2)}_j + q^{(2)}_j \quad \forall j \in [m] \]
\[ \sum_{j: (i,j) \in E} \tilde{y}_{ij} \leq \left( q^{(1)}_i + q^{(1)}_j \right) \sum_{j: (i,j) \in E} \tilde{\lambda}^*_j \frac{\tilde{\lambda}^*_j}{\tilde{\lambda}^*_j} = a^{(1)}_i + q^{(1)}_i \quad \forall i \in [n] . \]
We will use this feasible solution to lower bound the objective function of (14). But before, observe that as we are using max-weight matching policy, for all \((i, j) \in E\) if \(q_i^{(1)} > 0\) then \(q_j^{(2)} = 0\). In other words, at the start of each epoch, there are no compatible pairs waiting to be matched. So, we have

\[
\mathbb{E} \left[ \hat{y}_{ij} | q_i^{(1)} > A_{\text{max}} \mathbb{E}_{\hat{a}^*} [\mu_i] \right] = \mathbb{E} \left[ \min \left\{ (a_i^{(1)} + q_i^{(1)}) \frac{\hat{\lambda}^*_j}{\mathbb{E}_{\hat{a}^*} [\mu_i]}, (a_j^{(2)} + q_j^{(2)}) \frac{\hat{\lambda}^*_j}{\lambda_j^*} \right\} | q_i^{(1)} > A_{\text{max}} \mathbb{E}_{\hat{a}^*} [\mu_i] \right] = \mathbb{E} \left[ (a_j^{(2)} + q_j^{(2)}) \frac{\hat{\lambda}^*_j}{\lambda_j^*} | q_j^{(2)} = 0 \right] = \hat{\lambda}^*_j + \epsilon_\eta \frac{\hat{\lambda}^*_j}{\lambda_j^*}.
\]

Similarly, note that

\[
\mathbb{E} \left[ \hat{y}_{ij} | q_j^{(2)} > A_{\text{max}} \hat{\lambda}^*_j \right] = \mathbb{E} \left[ \min \left\{ (a_i^{(1)} + q_i^{(1)}) \frac{\hat{\lambda}^*_j}{\mathbb{E}_{\hat{a}^*} [\mu_i]}, (a_j^{(2)} + q_j^{(2)}) \frac{\hat{\lambda}^*_j}{\lambda_j^*} \right\} | q_j^{(2)} > A_{\text{max}} \hat{\lambda}^*_j \right] = \mathbb{E} \left[ (a_i^{(1)} + q_i^{(1)}) \frac{\hat{\lambda}^*_j}{\mathbb{E}_{\hat{a}^*} [\mu_i]} | q_i^{(1)} = 0 \right] = \hat{\lambda}^*_j.
\]

Now, we can lower bound the objective function as follows:

\[
\mathbb{E} \left[ \max_{\hat{y} \in (2)} \langle \hat{y}, q \rangle | q \right] \overset{(a)}{=} \mathbb{E} \left[ \langle \hat{y}, q \rangle | q \right] = \sum_{(i,j) \in E} \mathbb{E} \left[ \hat{y}_{ij} (q_i^{(1)} + q_j^{(2)}) | q \right] \overset{(b)}{=} \sum_{(i,j) \in E} \mathbb{E} \left[ \hat{y}_{ij} (q_i^{(1)} + q_j^{(2)}) | q_i^{(1)} , q_j^{(2)} \right] \overset{(c)}{=} \sum_{(i,j) \in E} \mathbb{E} \left[ \hat{y}_{ij} (q_i^{(1)} + q_j^{(2)}) \mathbb{1}_{q_i^{(1)} > A_{\text{max}} \mathbb{E}_{a^*} [\mu_i]} | q_i^{(1)} , q_j^{(2)} \right] + \sum_{(i,j) \in E} \mathbb{E} \left[ \hat{y}_{ij} (q_i^{(1)} + q_j^{(2)}) \mathbb{1}_{q_j^{(2)} > A_{\text{max}} \hat{\lambda}^*_j} | q_i^{(1)} , q_j^{(2)} \right] \overset{(d)}{=} \sum_{(i,j) \in E} \hat{\lambda}^*_j \left( q_i^{(1)} \mathbb{1}_{q_i^{(1)} > A_{\text{max}} \mathbb{E}_{a^*} [\mu_i]} + q_j^{(2)} \mathbb{1}_{q_j^{(2)} > A_{\text{max}} \hat{\lambda}^*_j} \right) + \epsilon_\eta \sum_{(i,j) \in E} \hat{\lambda}^*_j q_i^{(1)} \mathbb{1}_{q_i^{(1)} > A_{\text{max}} \mathbb{E}_{a^*} [\mu_i]} \geq \sum_{(i,j) \in E} \hat{\lambda}^*_j (q_i^{(1)} + q_j^{(2)}) + \epsilon_\eta \min_{i \in [n]} \left\{ \sum_{j: (i,j) \in E} \hat{\lambda}^*_j \right\} \langle 1_n , q^{(1)} \rangle - B_2,
\]
where
\[ B_2 = A_{\max} \sum_{(i,j) \in E} \hat{x}_{ij}^* (\mathbb{E}_{\tilde{\alpha}^*} [\mu_i] + \hat{\lambda}_{ij}^*) + A_{\max} \sum_{i=1}^n \left( \sum_{j: (i,j) \in E} \frac{\hat{x}_{ij}^*}{\lambda_{ij}^*} \mathbb{E}_{\tilde{\alpha}^*} [\mu_i] \right). \]

The inequality (a) follows as \( \hat{y} \) is a feasible solution to the optimization problem. Next, (b) follows as the feasible solution \( \hat{y}_{ij} \) only depends on \( q_i^{(1)} \) and \( q_j^{(2)} \). The inequality (c) follows as for all \( (i,j) \in E \), only one of \( q_i^{(1)} \) and \( q_j^{(2)} \) can be non-zero. Finally, (d) follows due to the following equation.

\[
\mathbb{E} \left[ \hat{y}_{ij}(q_i^{(1)} + q_j^{(2)}) 1_{\{q_j^{(1)} > A_{\max} \hat{\lambda}_{ij}^*\}} \right] = \mathbb{E} \left[ \hat{y}_{ij}|q_i^{(1)}, q_j^{(2)} \right] q_j^{(2)} 1_{\{q_j^{(2)} > A_{\max} \hat{\lambda}_{ij}^*\}} = \frac{\hat{x}_{ij}^*}{\lambda_{ij}^*} q_j^{(2)} 1_{\{q_j^{(2)} > A_{\max} \hat{\lambda}_{ij}^*\}},
\]

where (\( * \)) is true as the matching policy we are using the max-weight which makes sure there are no compatible pairs waiting in the system at the start of a time epoch.

\[ \square \]

**B.2 Proof of Lemma 5**

We will prove the more general lemma given below and then use this lemma to prove the Lemma 5.

**Lemma 8.** For the server pricing policy given by \( a(q) = \tilde{\alpha}^* \) for all \( q \in S \) and any given pricing policy for customers and any matching policy under which the system is stable and \( \mathbb{E} [(1_{\text{on}}, q)] < \infty \) the following holds:

\[
\sum_{j=1}^m \left( \hat{\lambda}_{ij}^* F_j(\hat{\lambda}_{ij}^*) + F_j(\hat{\lambda}_{ij}^*) \right) \left( \mathbb{E} [\lambda_j(q)] - \hat{\lambda}_{ij}^* \right) = 0.
\]

**Proof of Lemma 8.** Firstly, we will define a matrix to vector operation by stacking columns on top of each other. For the matrix \( \tilde{\chi} \), we will denote the corresponding vector by \( \hat{\chi} \). We define it as follows:

\[ \hat{\chi}_k \overset{\Delta}{=} \tilde{\chi}_{ij}, \text{ where, } i = k\% (n + 1), \ j = \left\lceil \frac{k}{n} \right\rceil \ \forall k \in \{1, \ldots, nm\}. \]

Here \( k\%n \) denotes the reminder obtained when \( k \) is divided by \( n \) and \( \lceil \cdot \rceil \) is the ceiling function which returns the smallest integer greater than or equal to the argument.

Add a constraint \( \tilde{\alpha} = \tilde{\alpha}^* \) in the probabilistic fluid model to get the following optimization problem:

\[
R_1^* = \max_{\hat{\lambda}, \hat{\chi}} g(\hat{\lambda}, \hat{\chi}) = \left< F(\tilde{\lambda}), \hat{\chi} \right> - \mathbb{E}_{\tilde{\alpha}^*} [c(\tilde{\mu})] \quad (15a)
\]

subject to
\[
\begin{align*}
\hat{h}_{ij}^{(2)} &= \hat{\lambda}_j - \frac{1}{n} \sum_{i=1}^n \hat{x}_{ij} = 0 \quad \forall j \in [m] \quad (15b) \\
\hat{h}_{ij}^{(1)} &= \mathbb{E}_{\tilde{\alpha}^*} [\bar{\mu}_i] - \frac{1}{n} \sum_{j=1}^m \hat{x}_{ij} = 0 \quad \forall i \in [n] \quad (15c) \\
\hat{\chi}_{ij} &= 0 \quad \forall (i, j) \notin E, \quad \hat{\chi}_{ij} \geq 0 \quad \forall (i, j) \in E, \quad (15d)
\end{align*}
\]

As the optimal value of (4) is achieved by the feasible point \((\tilde{\lambda}^*, \hat{\chi}^*)\) for (15), we have \( R_1^* \geq R^* \). In addition, as we added a constraint, the feasible region of (15) is a subset of the feasible region of (4), we have \( R^* \geq R_1^* \). Thus, we have \( R^* = R_1^* \) and the optimal solution of (15) is \((\tilde{\lambda}^*, \hat{\chi}^*)\). Now, we will use the KKT conditions in the following steps:
(1) First, we will show that the optimal point is a regular point, that is all the binding constraints are linearly independent.
(2) Then, we will use the given pricing policy to find a feasible direction for the optimization problem above.
(3) Finally, we will use the first order KKT optimality conditions as the objective function is concave and the feasible region is a polyhedron.

Part 1: Note that as \( E_{\tilde{q}} \cdot [\mu_i] > 0 \), it is not possible for \( \tilde{\lambda}_{ij}^* = 0 \) for all \( j \in [m] \). In addition, as the feasible region is a polyhedron, the gradient vectors of all the active constraints at the optimal solution are linearly independent. Thus, the optimal point is a regular point.

Part 2: By hypothesis of the lemma, the DTMC operating under the given pricing and matching policy is stable. Thus, by Lemma 1, (\( E [\lambda(q)] \), \( E_{\tilde{q}} \cdot [\mu] \cdot \chi^\dagger \)) is a feasible solution to the fluid problem (4), where \( \chi^\dagger \) is the corresponding ‘average’ rate assignment matrix (\( \chi \)) for the given policy. Thus, a feasible direction at the optimal point is given by

\[
d = \begin{cases} 
E [\lambda_j(q)] - \tilde{\lambda}_j^* & \forall k \in [m] \\
\tilde{\lambda}_k^* - \tilde{\chi}_k^\dagger & \forall k \in [nm] \setminus [m].
\end{cases}
\]

Part 3: Now, we will use the first order KKT optimality conditions for the optimization problem (15). There exists unique Lagrangian multipliers \((\kappa, \xi) \in \mathbb{R}^{nm+1} \times \mathbb{R}^{m} \) such that,

\[
\nabla g(\tilde{\lambda}^*, \tilde{\chi}^*) + \nabla h(\tilde{\lambda}^*, \tilde{\chi}^*) \kappa + \sum_{k : (k \% (n+1), \left\lfloor \frac{k}{n} \right\rfloor ) \in E} \xi_k \epsilon \bar{e}_{k+n+m} 1_{\tilde{\lambda}_k^*} = 0 \quad \forall k \in [nm] \setminus [m].
\]

where \( \nabla g(\tilde{\lambda}^*, \tilde{\chi}^*) \) is the gradient of the objective function at the optimal point given by

\[
\nabla g(\tilde{\lambda}^*, \tilde{\chi}^*) = \left( F'(\tilde{\lambda}^*) \tilde{\lambda}^* + F(\tilde{\lambda}^*) \right)_{nm}.
\]

In addition, as \( h : \mathbb{R}^{nm+1} \rightarrow \mathbb{R}^{nm} \), its gradient \( \nabla h(\tilde{\lambda}^*, \tilde{\chi}^*) \) is a matrix in \( \mathbb{R}^{(m+nm) \times (m+nm)} \). Now, we will take the inner product of the optimality equation with the feasible direction \( d \). Observe that

\[
\langle d, \nabla h_j^{(2)} \rangle = h_j^{(2)}(\tilde{\lambda}^*, \tilde{\chi}^*) - h_j^{(2)}(E [\lambda(q)], \chi^\dagger) = 0 \quad \forall j \in [m]
\]

\[
\langle d, \nabla h_i^{(1)} \rangle = h_i^{(1)}(\tilde{\lambda}^*, \tilde{\chi}^*) - h_i^{(1)}(E [\lambda(q)], \chi^\dagger) = 0 \quad \forall i \in [n]
\]

\[
\sum_{k : (k \% (n+1), \left\lfloor \frac{k}{n} \right\rfloor ) \in E} \xi_k (\tilde{\lambda}_k^* - \tilde{\chi}_k^\dagger) 1_{\tilde{\lambda}_k^*} = 0 \quad (By \ the \ assumption \ \tilde{\chi}^* > 0_{nm})
\]

\[
\sum_{k : (k \% (n+1), \left\lfloor \frac{k}{n} \right\rfloor ) \in E} \xi_k (\tilde{\lambda}_k^* - \tilde{\chi}_k^\dagger) = 0 \quad (As \ \tilde{\chi}_k^* = \tilde{\chi}_k^\dagger = 0 \ \forall (i, j) \notin E)
\]

Thus, we have \( \nabla g(\tilde{\lambda}^*, \tilde{\chi}^*), d \rangle = 0 \). This gives us the lemma.

Proof of Lemma 5. First note that, the sequence of DTMC operating under the pricing and matching policy given by (8) (9) is stable. In addition, \( E \left[ \langle 1_{n+m}, q_{\eta} \rangle \right] < \infty \) by the hypothesis of the Lemma 5. Thus, we can use Lemma 8. We have

\[
E [\lambda_j, \eta(q)] = \tilde{\lambda}_j^* + \epsilon_j \left( \mathbb{P} \left[ q_{j,\eta}^{(2)} = 0 \right] - \mathbb{P} \left[ q_{j,\eta}^{(2)} > 0 \right] \right) \quad \forall j \in [m].
\]
This gives us

\[ \sum_{j=1}^{m} \left( \hat{\lambda}_j^* F' \left( \hat{\lambda}_j^* \right) + F_j(\hat{\lambda}_j^*) \right) \left( \mathbb{P} \left[ q_{j,\eta}^{(2)} > 0 \right] - \mathbb{P} \left[ q_{j,\eta}^{(2)} = 0 \right] \right) = 0. \]

\[ \square \]

**B.3 Proof of Lemma 6**

**Proof.** We have

\[ \frac{L^*_\eta (\pi_\eta)}{\eta} = R^* - P_\eta (\pi_\eta) \]

\[ = \left\langle F(\hat{\lambda}^*), \hat{\lambda}^* \right\rangle - \mathbb{E}_{\hat{\mu}^*} \left[ c(\mu) \right] - \mathbb{E} \left[ \left\langle F \left( \lambda_\eta(q_\eta) \right), \lambda_\eta(q_\eta) \right\rangle \right] + \mathbb{E}_{\hat{\mu}^*} \left[ c(\mu) \right] \]

\[ = \left\langle F(\hat{\lambda}^*), \hat{\lambda}^* \right\rangle - \mathbb{E} \left[ \left\langle F \left( \lambda_\eta(q_\eta) \right), \lambda_\eta(q_\eta) \right\rangle \right] \]

\[ \overset{(a)}{=} \left\langle F(\hat{\lambda}^*), \hat{\lambda}^* \right\rangle - \sum_{j=1}^{m} \left( \hat{\lambda}_j^* + \epsilon_\eta \right) F_j \left( \hat{\lambda}_j^* + \epsilon_\eta \right) \mathbb{P} \left[ q_{j,\eta}^{(2)} = 0 \right] \]

\[ - \sum_{j=1}^{m} \left( \hat{\lambda}_j^* - \epsilon_\eta \right) F_j \left( \hat{\lambda}_j^* - \epsilon_\eta \right) \mathbb{P} \left[ q_{j,\eta}^{(2)} > 0 \right] \]

\[ \overset{(b)}{=} \left\langle F(\hat{\lambda}^*), \hat{\lambda}^* \right\rangle - \sum_{j=1}^{m} \left( \hat{\lambda}_j^* + \epsilon_\eta \right) \left( F_j(\hat{\lambda}_j^*) + \epsilon_\eta F'_j(\hat{\lambda}_j^*) + \frac{\epsilon_\eta^2}{2} F''(\hat{\lambda}_j^*) + O \left( \epsilon_\eta^2 \right) \right) \mathbb{P} \left[ q_{j,\eta}^{(2)} = 0 \right] \]

\[ - \sum_{j=1}^{m} \left( \hat{\lambda}_j^* - \epsilon_\eta \right) \left( F_j(\hat{\lambda}_j^*) - \epsilon_\eta F'_j(\hat{\lambda}_j^*) + \frac{(\epsilon_\eta)^2}{2} F''(\hat{\lambda}_j^*) + O \left( \epsilon_\eta^2 \right) \right) \mathbb{P} \left[ q_{j,\eta}^{(2)} > 0 \right] \]

\[ = \epsilon_\eta \sum_{j=1}^{m} \left( \hat{\lambda}_j^* F'_j(\hat{\lambda}_j^*) + F_j(\hat{\lambda}_j^*) \right) \left( \mathbb{P} \left[ q_{j,\eta}^{(2)} > 0 \right] - \mathbb{P} \left[ q_{j,\eta}^{(2)} = 0 \right] \right) \]

\[ - \epsilon_\eta^2 \sum_{j=1}^{m} \left( \frac{\hat{\lambda}_j^* F''(\hat{\lambda}_j^*)}{2} + F'_j(\hat{\lambda}_j^*) \right) + O \left( \epsilon_\eta^2 \right) \]

\[ \overset{(c)}{=} - \epsilon_\eta^2 \sum_{j=1}^{m} \left( \frac{\hat{\lambda}_j^* F''(\hat{\lambda}_j^*)}{2} + F'_j(\hat{\lambda}_j^*) \right) + O \left( \epsilon_\eta^2 \right) \]

where \((a)\) follows by the definition of the pricing policy given by \((8)\). Next, \((b)\) follows by Taylor’s series expansion and using the Assumption 1 that the demand curve \(F_j(.)\) is twice continuously differentiable. Finally, \((c)\) follows by Lemma 5. Also, note that

\[ \frac{1}{2} \left\langle F(\hat{\lambda}^*), \hat{\lambda}^* \right\rangle + \left( 1_m, F' \left( \hat{\lambda}^* \right) \right) = \frac{1}{2} \left( \left\langle F(\hat{\lambda}^*), \hat{\lambda}^* \right\rangle + \left( 1_m, F' \left( \hat{\lambda}^* \right) \right) \right) + \frac{1}{2} \left( 1_m, F' \left( \hat{\lambda}^* \right) \right) < 0, \]

as by Assumption 2, \(F_j(\lambda)\lambda_j \) is a concave function, thus the second derivative is non positive and by Assumption 1, the demand function is strictly decreasing, thus the derivative is negative. \[ \square \]
B.4 Proof of Theorem 4

Proof. The net profit loss is given by

\[ L_\eta = R^*_\eta - R_\eta \]

\[ = R^*_\eta - P_\eta + s\mathbb{E} \left[ \left\{ \mathbf{1}_{n+m}, \mathbf{q}_\eta \right\} \right] \]

\[ \overset{(a)}{=} -\eta_\eta^2 \sum_{j=1}^{m} \left( \frac{\hat{\lambda}_s F''(\hat{\lambda}_j^*)}{2} + F'(\hat{\lambda}_j^*) \right) + O \left( \eta_\eta^2 \right) + \mathbb{E} \left[ \left\{ \mathbf{s}, \mathbf{q}_\eta \right\} \right] \]

\[ \overset{(b)}{\leq} -\eta_\eta^2 \sum_{j=1}^{m} \left( \frac{\hat{\lambda}_s F''(\hat{\lambda}_j^*)}{2} + F'(\hat{\lambda}_j^*) \right) + \frac{||\mathbf{s}||_\infty (B_1 + 2B_2)}{\min_{j \in [n]} \left\{ \sum_{j \in E} \frac{e_j'}{\lambda_j'}, 1 \right\}} + O \left( \eta_\eta^2 \right) \]

\[ \overset{(c)}{=} O \left( \eta^{1/3} \right), \]

where (a) follows by Lemma 6, (b) follows by Lemma 4 and (c) follows by picking \( \epsilon_\eta = \eta^{-1/3} \) considering the trade-off between the profit loss \( (\eta_\eta^2) \) and the expected queue length \( (\frac{1}{\epsilon_\eta}) \). This completes the proof.

\[ \square \]

C LOWER BOUND

Proof of Theorem 5. We will start by defining the imbalance of the DTMC given by

\[ z \overset{\Delta}{=} \left\{ \mathbf{1}_n, \mathbf{q}^{(1)} \right\} - \left\{ \mathbf{1}_m, \mathbf{q}^{(2)} \right\}. \]

The update equation of imbalance given the queue length vector \( \mathbf{q}(k) \) can be written as

\[ z(k+1) = z(k) + \left\{ \mathbf{1}_n, \mathbf{a}^{(1)}(k) \right\} - \left\{ \mathbf{1}_m, \mathbf{a}^{(2)}(k) \right\}. \]

Note, that \( z \) itself is not a Markov chain as the arrival vector \( \left( \mathbf{a}(k) \right) \) depends on the queue length \( \left( \mathbf{q}(k) \right) \). Denote \( \gamma \overset{\Delta}{=} \max \left\{ m, n \right\} \) and also denote \( \rho \overset{\Delta}{=} \mathbb{P} \left[ \bar{z} \geq 0 \right], \) that is

\[ \rho = \sum_{x=0}^{\infty} \sum_{\mathbf{q} \in \mathbb{Q}} \mathbb{P} \left[ \bar{z} = \mathbf{q} \right]. \]

For this proof, we will couple the absolute value of the imbalance with a single server queue denoted by \( \gamma^+ \) and arrival and service rate denoted by \( a^+ \) and \( s^+ \). In particular, we will carry out the proof in the following steps:

1. First, we will construct the arrival and service process of the single server queue \( \gamma^+(k) \).
2. Then, we will couple the single server queue with the imbalance such that \( \gamma^+(k) \leq |z(k)| \) for all \( k \in \mathbb{Z}_+ \).
3. Then we will calculate \( \mathbb{E} \left[ \gamma^+ \right] \) and use this to lower bound \( \mathbb{E} \left[ \mathbf{1}_{n+m}, \mathbf{q} \right] \).

Step 1 (Single Server Queue): For all \( k \geq 0 \), generate the following random variables independent of all the other random variables:

\[ s^*_1(k) \geq s.t. \left\{ \mathbf{1}_n, \mathbf{a}^{(1)}(k) \right\}; \quad \mathbb{E} \left[ s^*_1(k) \right] = \left\{ \mathbf{1}_m, \hat{\lambda}^* \right\} + \gamma \epsilon, \quad \text{Var} \left[ s^*_1(k) \right] = \mathbf{1}_{nxn} \circ \Sigma^{(1)} \]

\[ s^*_2(k) \geq s.t. \left\{ \mathbf{1}_n, \mathbf{a}^{(2)}(k) \right\}; \quad \mathbb{E} \left[ s^*_2(k) \right] = \left\{ \mathbf{1}_m, \hat{\lambda}^* \right\} + \gamma \epsilon, \quad \text{Var} \left[ s^*_2(k) \right] = \mathbf{1}_{nxn} \circ \Sigma^{(2)} \]

\[ a^*_1(k) \leq s.t. \left\{ \mathbf{1}_n, \mathbf{a}^{(1)}(k) \right\}; \quad \mathbb{E} \left[ a^*_1(k) \right] = \left\{ \mathbf{1}_m, \hat{\lambda}^* \right\} - \gamma \epsilon, \quad \text{Var} \left[ a^*_1(k) \right] = \mathbf{1}_{nxn} \circ \Sigma^{(1)} \]

\[ a^*_2(k) \leq s.t. \left\{ \mathbf{1}_n, \mathbf{a}^{(2)}(k) \right\}; \quad \mathbb{E} \left[ a^*_2(k) \right] = \left\{ \mathbf{1}_m, \hat{\lambda}^* \right\} - \gamma \epsilon, \quad \text{Var} \left[ a^*_2(k) \right] = \mathbf{1}_{nxn} \circ \Sigma^{(2)} \].
where $\Sigma^{(1)} = \Sigma^{(1)}(\tilde{\alpha}^*)$, and $\Sigma^{(2)}_{\min} \leq \Sigma^{(2)}_l \leq \Sigma^{(2)}_{\max}$ for $l \in \{a, s\}$. In addition, we also have $s^+_i(k) \leq yA_{\max}$ and $a^+_i(k) \leq yA_{\max}$ with probability 1 for $i \in \{1, 2\}$. It suffices to just consider $s^+_2(k)$ to have the same distribution as $\langle 1_m, a^{(2)}(k) \rangle + \epsilon \left( \frac{\lambda}{\mu} - 1 \right)$ where the price $p(k)$ is such that $\lambda(k) = \mathbb{E} \left[ a^{(2)}(k) \right] = \lambda^* + \epsilon 1_n$. Similarly, there exists $s^+_1$, $a^+_1$ and $a^+_2$ that satisfies the above conditions. Note that $\langle 1_m, \lambda^* \rangle = \langle 1_m, \mathbb{E}_{\alpha^*} \{ \mu \} \rangle$ by the constraints of the probabilistic fluid model (4). Thus, it is possible to generate such random variables as their mean is greater than or equal to the corresponding arrival process of the imbalance and their variance are equal. Now, we define the arrival and service process of the single server queue. Consider a random variable $y \sim \text{Bernoulli}(p)$ independent of $s^+_1$, $s^+_2$, $a^+_1$ and $a^+_2$. For all $k \in \mathbb{Z}_+$, we define

$$s^+_1(k) = s^+_1(k) \mathbb{I}_{\{y < 0\}} + s^+_2(k) \mathbb{I}_{\{y \geq 0\}}$$

$$a^+_1(k) = a^+_1(k) \mathbb{I}_{\{y \geq 0\}} + a^+_2(k) \mathbb{I}_{\{y < 0\}}$$

The marginal distribution of the arrival and service process is given by

$$\mathbb{P} \left[ s^+_1(k) \leq x \right] = (1 - p) \mathbb{P} \left[ s^+_1(k) \leq x \right] + p \mathbb{P} \left[ s^+_2(k) \leq x \right] \quad \forall x \in \mathbb{R}$$

$$\mathbb{P} \left[ a^+_1(k) \leq x \right] = p \mathbb{P} \left[ a^+_1(k) \leq x \right] + (1 - p) \mathbb{P} \left[ a^+_2(k) \leq x \right] \quad \forall x \in \mathbb{R}.$$ 

Note that the arrival and service process are not independent and the mean and variance of them are

$$\mathbb{E} [s^+_1(k)] = \left< 1_m, \lambda^* \right> + \epsilon \mu; \quad \text{Var} [s^+_1(k)] = (1 - p) 1 \circ \Sigma^{(1)} + p 1 \circ \Sigma^{(2)}_s$$

$$\mathbb{E} [a^+_1(k)] = \left< 1_m, \lambda^* \right> - \epsilon \mu; \quad \text{Var} [a^+_1(k)] = p 1 \circ \Sigma^{(1)} + (1 - p) 1 \circ \Sigma^{(2)}_a$$

$$\text{Cov} [a^+_1(k), s^+_1(k)] = 0.$$ 

The variance can be calculated as follows

$$\text{Var} [a^+_1(k)] = \mathbb{E} \left[ (a^+_1(k))^2 \right] - \mathbb{E} [a^+_1(k)]^2$$

$$= \mathbb{E} \left[ \left( a^+_1(k) \mathbb{I}_{\{y > 0\}} + a^+_2(k) \mathbb{I}_{\{y < 0\}} \right)^2 \right] - \mathbb{E} \left[ a^+_1(k) \mathbb{I}_{\{y > 0\}} + a^+_2(k) \mathbb{I}_{\{y < 0\}} \right]^2$$

$$= \mathbb{E} \left[ (a^+_1(k))^2 \right] p + \mathbb{E} \left[ (a^+_2(k))^2 \right] (1 - p) - \left( \left< 1_m, \lambda^* \right> - \epsilon \mu \right)^2$$

$$= \left( \text{Var} [a^+_1(k)] + \mathbb{E} [a^+_1(k)]^2 \right) p + \left( \text{Var} [a^+_2(k)] + \mathbb{E} [a^+_2(k)]^2 \right) (1 - p) - \left( \left< 1_m, \lambda^* \right> - \epsilon \mu \right)^2$$

$$= p 1_{m \times n} \circ \Sigma^{(1)} + (1 - p) 1_{m \times n} \circ \Sigma^{(2)}_a.$$ 

Similarly, we can also calculate the variance of $s^+_1(k)$ and we omit it here as the steps are repetitive. In addition, we can also find the co-variance between the arrival and service process as follows:

$$\text{Cov} [a^+_1(k), s^+_1(k)] = \mathbb{E} \left[ a^+_1(k) s^+_1(k) \right] - \mathbb{E} [a^+_1(k)] \mathbb{E} [s^+_1(k)]$$

$$= \mathbb{E} \left[ \left( a^+_1(k) \mathbb{I}_{\{y > 0\}} + a^+_2(k) \mathbb{I}_{\{y < 0\}} \right) \left( s^+_1(k) \mathbb{I}_{\{y > 0\}} + s^+_2(k) \mathbb{I}_{\{y > 0\}} \right) \right]$$

$$- \mathbb{E} \left[ a^+_1(k) \mathbb{I}_{\{y > 0\}} + a^+_2(k) \mathbb{I}_{\{y < 0\}} \right] \mathbb{E} \left[ s^+_1(k) \mathbb{I}_{\{y > 0\}} + s^+_2(k) \mathbb{I}_{\{y > 0\}} \right]$$

$$= p \mathbb{E} \left[ a^+_1(k) s^+_2(k) \right] + (1 - p) \mathbb{E} \left[ a^+_2(k) s^+_1(k) \right] - \left< 1_m, \lambda^* \right>^2 + \epsilon^2 \mu^2 = 0,$$

where the last equality follows as $a^+_1$, $a^+_2$, $s^+_1$ and $s^+_2$ are independent of each other.
Step 2 (Coupling): We couple the arrival and service process of the multiple link two sided queue and the single server queue as follows: If \( z(k) \geq 0 \) then \( s^T(k) \geq a_2(k) \) and \( a^T(k) \leq a_1(k) \) with probability 1. Also, if \( z(k) < 0 \), then \( a^T(k) \leq a_2(k) \) and \( s^T(k) \geq a_1(k) \). Note that, such a coupling is possible if \( P\left[ z(k) \geq 0 \right] = p \) for all \( k \in \mathbb{Z}_+ \). To achieve this, we will initialize \( z(k) \) appropriately. Now, we prove by induction that under the above defined coupling, \( q^T(k) \leq |z(k)| \) for all \( k \in \mathbb{Z}_+ \).

**Base Case:** Initialize \( q(0) \) by its stationary distribution, so we have

\[
P [ z(k) = x ] = \sum_{q(1,m,q(2))} P [ q = q ] \quad \forall x \in \mathbb{Z}, \forall k \in \mathbb{Z}_+.
\]

In addition, initialize \( q^T(0) \) with the same distribution as \( |z(0)| \). As both of the them has the same distribution, we can couple the two random variables such that \( q^T(0) = |z(0)| \). So, the base case is satisfied. In addition, \( P [ z(k) > 0 ] = p \) for all \( k \in \mathbb{Z}_+ \).

**Induction Hypothesis:** \( q^T(k') \leq |z(k')| \) for all \( k' \in [k] \).

**Induction Step:** We will consider the following two cases:

Case I: \( z(k) \geq 0 \). In this case, we have \( s^T(k) \geq a_2(k) \) and \( a^T(k) \leq a_1(k) \). So, we have

\[
q^T(k + 1) = \max \left\{ 0, q^T(k) + a^T(k) - s^T(k) \right\} 
\leq \max \left\{ 0, z(k) + a^T(k) - s^T(k) \right\} \quad \text{(Induction Hypothesis)}
\leq \max \left\{ 0, z(k) + a_1(k) - a_2(k) \right\} \quad \text{(Coupling)}
\leq |z(k) + a_1(k) - a_2(k)| = |z(k + 1)|.
\]

Case II: \( z(k) < 0 \). In this case, we have \( a^T(k) \leq a_2(k) \) and \( s^T(k) \geq a_1(k) \). So, we have

\[
q^T(k + 1) = \max \left\{ 0, q^T(k) + a^T(k) - s^T(k) \right\}
= - \min \left\{ 0, -q^T(k) - a^T(k) + s^T(k) \right\}
\leq - \min \left\{ 0, z(k) - a^T(k) + s^T(k) \right\} \quad \text{(Induction Hypothesis)}
\leq - \min \left\{ 0, z(k) - a_2(k) + a_1(k) \right\} \quad \text{(Coupling)}
\leq |z(k + 1)|.
\]

This completes our proof that \( q^T(k) \leq |z(k)| \) for all \( k \in \mathbb{Z}_+ \). Thus, \( P [ q^T(k) \leq x ] \geq P [ |z(k)| \leq x ] \) for all \( x \in \mathbb{R}_+ \). Taking the limit as \( k \) goes to infinity, we get \( P [ q^T \leq x ] \geq P [ |z| \leq x ] \) and thus, we have \( E [q^T] \leq E [ |z| ] \).

Step 3 (\( E [q^T] \)): Now, we will analyze the single server queue to find its expectation in steady state. By taking \( V(q^T) = (q^T)^2 \) as the Lyapunov function, in steady state, we have

\[
E \left[ \Delta V(q^T) \right] = 0 \Rightarrow E \left[ (q^{T,+})^2 - (q^{T})^2 \right] = 0
\Rightarrow E \left[ (q^{T,+} - \bar{u}^{T} + \hat{u}^{T})^2 - (q^{T})^2 \right] = 0
\Rightarrow E \left[ (q^{T} + \bar{a}^{T} - s^{T})^2 - (\bar{a}^{T})^2 - (q^{T})^2 \right] = 0
\Rightarrow E \left[ (\bar{a}^{T} - s^{T})^2 + 2q^{T}(\bar{a}^{T} - s^{T}) - (\bar{a}^{T})^2 \right] = 0
\Rightarrow \text{Var} \left[ \bar{a}^{T} \right] + \text{Var} \left[ s^{T} \right] - 2\text{Cov} \left[ \bar{a}^{T}, s^{T} \right] + E \left[ \bar{a}^{T} - s^{T} \right]^2 - 4\gamma E \left[ q^{T} \right] - 2\gamma^2 A_{\text{max}} \epsilon = 0,
\]

(16)

where (*) follows by taking \( V(q^T) = q^T \) as the Lyapunov function. We have

\[
E \left[ \Delta V(q^T) \right] = 0 \Rightarrow E \left[ \bar{a}^{T,+} - \bar{a}^{T} \right] = 0 \Rightarrow E \left[ \bar{a}^{T} - s^{T} + \hat{u}^{T} \right] = 0 \Rightarrow E \left[ \bar{a}^{T} \right] = 2\gamma \epsilon.
\]

, Vol. 1, No. 1, Article . Publication date: December 2021.
In addition, as \( u^* \leq s^* \leq \gamma A_{\max} \), we have \( \mathbb{E} \left[ (u^*)^2 \right] \leq \gamma A_{\max} \mathbb{E} \left[ u^* \right] = 2\gamma^2 A_{\max} \varepsilon \). Now, simplifying (16), we get

\[
\Rightarrow \mathbb{E} \left[ q^* \right] = \frac{1_{n\times n} \circ \Sigma^{(1)} + \rho 1_{m\times m} \circ \Sigma^{(2)} + (1 - \rho) 1_{m\times m} \circ \Sigma_d^{(2)} + 4\gamma^2 \varepsilon^2 - 2\gamma^2 A_{\max} \varepsilon}{4\gamma \varepsilon} \geq \frac{1_{n\times n} \circ \Sigma^{(1)} + 1_{m\times m} \circ \Sigma^{(2)} - 1}{4\gamma \varepsilon} \quad \forall \varepsilon \leq \frac{1}{2\gamma^2 A_{\max}}
\]

Thus, we have

\[
\mathbb{E} \left[ (1_{n+m}, \tilde{q}) \right] \geq \mathbb{E} \left[ \tilde{z} \right] \geq \mathbb{E} \left[ q^* \right] \geq \frac{1_{n\times n} \circ \Sigma^{(1)} + 1_{m\times m} \circ \Sigma^{(2)} - 1}{4\gamma \varepsilon} \quad \forall \varepsilon \leq \frac{1}{2\gamma^2 A_{\max}}
\]

\[
\square
\]

We now present a lemma which will assist us in proving Theorem 6.

**Lemma 9.** Under the hypothesis of Theorem 6, there exists a constant \( \delta > 0 \) independent of \( \eta \) and \( \eta_1 > 0 \) such that for all \( \eta > \eta_1 \)

\[
\mathbb{E} \left[ \sum_{j=1}^{m} q_j^* \left( \frac{q_j}{\eta^{\alpha}} \right) \right] \geq \delta
\]

**Proof of Lemma 9.** In this proof, we will couple the sequence of DTMCs \( \{q_\eta(k) : k \in \mathbb{Z}_+\} \) with a sequence of single server queues \( q_\eta^* \) with arrival and service defined as in the proof of Theorem 5 with \( \varepsilon \) dependent on \( \eta \). In particular, we have \( \epsilon_\eta = M\eta^{\beta} \). By the coupling defined above, we have

\[
\mathbb{P} \left[ q_\eta^* > x \right] \leq \mathbb{P} \left[ |z_\eta| > x \right] \quad \text{for all } x > 0.
\]

In addition, we know that as \( \eta \to \infty \), we have \( \epsilon_\eta \to 0 \) as \( \beta < 1 \). Thus, by [13] we know that

\[
\epsilon_\eta q_\eta^* \overset{d}{\to} \text{Exp} \left( \frac{1_{n\times n} \circ \Sigma^{(1)} + 1_{m\times m} \circ \rho \Sigma^{(2)} + (1 - \rho) \Sigma_d^{(2)}}{4\gamma} \right)
\]

Even though, in [13] they assume the arrival process and service process are independent of each other, it suffices to have them uncorrelated. Now, by the definition of weak convergence, for \( K > 0 \)

\[
\lim_{\eta \to \infty} \mathbb{P} \left[ \epsilon_\eta q_\eta^* > (n+m)K \right] = e^{-\frac{(n+m)KM}{\sigma_\varepsilon^2}}.
\]

Thus, for a given \( K > 0 \), there exists \( \eta_1(K) > 0 \) such that for all \( \eta > \eta_1 \), we have

\[
\mathbb{P} \left[ \epsilon_\eta q_\eta^* > (n+m)K \right] \geq \frac{1}{2} e^{-\frac{(n+m)KM}{\sigma_\varepsilon^2}}
\]

Now, by using the coupling, we have

\[
\mathbb{P} \left[ |z_\eta| > (n+m)K \eta^{\alpha} \right] \geq \mathbb{P} \left[ q_\eta^* > (n+m)K \eta^{\alpha} \right] = \mathbb{P} \left[ M\eta^{\beta} q_\eta^* > (n+m)K \eta^{\alpha+\beta} \right] \geq \mathbb{P} \left[ \epsilon_\eta q_\eta^* > (n+m)K \right] \geq \frac{1}{2} e^{-\frac{(n+m)KM}{\sigma_\varepsilon^2}} \quad \forall \eta > \eta_1
\]

Finally, note that \( \{z_\eta > (n+m)K \eta^{\alpha} \} \subseteq \{|\|q_\eta||_\infty > K \eta^{\alpha} \} \), so we have

\[
\mathbb{E} \left[ \sum_{j=1}^{m} q_j^* \left( \frac{q_j}{\eta^{\alpha}} \right) \right] \geq \sigma^2 \mathbb{P} \left[ |\|q_\eta||_\infty > K \eta^{\alpha} \right] \geq \sigma^2 \mathbb{P} \left[ z_\eta > (n+m)K \eta^{\alpha} \right] \geq \frac{\sigma^2}{2} e^{-\frac{(n+m)KM}{\sigma_\varepsilon^2}} \equiv \delta \quad \forall \eta > \eta_1.
\]
Proof of Theorem 6. In this proof, we will use Taylor’s theorem to expand the profit-loss and show that the second order term does not vanish using Lemma 9. This proof follows similarly as in [28]. The only non trivial step was to prove Lemma 9.

\[
\begin{align*}
\frac{R^*_\eta - P_{\eta}}{\eta} \\
= \left( F(\lambda^*_p), \lambda^*_p \right) - \mathbb{E}_{\hat{\alpha}^*} \left[ c(\mu) \right] - \mathbb{E} \left[ \left( F(\lambda_\eta(\hat{q}_\eta)), \lambda_\eta(\hat{q}_\eta) \right) \right] + \mathbb{E}_{\hat{\alpha}^*} \left[ c(\mu) \right] \\
= \left( F(\lambda^*_p), \lambda^*_p \right) - \mathbb{E} \left[ \left( F(\lambda_\eta(\hat{q}_\eta)), \lambda_\eta(\hat{q}_\eta) \right) \right] \\
= \left( F(\lambda^*_p), \lambda^*_p \right) - \sum_{j=1}^{m} \mathbb{E} \left[ \left( \lambda_j^* + \phi_j \left( \frac{\hat{q}_\eta}{\eta^\alpha} \right) \right) F_j \left( \hat{\lambda}_j^* + \phi_j \left( \frac{\hat{q}_\eta}{\eta^\alpha} \right) \right) \right] \\
= \left( F(\lambda^*_p), \lambda^*_p \right) - \sum_{j=1}^{m} \mathbb{E} \left[ \left( \lambda_j^* + \phi_j \left( \frac{\hat{q}_\eta}{\eta^\alpha} \right) \right) \right] \eta^\beta - \sum_{j=1}^{m} \mathbb{E} \left[ \phi_j^3 \left( \frac{\hat{q}_\eta}{\eta^\alpha} \right) \right] \eta^{3\beta} \\
\approx - \delta \left( \min_{j \in [m]} \{ -F_j' \left( \hat{\lambda}_j^* \right) \hat{\lambda}_j^* - F_j' (\hat{\lambda}_j^*) \} \right) \eta^{2\beta} - \sum_{j=1}^{m} \mathbb{E} \left[ \phi_j^3 \left( \frac{\hat{q}_\eta}{\eta^\alpha} \right) \right] \eta^{3\beta} \\
\geq \frac{\delta}{4} \left( \min_{j \in [m]} \{ -F_j' \left( \hat{\lambda}_j^* \right) \hat{\lambda}_j^* - F_j' (\hat{\lambda}_j^*) \} \right) \eta^{2\beta}.
\end{align*}
\]

The remainder term of the Taylor’s expansion is \( F''(\hat{\lambda}_j^*(\hat{q}_\eta)) \) for some \( \hat{\lambda}_j^*(\hat{q}_\eta) \) \( \in [\hat{\lambda}_j^* - M\eta^\beta, \hat{\lambda}_j^* + M\eta^\beta] \) for all \( \hat{q}_\eta \in S \). Note that the second derivative of \( \lambda_j F(\lambda_j) \) is negative as it is concave by Assumption 2 and \( F_j(\cdot) \) is strictly decreasing by Assumption 1. Thus, the coefficient of \( \eta^{2\beta} \) is positive. This completes the proof. Now we will justify (a), (b) and (c) below. Proof of (a) follows by Lemma 8.

Proof of (b) follows by uniform convergence of \( F_j''(\hat{\lambda}_j^*(\hat{q}_\eta)) \) to \( F''(\hat{\lambda}_j^*) \). To expound, by Taylor’s Theorem and Condition 3 (a), we have \( \hat{\lambda}_j^*(\hat{q}_\eta) \in [\hat{\lambda}_j^* - M\eta^\beta, \hat{\lambda}_j^* + M\eta^\beta] \). By Assumption 1, \( F''(\cdot) \) is continuous, thus, given \( \hat{\gamma} = \frac{1}{2} \min_{j \in [m]} \{ -F_j'' \left( \hat{\lambda}_j^* \right) - F_j' (\hat{\lambda}_j^*) / \hat{\lambda}_j^* \} \), there exists \( \delta_2 > 0 \), such that for all \( \hat{\lambda}_j^* - \hat{\lambda}_j^* < \delta_2 \), we have \( |F''(\hat{\lambda}_j^*) - F''(\hat{\lambda}_j^*)| \) < \( \hat{\gamma} \). Thus, for all \( \eta > \left( \frac{\delta}{M} \right)^{1/\beta} \), we have

\[
\sup_{q_\eta \in S} \left| F_j''(\hat{\lambda}_j^*(\hat{q}_\eta)) - F_j''(\hat{\lambda}_j^*) \right| < \hat{\gamma} \quad \forall j \in [m].
\]
Thus, we have

\[- \left( \sum_{j=1}^{m} \mathbb{E} \left[ \phi_j^3 \left( \frac{\bar{q}_j}{\eta^\alpha} \right) (F_j''(\bar{x}_j^*(\bar{q}_j))) \bar{x}_j^* + F_j'(\bar{x}_j^*) \right] \right) \geq \sum_{j=1}^{m} \left( -F_j''(\bar{x}_j^*) \bar{x}_j^* - \tilde{v}\bar{x}_j^* - F_j'(\bar{x}_j^*) \right) \mathbb{E} \left[ \phi_j^3 \left( \frac{\bar{q}_j}{\eta^\alpha} \right) \right] \]

\[\geq \frac{1}{2} \sum_{j=1}^{m} \left( -F_j''(\bar{x}_j^*) \bar{x}_j^* - F_j'(\bar{x}_j^*) \right) \mathbb{E} \left[ \phi_j^3 \left( \frac{\bar{q}_j}{\eta^\alpha} \right) \right] \]

\[\geq \frac{\delta}{2} \left( \min_{j \in [m]} \left( -F_j''(\bar{x}_j^*) \bar{x}_j^* - F_j'(\bar{x}_j^*) \right) \right) \]

where (*) follows by the definition of \( \bar{v} \) and (**) follows by Lemma 9.

Proof of (c) follows as \( \eta^3 \beta \) is of lower order than \( \eta^{2\beta} \) as \( \beta < 0 \). In particular

\[- \sum_{j=1}^{m} \mathbb{E} \left[ \phi_j^3 \left( \frac{\bar{q}_j}{\eta^\alpha} \right) F_j''(\bar{x}_j^*(\bar{q}_j)) \right] \eta^{3\beta} \geq \frac{3}{2} \sum_{j=1}^{m} \mathbb{E} \left\| \phi_j^3 \left( \frac{\bar{q}_j}{\eta^\alpha} \right) F_j''(\bar{x}_j^*) \right\| \eta^{3\beta} \quad \forall \eta > \eta_2 \]

\[\geq \frac{3M^3}{2} \sum_{j=1}^{m} |F_j''(\bar{x}_j^*)| \eta^{3\beta} \quad \forall \eta > \eta_2 \]

Now, as \( \beta < 0 \), with \( \eta_3 \equiv \frac{\Delta}{\delta \min_{j \in [m]} \left| -F_j''(\bar{x}_j^*) \bar{x}_j^* - F_j'(\bar{x}_j^*) \right|} \sum_{j=1}^{m} |F_j''(\bar{x}_j^*)|^{-1/\beta} \) for all \( \eta > \max\{\eta_2, \eta_3\} \), we have

\[\sum_{j=1}^{m} \mathbb{E} \left[ \phi_j^3 \left( \frac{\bar{q}_j}{\eta^\alpha} \right) F_j''(\bar{x}_j^*) \right] \eta^{3\beta} \geq -\frac{\delta}{4} \left( \min_{j \in [m]} \left| -F_j''(\bar{x}_j^*) \bar{x}_j^* - F_j'(\bar{x}_j^*) \right| \right) \eta^{2\beta} \]

This completes the proof. \( \square \)

D THEOREM 8

Proof of Theorem 8. In this proof we will use Lemma 4, Theorem 5 and Lemma 6. First, by Lemma 4, with \( \epsilon_\eta = \epsilon' \), we have

\[\mathbb{E} \left[ \langle 1_{n+m}, \bar{q} \rangle \right] \leq \frac{B_1 + 2B_2}{2 \ min_{i \in [n]} \left\{ \sum_{j \in (i,j) \in E} \frac{\bar{x}_j^*}{\lambda_j^*}, 1 \right\}} \frac{1}{\epsilon'} \]

As, \( \mathbb{E} \left[ \langle 1_{n+m}, \bar{q} \rangle \right] = C \), we have

\[\epsilon' \leq \frac{B_1 + 2B_2}{2 \ min_{i \in [n]} \left\{ \sum_{j \in (i,j) \in E} \frac{\bar{x}_j^*}{\lambda_j^*}, 1 \right\}} \frac{1}{C}. \]

Now, by Lemma 6, with \( \eta \) such that \( \epsilon_\eta = \epsilon' \), we have

\[L_P \equiv \frac{L_P^P}{\eta} = -(\epsilon')^2 \sum_{j=1}^{m} \left( \frac{\bar{x}_j^* F_j''(\bar{x}_j^*)}{2} + F_j'(\bar{x}_j^*) \right) + O \left((\epsilon')^2\right) \]

\[\leq - \sum_{j=1}^{m} \left( \frac{\bar{x}_j^* F_j''(\bar{x}_j^*)}{2} + F_j'(\bar{x}_j^*) \right) \left( \frac{B_1 + 2B_2}{2 \ min_{i \in [n]} \left\{ \sum_{j \in (i,j) \in E} \frac{\bar{x}_j^*}{\lambda_j^*}, 1 \right\}} \right)^2 \frac{1}{C^2} + O \left(\frac{1}{C^2}\right) \]
where, (*) follows by the definition of asymptotic regime 2 and as \( \sum_{j=1}^{m} \left( \frac{\hat{\lambda}^* F''(\hat{\lambda}^*)}{2} + F'_j(\hat{\lambda}^*_j) \right) < 0 \), (**) follows. This completes one part of the proof. Now, as the two price policy satisfies the hypothesis of Theorem 5 with \( \epsilon = \epsilon' \), we have

\[
\mathbb{E} \left[ \langle 1_{n+m}, \hat{q} \rangle \right] \geq \frac{1_{n \times n} \circ \Sigma^{(1)}(\epsilon) + 1_{m \times m} \circ \Sigma^{(2)}(\epsilon) - 1}{4 \max\{m, n\} \epsilon'}.
\]

As, \( \mathbb{E} \left[ \langle 1_{n+m}, \hat{q} \rangle \right] = C \), we have

\[
\epsilon' \geq \frac{1_{n \times n} \circ \Sigma^{(1)}(\epsilon) + 1_{m \times m} \circ \Sigma^{(2)}(\epsilon) - 1}{4 \max\{m, n\} / C}.
\]

Now, again by Lemma 3, we have

\[
L_p = -(\epsilon')^2 \sum_{j=1}^{m} \left( \frac{\hat{\lambda}^* F''(\hat{\lambda}^*_j)}{2} + F'_j(\hat{\lambda}^*_j) \right) + O\left( (\epsilon')^2 \right)
\]

\[
\geq - \sum_{j=1}^{m} \left( \frac{\hat{\lambda}^* F''(\hat{\lambda}^*_j)}{2} + F'_j(\hat{\lambda}^*_j) \right) \left( \frac{1_{n \times n} \circ \Sigma^{(1)}(\epsilon) + 1_{m \times m} \circ \Sigma^{(2)}(\epsilon) - 1}{4 \max\{m, n\} / C} \right)^2 \frac{1}{C^2} + O\left( \frac{1}{C^2} \right).
\]

This completes the proof. \(\Box\)

### E COST FUNCTION AND ITS VARIATIONS

#### E.1 Proof of Proposition 3

**Proof of 1.** The domain of \( c^1(\cdot) \) is a subset of the domain of \( c^{1*} \), which is \( \mathbb{R}^n \) and they are equal for all \( \mu \in \Omega \). Thus, \( c^{1*} \leq c^1(\mu) \) for all \( \mu \in \mathbb{R}^n \). So, we have

\[
\mathbb{E}_\alpha \left[ c^1(\mu) \right] \geq \mathbb{E}_\alpha \left[ c^{1*}(\mu) \right] \geq c^{1*}(\mathbb{E}_\alpha [\mu]) \quad \forall \alpha \in \mathcal{P},
\]

where (*) follows as \( c^1(\cdot) \) is convex by definition. Thus, we have

\[
R^1 = \max_{\hat{\lambda}, \hat{\lambda}_j} \left( F(\hat{\lambda}), \hat{\lambda}_j \right) - \mathbb{E}_{\hat{\alpha}} \left[ c^1(\hat{\mu}) \right] \leq \left( F(\hat{\lambda}), \hat{\lambda}_j \right) - c^{1*}(\mathbb{E}_{\hat{\alpha}} [\hat{\mu}])
\]

subject to,

\[
\hat{\lambda}_j = \sum_{i=1}^{n} \hat{\lambda}_{ij} \forall j \in [m] \quad \mathbb{E}_{\hat{\alpha}} [\hat{\mu}_i] = \sum_{j=1}^{m} \hat{\lambda}_{ij} \forall i \in [n]
\]

\[
\hat{\lambda}_{ij} = 0 \quad \forall (i, j) \notin E, \quad \hat{\lambda}_{ij} \geq 0 \quad \forall (i, j) \in E.
\]

Now, substituting \( \mathbb{E}_{\hat{\alpha}} [\hat{\mu}] = \mu \) and \( c^{1*}(\mu) = \langle G(\mu), \mu \rangle \) in the above optimization problem, we get

\[
\max_{\hat{\lambda}, \mu, \hat{\lambda}_j} \left( F(\hat{\lambda}), \hat{\lambda}_j \right) - \langle G(\mu), \mu \rangle = R^{1*}
\]

subject to,

\[
\hat{\lambda}_j = \sum_{i=1}^{n} \hat{\lambda}_{ij} \forall j \in [m] \quad \mu_i = \sum_{j=1}^{m} \hat{\lambda}_{ij} \forall i \in [n]
\]

\[
\hat{\lambda}_{ij} = 0 \quad \forall (i, j) \notin E, \quad \hat{\lambda}_{ij} \geq 0 \quad \forall (i, j) \in E.
\]

This shows that \( R^1 \leq R^{1*} \). Now, if the condition \( c_{il} \geq G_i(\mu^{*1}) - G_i(\mu^{**1}) \) for all \( i, l \in [n] \) is satisfied, then \( \mu^{*1} \in \Omega \). Thus, \( \hat{\alpha} = \mu^{*1} \) with probability 1 is a feasible solution and we have \( R^{1*} \leq R^1 \). This completes the proof. \(\Box\)
E.2 Strong Duality

By solving the primal formulation in the previous section, we noticed that it is taking more than a day to solve for the case of SD and β-IC for small values of β and it does not scale well with the graph. In addition, as Gurobi is implementing branch and bound, the simulation uses a lot of memory. In this section, we will analyze the dual of the fluid optimization problem and prove that strong duality holds and later solve the dual problem numerically. It turns out that the dual problem is a convex optimization problem and thus, standard optimization methods like (accelerated) gradient descent can be employed to solve this problem. We will start by presenting the Lagrangian function $L : \mathbb{R}^{n+m} \times \mathbb{R}_+ \times \mathcal{P} \times \mathbb{R}_+^{|E|} \rightarrow \mathbb{R}$ with $\kappa \in \mathbb{R}^{m+n}$ as the dual variables. Here, $\mathcal{P}$ is the set of measures defined on the Borel sigma algebra generated by $\Omega$. The Lagrangian function $L(\kappa, (\lambda, \alpha, \chi))$ is given by

$$
\langle F(\lambda), \lambda \rangle - \mathbb{E}_\alpha [c(\mu)] + \sum_{j=1}^n \kappa_j^{(2)} \left( \lambda_j - \sum_{i : (i, j) \in E} \chi_{ij} \right) + \sum_{i=1}^n \kappa_i^{(1)} \left( \mathbb{E}_\alpha [\mu_i] - \sum_{j : (i, j) \in E} \chi_{ij} \right).
$$

The domain of the above defined Lagrangian function is $\mathbb{R}^{n+m} \times Y$ where $Y = \mathbb{R}_+^m \times \mathcal{P} \times \mathbb{R}_+^{|E|}$ given by

$$
Y = \left\{ (\lambda, \alpha, \chi) \in \mathbb{R}_+^m \times \mathcal{P} \times \mathbb{R}_+^{|E|} : \int_{\Omega} d\alpha = 1, \alpha \geq 0 \right\}.
$$

In words, we are imposing the constraints that the arrival rates $\lambda$ and the rate of matching $\chi$ is non negative and in addition, $\alpha$ is restricted only to a set of probability measures. The Lagrangian function is defined to be $-\infty$ outside its domain by convention as we are maximizing with respect to $(\lambda, \alpha, \chi)$. Now, the dual function can be written as follows:

$$
D_* = \min_{\kappa \in \mathbb{R}^{m+n}} \left\{ \max_{(\lambda, \alpha, \chi) \in Y} L(\kappa, (\lambda, \alpha, \chi)) \right\}.
$$

This can be expanded by substituting the expression on $L$ and then separating the inner maximization to get

$$
\min_{\kappa \in \mathbb{R}^{m+n}} \left\{ \sum_{j=1}^n \max_{\lambda_j \in \mathbb{R}_+} \left\{ F_j(\lambda_j) \lambda_j + \kappa_j^{(2)} \lambda_j \right\} - \min_{\alpha \in \mathcal{P}, \int_{\Omega} d\alpha = 1, \alpha \geq 0} \mathbb{E}_\alpha \left[ c(\mu) - \sum_{i=1}^n \mu_i \kappa_i^{(1)} \right] \right\}.
$$

The second minimization can be reduced to minimizing only over all the Dirac measures as taking a convex combination will only increase the objective function value. In addition, if $\kappa_i^{(1)} + \kappa_j^{(2)} < 0$, then $\chi_{ij}$ can be taken arbitrarily large which will make the objective function arbitrarily large and, if $\kappa_i^{(1)} + \kappa_j^{(2)} \geq 0$, then the minimization is achieved at $\chi_{ij} = 0$. Thus, the above optimization problem can be reduced to the following:

$$
\min_{\kappa \in \mathbb{R}^{m+n}} \left\{ \sum_{j=1}^n \max_{\lambda_j \in \mathbb{R}_+} \left\{ F_j(\lambda_j) \lambda_j + \kappa_j^{(2)} \lambda_j \right\} - \min_{\mu \in \Omega} \left\{ c(\mu) - \sum_{i=1}^n \mu_i \kappa_i^{(1)} \right\} \right\} \quad (17a)
$$

subject to $\kappa_i^{(1)} + \kappa_j^{(2)} \geq 0 \quad \forall (i, j) \in E.$ \hspace{1cm} (17b)

Note that, the above optimization problem is a convex optimization problem with affine constraints as $\max_{\lambda_j \geq 0} \left\{ F_j(\lambda_j) \lambda_j + \kappa_j^{(2)} \lambda_j \right\}$ is the conjugate of the function $-F_j(\lambda_j) \lambda_j$ and $-\min_{\mu \in \Omega} \left\{ c(\mu) - \sum_{i=1}^n \mu_i \kappa_i^{(1)} \right\}$.
The optimal values of the problems (4) and (17) are equal, that is \( R = D \).

The proof of the proposition follows by verifying some regularity conditions and the details are presented in the appendix. As the dual (17) is a convex optimization problem with finite number of variables and constraints, it is easier to solve it compared to the primal. The above proposition allows us to solve the dual rather than the primal.

E.3 Proof of Proposition 4

Proof. We will use the Theorem 7.10 from the lectures on stochastic programming [24]. We will verify the following three conditions:

1. For every \( \mathbf{k} \in \mathbb{R}^{n+m} \), the function \( L(\mathbf{k}, \cdot) \) is concave.
2. For every \( (\lambda, \alpha, \chi) \), the function \( L(\cdot, (\lambda, \alpha, \chi)) \) is convex and lower semi continuous.
3. The dual optimization problem (17) has a nonempty and bounded set of optimal solutions.

Proof of 1. If \( \mathbf{k} : k_i^{(1)} + k_j^{(2)} \geq 0 \forall (i, j) \in E \), then we know that \( L(\mathbf{k}, \cdot) \) is concave with respect to \( \lambda \) by Assumption 2, and affine with respect to \( \alpha \) and \( \chi \) in its domain \( Y \) which is convex. In addition, if \( \mathbf{k} \) does not belong to the above set, then \( L(\mathbf{k}, \cdot) = +\infty \) which is concave.

Proof of 2. For \( (\lambda, \alpha, \chi) \in Y, \ L(\cdot, (\lambda, \alpha, \chi)) \) is an affine function of \( \mathbf{k} \), thus it is convex and lower semi continuous. For \( (\lambda, \alpha, \chi) \not\in Y \), we have \( L(\cdot, (\lambda, \alpha, \chi)) = -\infty \) everywhere and thus it is convex and lower semi continuous.

Proof of 3. We already know that the dual objective function is convex and the constraints are affine. Now, we will show that the objective function is coercive which will suffice to show that the optimal solution is nonempty and bounded. Let \( \hat{\lambda}^* = 0 \) and \( \hat{\mu}^* \in \text{dom} F_j \) for all \( j \in [m] \) and \( \mu^* > 0_m \) and \( \mu^* \in \Omega \). Then we have

\[
\sup_{\lambda_j \geq 0} \left\{ F_j(\lambda_j)\lambda_j + k_j^{(2)}\hat{\lambda}^*_j \right\} \geq \max \left\{ 0, F_j(\hat{\lambda}^*_j)\hat{\lambda}^*_j + k_j^{(2)}\hat{\lambda}^*_j \right\}
\]

\[
\inf_{\mu \geq 0_m} \left\{ c(\mu^*) - \left( k^{(1)}(\cdot), \mu^* \right) \right\} \leq \min \left\{ 0, c(\mu) - \left( k^{(1)}, \mu^* \right) \right\}
\]

The above results in the following lower bound on the objective function of the dual (17).

\[
\sum_{j=1}^{m} \max \left\{ 0, F_j(\hat{\lambda}^*_j)\hat{\lambda}^*_j + k_j^{(2)}\hat{\lambda}^*_j \right\} - \min \left\{ 0, c(\mu^*) - \left( k^{(1)}, \mu^* \right) \right\} \geq \infty.
\]

Now, if \(||\mathbf{k}|| \to \infty\) such that \( k_i^{(1)} + k_j^{(2)} \geq 0 \) for all \( (i, j) \in E \), then there exists an \( i \in [n] \) or a \( j \in [m] \) such that either \( k_i^{(1)} \to \infty \) or \( k_j^{(2)} \to \infty \). This is true by the assumption that the bipartite graph is connected. This implies that (18) \( \to \infty \). Thus, the objective function of the dual (17) \( \to \infty \). Thus, it is coercive. This completes the proof. □

F SIMULATIONS: A GENERIC CITY MODEL

F.1 IC vs FB: IC

Motivated by our ridesharing example, we simulate the network given by Fig. 9 with linear supply and demand curves. In particular, the demand curves are \( F_1(\lambda_1) = 10 - \lambda_1 / 2, F_2(\lambda_2) = 12 - \lambda_3 / 2, F_3(\lambda_3) = 12 - \lambda_3 / 2, F_4(\lambda_4) = 18 - \lambda_4 \) and the supply curves are \( G_1(\mu_1) = 3\mu_1 - 3, G_2(\mu_2) = 2\mu_2, G_3(\mu_3) = \mu_3, G_4(\mu_4) = 2.5\mu_4 \) and \( G_5(\mu_5) = \mu_5 \). Each type of customer is described by the destination they wish to go and each type of server is described the list of destinations or a single
destination they wish to go. The compatibility between a pair of customer and server holds if they wish to go to the same destination. The penalty due to waiting \( (c) \) is given in Fig. 9 and is parametrized by a scalar \( \hat{c} \). For a given \((i, l)\) pair, \(c_{il}\) is high if the destinations are in the opposite directions and lower otherwise. For example, \(c_{14}\) is high as the choices of destination of type 1 server does not match at all with type 2 server. Now, we compare the solution of the fluid model for IC and FB:IC for different values of \(c\). The result is plotted in Fig. 13. We can observe that the two optimal solutions are not too different from each other. In addition, we parametrize the supply curve \(G_5 = i \times \frac{\hat{c}}{70}\) and analyze the fluid solution of FB:IC as \(i\) varies. The results are plotted in Fig. 11 and Fig. 12.
F.2 Stochastic Simulations

We analyze the proposed two price policy and max weight matching policy for $\eta = \{1, 5, 10, 20, 30, 50, 100\}$ and report the percentage loss compared to the fluid upper bound for the case of IC and FB: IC. We pick $G_5 = \mu_5/5$ and $\bar{c} = 0$. The results are summarized in Fig. 14. Thus, we conclude that the percentage loss is also robust for the choice of the bipartite graph and decays very fast as $\eta$ increases. Finally, we also simulate the system free of any asymptotic regime for the generic city model and plot the trade-off between the average sum of queue length and profit loss in Fig. 10. The trade-off is not sensitive to the cost function but it is sensitive to the size of the network.

G GENERAL UTILITY FUNCTION

It is often the case in practice that the servers are aware of the probability with which they will be matched to a type of customer given the type of server. In particular, in steady state, an $i$ type of server is matched to a $j$ type of customer with rate $\mathbb{E} \left[ \tilde{x}_{ij}(q) \right]$ which is known to the servers. Motivated by this, we extend our model to incorporate a general utility function given by

$$u_{il}(k) = f \left( p^{(1)}(k), \mathbb{E} \left[ \tilde{x} \right] \right) \quad \forall i, l \in [n]$$

for any given function $f$. The expectation is with respect to the stationary distribution of the underlying Markov chain given the pricing and matching policy. After re-defining the utility function,
the cost function is given similar to (1) with an additional dependence on $E[\tilde{x}]$. We have
\[
c(\mu, E[\tilde{x}]) \triangleq \min \left\{ \mu, p^{(1)} \right\} \text{ subject to } p^{(1)} \in \mathcal{M}(\mu, E[\tilde{x}]).
\]
This makes the model even more endogenous as the matching policy needs to be coherent to ensure Nash equilibrium.

### G.1 Extending Previous Analysis

The probabilistic fluid model with the re-defined utility function is similar to (4) and is defined below:

\[
\tilde{G}^* \triangleq \max_{(\tilde{\lambda}, \tilde{x}, \tilde{\alpha}, \tilde{\gamma}) \in \mathcal{Q}} \left( F(\tilde{\lambda}), \tilde{\lambda} \right) - E[\tilde{\alpha}] \left[ c(\tilde{\mu}, \tilde{x}) \right]
\]

subject to
\[
\tilde{\lambda}_j = \sum_{i=1}^{m} \tilde{x}_{ij} \quad \forall j \in [m]\]
\[
E[\tilde{\alpha}] [\tilde{\mu}_i] = \sum_{j=1}^{m} \tilde{x}_{ij} \quad \forall i \in [n]\]
\[
\tilde{x}_{ij} = 0 \quad \forall (i, j) \notin E, \quad \tilde{x}_{ij} \geq 0 \quad \forall (i, j) \in E.
\]

Here, $c(.)$ is a function of the fluid server arrival rates $\tilde{\mu}$ and fluid matching rates $\tilde{x}$ and the probability distribution $\tilde{\alpha}$ is defined on the space of fluid server arrival rates $\Omega$. Now, we will show that Proposition 1 still holds for this general setting. In particular, under an arbitrary state description of the Markov chain (which is required for later analysis) and utility function defined in (19), the result still holds. In particular, we expand our space of pricing and matching policies and allow stationary policies with respect to an expanded state space denoted by $q_e \in S_e$, where $S_e \subseteq \mathbb{Z}^b_+$ for some $b > 0$. By allowing this, we are expanding the state of our underlying Markov chain to $(q, q_e)$ and consider policies under which it is stable.

**Proposition 5.** Let $\pi = (\lambda(\cdot), \alpha(\cdot), x(\cdot))$ be a stationary policy w.r.t. $q_e \in S_e$ and is a feasible solution of (3) with utility function as defined in (19), then
\[
R(\pi) \leq P(\pi) \leq \tilde{G}^*.
\]
That is, the fluid profit is an upper bound for the stochastic profit and net profit.

Now, we will consider the two-pricing policy (8) and max-weight matching policy (9) and discuss the challenges that arise in the stochastic analysis by generalizing the utility function. From Lemma 1, we know that under max-weight matching, the following will be satisfied:

\[
E[\lambda_j(\tilde{q})] = \sum_{i=1}^{n} E[\tilde{x}_{ij}(\tilde{q})] \quad \forall j \in [m], \quad E[\tilde{\alpha}(\tilde{q}) [\tilde{\mu}_i]] = \sum_{j=1}^{m} E[\tilde{x}_{ij}(\tilde{q})] \quad \forall i \in [n]
\]
\[
E[\tilde{x}_{ij}(\tilde{q})] = 0 \quad \forall (i, j) \notin E, \quad E[\tilde{x}_{ij}(\tilde{q})] \geq 0 \quad \forall (i, j) \in E.
\]

If multiple $E[\tilde{x}] \in \mathbb{R}_{+}^{m}$ satisfies these set of equations, then, it is an extremely challenging task to characterize $E[\tilde{x}]$ exactly or even approximately. This makes the task of verifying (let alone ensuring) if the system is in Nash equilibrium difficult.

Thus, we need to modify the matching policy such that we ensure the following two constraints are satisfied: 1) $E[\tilde{x}]$ and $p^{(1)}(q)$ are such that the system is operating under a Nash equilibrium 2) The pricing and matching policy achieves $\eta^{1/3}$ loss in net-profit compared to the upper bound given by the probabilistic fluid model (20). To achieve optimality, from the intuition of Theorem 4, we need to operate close to the fluid solution. Thus, we need $E[\tilde{x}_{ij}] = \tilde{x}_{ij}$ for all $(i, j) \in E$ to
ensure Nash equilibrium. In fact, if the cost function is discontinuous at the fluid optimal solution, then we need the above to hold with equality as otherwise, we will have a non zero limiting net profit loss. This motivates the introduction of random matching policy which routes the arrivals with probability proportional to the fluid solution $\tilde{\chi}^\star$. Although, this may lead to poor queueing performance and unstable system and we modify the pricing policy to ensure that doesn’t happen. We will formalize this intuition in the next subsection.

### G.2 Multiple Pricing Policy and Random Matching

We expand the state space of the Markov chain by introducing secondary queues for each type of customers and servers. In particular, for a type $j$ customer, we introduce $q_{jl}$ for $l \in [N(j)]$. Each secondary queue corresponds to one of its neighbours. The random matching policy will randomly route the incoming arrival immediately to one of these secondary queues. Then, the customers/servers wait in these secondary queues until they are matched. The compatibility graph between the secondary queues is one to one. That is, for a given $j$ and $l$, there exists a unique $i$ and $m$ such that $q_{jl}$ is the neighbor of $q_{im}$.

The pricing policy is a two price policy corresponding to these secondary queues. In particular, the pricing policy is given by

$$\lambda_{j,\eta}(q) = \lambda_j^\star - \epsilon_{\eta} \sum_{l=1}^{N(j)} \mathbb{1}_{\{q_{jl}>0\}} + \epsilon_{\eta} \sum_{l=1}^{N(j)} \mathbb{1}_{\{q_{jl}=0\}} \quad \forall j \in [m], \forall q \in S, \quad (21a)$$

$$\alpha_{q}(q) = \tilde{\alpha}^\star \quad \forall q \in S. \quad (21b)$$

The matching policy routes the arrivals to the secondary queue immediately such that the effective arrival rate to the secondary queues is given by

$$\lambda_{jl,\eta}(q) = \tilde{\lambda}^\star_{lj} - \epsilon_{\eta} \mathbb{1}_{\{q_{lj}>0\}} + \epsilon_{\eta} \mathbb{1}_{\{q_{lj}=0\}} \quad \forall l \in [N(j)], j \in [m], q \in S,$$

$$\mu_{im,\eta}(q) = \tilde{\mu}^\star_{im} \quad \forall m \in [N(i)], i \in [n], q \in S.$$

Now, we can visualize the bipartite graph formed by the secondary queues operating under the two price policy and max-weight matching policy (trivially) and has a one to one compatibility structure with $|E|$ number of customer and server types. Thus, we can essentially apply Theorem 4 to get $\eta^{1/3}$ loss in net profit. In addition, as the system is stable, by Lemma 1 and the compatibility structure of the secondary queues, we will have $\mathbb{E} \left[ \tilde{x}_{lj}(q) \right] = \tilde{\chi}^\star_{lj}$ for all $(i, j) \in E$. This will ensure Nash equilibrium. We present this formally in the following corollary:

**Corollary 10.** Consider a sequence of DTMCs parametrized by $\eta$ operating under the pricing policy given by (21) and random matching policy. Then the the system is operating under a Nash equilibrium such that the net profit loss $L_\eta$ is $O(\eta^{1/3})$ for the choice of $\epsilon_{\eta} = \eta^{-1/3}$.

This is a strong result as this provides a stochastic pricing and matching policy which operates in a Nash equilibrium governed by a general utility and cost function and achieves optimal rate of convergence to the optimum profit $G^\star$. Although, it is known in the queueing literature that closed loop policies like max-weight performs much better than open loop policies like random matching in practice. In addition, we are not exploiting the network structure in the random matching policy. Motivated by this, we propose an improved random matching policy and show optimality. We believe that this policy achieves $\delta$ Nash equilibrium in the sense that achieved utility of all the servers is at most $\delta$ away from the maximum possible utility and $\delta \to 0$ as $\eta \to \infty$. 

, Vol. 1, No. 1, Article . Publication date: December 2021.
G.3 Two Pricing Policy and Improved Random Matching

In the context of load balancing, max-weight is equivalent to join the shortest queue (JSQ) algorithm. In addition, random matching in both these contexts are equivalent. The improved random matching we will present in this section is equivalent to join the idle queue (JIQ). It is known in the literature that JIQ is better than random matching but worse than JSQ. In each decision epoch, we match $y_{ij}(k)$ number of $i$ type of servers to $j$ type of customers in expectation where $y_{ij}(k)$ is defined as follows:

$$y_{ij}(k) = \min \left\{ \frac{\hat{\lambda}^*_i (q^{(1)}_i (k) + a^{(1)}_i (k))}{\mathbb{E} \hat{\alpha}_i [\mu_i]} , \frac{\hat{\lambda}^*_j (q^{(2)}_j (k) + a^{(2)}_j (k))}{\hat{\lambda}^*_j} \right\} .$$

In particular, we divide the customers and servers waiting in the queues proportional to the fluid solution and then match as many as possible. This is precisely the feasible solution that we have used to prove Lemma 7. Thus, the optimality of two price policy with improved random matching will follow similarly and we omit the details for brevity. In addition, note that $\mathbb{E} [y_{ij}]$ is at least $\hat{\lambda}^*_i$ if either one of $q^{(1)}_i$ or $q^{(2)}_j$ is larger than a constant. Thus, to show Nash equilibrium, we need to analyze $\mathbb{P} \left[ \max \{q^{(1)}_i, q^{(2)}_j\} > c \right]$ and show that it converges to 1 as $\eta \to \infty$. This is intuitive as the queue lengths scale as $\eta^{1/3}$. Although, we do not have handle on the individual queue lengths and this is the major challenge to show Nash equilibrium.

G.4 Proof of Proposition 5

Proof. Consider a feasible policy $\pi = (\lambda(\cdot), \alpha(\cdot), x(\cdot))$ under which we have a stable Markov chain $(q, q_e)$ as the policy is a stationary policy w.r.t. $q_e$. We will work with this expanded state space for this proof.

Lemma 1 still holds as the result does not depend on the cost function $c(\cdot)$. Now, define $\hat{\lambda} \triangleq \mathbb{E} [\lambda(q, q_e)]$, $\hat{\alpha} \triangleq \mathbb{E} [\alpha(q, q_e)]$ and $\hat{\chi} = \mathbb{E} [x(q, q_e)]$ and note that by Lemma 1, we have

$$\hat{\lambda}_j = \sum_{i=1}^{n} \hat{\chi}_{ij} \quad \forall j \in [m]$$

$$\mathbb{E} \hat{\alpha} [\mu_i] = \sum_{j=1}^{m} \hat{\chi}_{ij} \quad \forall i \in [n]$$

$$\hat{\chi}_{ij} = 0 \quad \forall (i, j) \notin E, \hat{\chi} \geq 0 \quad \forall (i, j) \in E.$$

Now, we will simplify the net profit under $\pi$. We have

$$\mathbb{E} \left[ \sum_{j=1}^{m} F_j (\lambda_j(q, q_e)) \right] \lambda_j(q, q_e) - \mathbb{E} \alpha(q_e) [c(\mu|\mathbb{E} [x(q, q_e)])] - s(1, q)$$

$$\leq \mathbb{E} \left[ \sum_{j=1}^{m} F_j (\lambda_j(q, q_e)) \right] \lambda_j(q, q_e) - \mathbb{E} \alpha(q_e) [c(\mu|\mathbb{E} [x(q, q_e)])]$$

$$\leq \sum_{j=1}^{m} F_j \left( \mathbb{E} [\lambda_j(q, q_e)] \right) \mathbb{E} [\lambda_j(q, q_e)] - \mathbb{E} \alpha(q_e) [c(\mu|\mathbb{E} [x(q, q_e)])]$$

$$= \sum_{j=1}^{m} F_j \left( \hat{\lambda}_j \right) \hat{\lambda}_j - \mathbb{E} \alpha(q_e) [c(\mu|\hat{\chi})] = \sum_{j=1}^{m} F_j \left( \hat{\lambda}_j \right) \hat{\lambda}_j - \mathbb{E} \alpha [c(\mu|\hat{\chi})] ,$$
where the last two equality follows by the definition of \( \tilde{x}, \tilde{a} \) and \( \tilde{\chi} \). As \( \pi \) is an arbitrary policy, this proves the proposition. \( \square \)

### G.5 Proof of Corollary 10

**Proof.** Using Lemma 4 on the secondary queues, we know that the system is stable and the expected queue length is finite. Now, by Lemma 1 and the one to one compatibility structure of the bipartite graph formed by the secondary queues, we have \( \mathbb{E} [\tilde{x}_{ij}(\tilde{q})] = \tilde{x}_{ij}^{*} \) for all \((i, j) \in E\). In particular, for a given \((i, j) \in E\), let \( l \) and \( m \) be such that \( im \) and \( jl \) are compatible. Thus, we must have

\[
\mathbb{E} [\lambda_{ij}(\tilde{q})] = \mathbb{E} [\mu_{im}(\tilde{q})] = \mathbb{E} [\tilde{x}_{ij}(\tilde{q})]
\]

\[
\Rightarrow \tilde{x}_{ij}^{*} + \epsilon_{\eta} \sum_{l=1}^{[N(j)]} (\mathbb{P} [q_{jl} = 0] - \mathbb{P} [q_{jl} > 0]) = \tilde{x}_{ij}^{*} = \mathbb{E} [\tilde{x}_{ij}(\tilde{q})]. \tag{22}
\]

In addition, as we have \( \alpha(q) = \tilde{\alpha}^{*} \) for all \( q \in S \), the system is in Nash equilibrium. Now, we will show optimality. Applying Lemma 4 on the secondary queues, we have

\[
\mathbb{E} [\langle 1_{n+m}, \tilde{q} \rangle] \leq B \frac{1}{\epsilon_{\eta}}
\]

for some \( B > 0 \). Now, we will show the profit loss is of the order \( \eta \epsilon_{\eta}^{2} \) similar to the proof of Lemma 6. By Taylor’s series expansion, we have

\[
\frac{I_{\eta}}{\eta} = \sum_{j=1}^{m} F_{j}(\hat{x}_{j}^{*}) \hat{\lambda}_{j}^{*} - \mathbb{E} \hat{\alpha}^{*} \left[ c(\mu, \hat{x}^{*}) \right] - \mathbb{E} \left[ \sum_{j=1}^{m} F_{j}(\hat{\lambda}_{j,\eta}(\tilde{q})) \lambda_{j,\eta}(\tilde{q}) - \mathbb{E} \hat{\alpha}^{*} \left[ c(\mu, \mathbb{E} [\tilde{x}]) \right] \right]
\]

\[
= \sum_{j=1}^{m} F_{j}(\hat{x}_{j}^{*}) \hat{\lambda}_{j}^{*} - \mathbb{E} \left( \sum_{j=1}^{m} F_{j}(\hat{\lambda}_{j,\eta}(\tilde{q})) \lambda_{j,\eta}(\tilde{q}) \right)
\]

\[
= \sum_{j=1}^{m} F_{j}(\hat{x}_{j}^{*}) \hat{\lambda}_{j}^{*} - \mathbb{E} \left[ \sum_{j=1}^{m} F_{j}(\hat{\lambda}_{j,\eta}(\tilde{q})) \lambda_{j,\eta}(\tilde{q}) \right]
\]

\[
= \sum_{j=1}^{m} \left( \mathbb{E} \left[ \sum_{l=1}^{[N(j)]} \hat{\lambda}_{j}^{*} - \epsilon_{\eta} \sum_{l=1}^{[N(j)]} \mathbb{1}_{\{q_{jl} = 0\}} + \epsilon_{\eta} \sum_{l=1}^{[N(j)]} \mathbb{1}_{\{q_{jl} > 0\}} \right] \right)
\]

\[
\mathcal{E} \hat{\epsilon}_{\eta} \sum_{j=1}^{m} \sum_{l=1}^{[N(j)]} \mathbb{E} \left[ \mathbb{P} [q_{jl} = 0] - \mathbb{P} [q_{jl} > 0] \right] \left( \hat{\lambda}_{j}^{*} F'_{j}(\hat{\lambda}_{j}^{*}) + \hat{\lambda}_{j}^{*} \right) + O(\epsilon_{\eta}^{2}) \sim O(\epsilon_{\eta}^{2}),
\]

where \((*)\) follows by the Taylor’s series expansion and the higher order terms are denoted by \( O(\epsilon_{\eta}^{2}) \) and \((***)\) follows by (22). This completes the proof. \( \square \)

### H PESSIMISTIC NASH EQUILIBRIUM

In this section, we will assume the following: if for a set price by the system operator \( p^{(1)} \) there are multiple Nash equilibrium, the drivers will choose the one which is worst for the system operator. In particular, the drivers would strive to minimize the profit obtained by the system operator. We are also implicitly assuming that the drivers only chooses the Nash equilibrium that results in a stable system. Now, under this new model, we will analyze the fluid model. But first, we need to introduce some notations. We will first redefine the cost function as a function of prices and arrival
rates. For this, we define the set of arrival rates that are consistent with $p^{(1)}$ by

$$M_\rho(p^{(1)}) \triangleq \left\{ \mu \in \mathbb{R}^n_+ : \exists \nu \in \mathbb{R}^{nxn}_+ \text{ satisfying (EQ), } G_i(\mu_i) = u_i, \ \mu_i = \sum_{l=1}^n \mu_l \nu_{li} \ \forall i \in [n] \right\}.$$ 

Now, the cost function is defined as follows:

$$c_\rho(p^{(1)}, \mu) \triangleq \begin{cases} \langle \mu, p^{(1)} \rangle & \text{if } \mu \in M(p^{(1)}) \\ \infty & \text{otherwise.} \end{cases} \quad (23)$$

Also, define $\zeta(\mu|p^{(1)}, q)$ to be a probability measure over all the Borel subsets of $M(p^{(1)})$ for all $p^{(1)} \in \mathbb{R}^n_+$ and $q \in S$. Denote such a probability measure by $P^{EQ}_\rho$. Also, let $\alpha(p^{(1)}|q)$ be a probability measure over all the Borel subsets of $\mathbb{R}^n_+$ for all $q \in S$. Given the state $q$, the system operator sets a price $p^{(1)}$ according to the probability distribution $\alpha(p^{(1)}|q)$ and the servers react to it by picking a probability distribution $\zeta(\mu|p^{(1)}, q)$ over all possible Nash equilibrium given by $M(p^{(1)})$. Now, we can re-define stability as follows:

**Definition 11 (Stability).** The discrete time Markov chain is stable if under a given pricing and matching policy $(\lambda(\cdot), \alpha(\cdot), x(\cdot))$, there exists $\zeta(\mu|p^{(1)}, q)$ for all $p^{(1)} \in \mathbb{R}^n_+$ and $q \in S$ such that the communicating class containing the state $0_{n \times m}$ is positive recurrent and all the other states (if any) are transient. We use $E_\rho$ to denote the set of stationary Markovian pricing and matching policies that make the system stable.

In addition, given a policy $\pi \in E_\rho$, let $Z_\rho(\pi)$ denote the set of measures $(\zeta(\mu|p^{(1)}, q) \in P^{EQ}_\rho)_{p^{(1)} \in \mathbb{R}^n_+}$ for all $q \in S$ such that $(\lambda(\cdot), \alpha(\cdot), x(\cdot), \zeta(\cdot))$ makes the system stable. By the definition of stability, $Z_\rho(\pi) \neq \emptyset$.

Now, the objective of the system operator can be re-written as follows:

$$R_\rho^* \triangleq \sup_{\pi=(\lambda(\cdot), \alpha(\cdot), x(\cdot)) \in E_\rho} \inf_{\zeta(\mu|p^{(1)}, q) \in Z_\rho(\pi)} \mathbb{E}_q \left[ \langle F(\lambda(q)), \lambda(q) \rangle \right] - \mathbb{E}_q \mathbb{E}_\alpha(p^{(1)}|q) \left[ \mathbb{E}_\zeta(\mu|p^{(1)}, q) \left[ c(\mu, p^{(1)}) \right] \right] - \langle s, q \rangle \right\} \quad (24a)$$

subject to, \( \lambda(q) \in \mathbb{R}^m_+ \), \( \forall q \in S \) (24b) \( x(\cdot) \) satisfies (2). (24c)

The inner infimum over all the possible Nash equilibrium under which the system is stable is to make sure that the servers picks the set of arrival rates which minimizes the profit of the system operator. The outer supremum is the system operator picking a pricing policy which maximizes it’s profit.

For the above defined pessimistic model, the probabilistic fluid model can be written as follows:

$$\hat{R}_\rho^* = \max_{\lambda_0, \hat{\lambda}} \left\{ \min_{\hat{\lambda} \in \mathbb{R}^n} \left\{ \mathbb{E}_\hat{\lambda} \left[ c(p^{(1)}, \mu) \right] \right\} \right\} \quad (25a)$$

subject to, \( \lambda_j = \sum_{i=1}^n \hat{x}_{ij} \ \forall j \in [m] \) (25b)

$$\mathbb{E}_\hat{\lambda} \left[ \mathbb{E}_\zeta(\mu_i) \right] = \sum_{j=1}^m \hat{x}_{ij} \ \forall i \in [n]$$ (25c)

$$\hat{x}_{ij} = 0 \ \forall (i, j) \notin E.$$ (25d)
Now, we will show that this fluid model provides an upper bound on the achievable profit under any given policy.

**Proposition 6.** Let \( \pi = (\dot{\lambda}(\cdot), \alpha(\cdot), x(\cdot)) \) be a feasible solution of (24) then
\[
R_p(\pi) \leq P_\rho(\pi) \leq \tilde{R}_p^*.
\]
That is, the fluid profit is an upper bound for the stochastic profit and net profit.

Thus, this proposition provides us with an upper bound on the net average profit achievable under any policy. We now present the following lemma which is a crucial step in the proof of the proposition.

**Lemma 10.** For a given stationary Markovian pricing and matching policy \( (\dot{\lambda}(\cdot), \alpha(\cdot), x(\cdot)) \), let \( \hat{\lambda} = \mathbb{E} [\lambda(q)], \hat{\alpha} = \mathbb{E}_q [\alpha(q)] \) and \( \hat{x} = \mathbb{E} [x(q)] \). Assume that \( \mathbb{E} [1_{t+h}, q] < \infty \). If \((\dot{\lambda}(\cdot), \alpha(\cdot), x(\cdot)) \in \mathcal{E}_\rho \) and \( x(\cdot) \) satisfies (2), then \((\hat{\lambda}, \hat{\alpha}, \hat{x})\) is feasible in the probabilistic fluid problem (25).

We first use this lemma to prove the proposition and later prove the lemma.

**Proof of Proposition 6.** Given \((\dot{\lambda}(\cdot), \alpha(\cdot), x(\cdot)) \in \mathcal{E}\), the profit under this policy can be written as follows:

\[
\begin{align*}
\min_{(\zeta(\mu|p(1), q))_{(p(1))} \in \mathbb{R}_+^{aN}\in \mathbb{R}_+} & \quad \mathbb{E}_q \left[ (F(\lambda(q)), \lambda(q)) - \mathbb{E}_x(\mu|p(1), q) \left[ \mathbb{E}_z(\mu|p(1), q) \left[ c(p(1), \mu) \right] \right] \right] \\
& \leq \min_{(\zeta(\mu|p(1), q))_{(p(1))} \in \mathbb{R}_+^{aN}\in \mathbb{R}_+} \left[ F(\tilde{\lambda}), \tilde{\lambda} \right] - \mathbb{E}_\tilde{\alpha}(p(1)) \left[ \mathbb{E}_{\tilde{\zeta}(\mu|p(1))} \left[ c(p(1), \mu) \right] \right] \\
& \leq \min_{(\tilde{\zeta}(\mu|p(1)) \in \mathbb{E}_{\rho}^{p_{1Q})}} \left[ F(\tilde{\lambda}), \tilde{\lambda} \right] - \mathbb{E}_{\tilde{\alpha}(p(1))} \left[ \mathbb{E}_{\tilde{\zeta}(\mu|p(1))} \left[ c(p(1), \mu) \right] \right] \leq R^*,
\end{align*}
\]

where (a) follows by Assumption 2 and using Jensen’s inequality and (b) follows by defining
\[
\tilde{\zeta}(\mu|p(1)) = \frac{\mathbb{E}_q [\zeta(\mu|p(1), q) \alpha(p(1)|q)]}{\mathbb{E}_q [\alpha(p(1)|q)].}
\]

In particular, for any function \( c(\cdot) \) of \( p(1) \) and \( \mu \), we have
\[
\begin{align*}
\mathbb{E}_x(\mu|p(1), q) \left[ \mathbb{E}_z(\mu|p(1), q) \left[ c(p(1), \mu) \right] \right] &= \sum_{q \in S} \int_{\mathbb{R}_+^a} \int_{\mathbb{R}_+^a} c(p(1), \mu) d\zeta(\mu|p(1), q) d\alpha(p(1)|q) \pi(q) \\
&= \int_{\mathbb{R}_+^a} \int_{\mathbb{R}_+^a} c(p(1), \mu) |\sum_{q \in S} d\zeta(\mu|p(1), q) d\alpha(p(1)|q) \pi(q) \\
&= \int_{\mathbb{R}_+^a} \int_{\mathbb{R}_+^a} c(p(1), \mu) d\tilde{\zeta}(\mu|p(1), q) d\tilde{\alpha}(p(1)) \\
&= \mathbb{E}_{\tilde{\alpha}(p(1))} \left[ \mathbb{E}_{\tilde{\zeta}(\mu|p(1))} \left[ c(p(1), \mu) \right] \right].
\end{align*}
\]

Finally, (c) follows as by Lemma 10, \((\hat{\lambda}, \hat{\alpha}, \hat{x})\) is feasible for the pessimistic fluid model. This completes the proof. \( \square \)
Proof of Lemma 10. By the hypothesis of the Lemma, we have $E_q \frac{\langle 1_{n+m}, q \rangle}{q} < \infty$. Thus, in steady state, we have $E_q [q] = E [q^n] \Rightarrow E [a] = E [\bar{x}]$, where we denote the queue length one time slot after $q$ by $q^n = q + \bar{a} - \bar{x}$. Now, we will simplify the RHS and LHS separately. We have

$$E [\bar{a}] = E_q [E [\bar{a} | q]] = E_q \left[ \left( \lambda(q), E_{\bar{a} \in (p^{(1)} | q)} \left[ E_{|v| \mu \in (1, q)} | \mu | \right] \right) \right]$$

$$= \left( E_q [\lambda(q)], E_{\bar{a} \in (p^{(1)} | q)} \left[ E_{|v| \mu \in (1, q)} | \mu | \right] \right)$$

$$= \left( \lambda, E_{\bar{a} \in (p^{(1)} | q)} \left[ E_{|v| \mu \in (1, q)} | \mu | \right] \right),$$

(26)

Now, we will simplify the right hand side. First define $E [\bar{x}_{ij}(q)] = \bar{x}_{ij}$ for all $(i, j)$. By (2)(c), we have $\bar{x}_{ij} = 0$ for all $(i, j) \notin E$. Next, we have

$$E \left[ x^{(1)}_i(q) \right] = \sum_{j=1}^m E \left[ \bar{x}_{ij}(q) \right] = \sum_{j=1}^m \bar{x}_{ij} \forall i \in [n], E \left[ x^{(2)}_j(q) \right] = \sum_{i=1}^n E \left[ \bar{x}_{ij}(q) \right] = \sum_{i=1}^n \bar{x}_{ij} \forall j \in [m].$$

(27)

Now, simplifying $E [\bar{a}] = E [\bar{x}]$ using (26) and (27), we get the constraints of the optimization problem (25).

Once we obtain a fluid model which provides an upper bound on the achievable profit under any pricing and matching policy, we can define a two price policy and max-weight matching policy similar to the optimistic case. Retracing the same steps, we should be able to show that the resultant policy is asymptotically optimal. As this will mostly be repetition of the main content of the paper, we omit the details here and conclude our discussion on the pessimistic, probabilistic fluid model.
