In switchback experiments, a firm sequentially exposes an experimental unit to a random treatment, measures its response, and repeats the procedure for several periods to quantify the treatment effect. Although practitioners have widely adopted this experimental design technique, the development of its theoretical properties and the derivation of optimal designs have been elusive. In this paper, we establish the necessary results for practitioners to apply this powerful class of experiments with minimal assumptions. Our main result is the derivation of the optimal design of switchback experiments under a range of different assumptions on the order of the carryover effect — that is, the length of time a treatment persists in impacting the outcome. We cast the optimal experimental design problem as a minimax discrete optimization problem, identify the worst-case adversarial strategy, establish structural results, and solve the reduced problem via a continuous relaxation. For switchback experiments conducted under the optimal design, we provide two approaches for performing inference. The first provides exact randomization based \( p \)-values, and the second uses a new finite population central limit theorem to conduct conservative hypothesis tests and build confidence intervals. We further provide theoretical results when the order of the carryover effect is misspecified.

For firms that possess the capability to run multiple switchback experiments, we also provide a data-driven procedure to identify the likely order of the carryover effect. We conduct extensive simulations to study the empirical properties of our results, and conclude with some practical suggestions.

1. Introduction

Academic scholars have appreciated the benefits that experimentation brings to firms for many decades (March 1991, Sitkin 1992, Sarasvathy 2001, Thomke 2001, Kohavi and Thomke 2017, Sun et al. 2018, Xiong et al. 2019). However, widespread adoption of the practice has only taken off in the last decade, partly fueled by the rapid cost reductions achieved by firms in the technology sector (Kohavi et al. 2007, 2009, Azevedo et al. 2019, Kohavi et al. 2020a). Most large firms now possess internal tools for experimentation, and a growing number of smaller and more conventional companies are purchasing the capabilities from third-party sellers that offer full-stack integration.
These tools typically allow simple “A/B” tests that compare the standard offering “A” to a new or improved version “B”. The comparisons are made across a range of different business outcomes, and the tests are usually conducted for at least a week. This simple practice has provided tremendous value to firms. Some firms and authors, however, have recognized the limitations of these simple A/B tests. Principle amongst these is adequately handling interference (the scenario where the assignment of one subject impacts another) and estimating heterogeneous (or personalized) effects.

In this paper, we simultaneously tackle both of these challenges by developing a theoretical framework for the optimal design and analysis of switchback experiments under the minimal amount of assumptions. In switchback experiments, we sequentially expose a unit to a random treatment, measure its response, and repeat the procedure for a fixed period of time. By administering alternate treatments to the same unit, we can directly estimate an individual level causal effect and alleviate the challenges posed by interference.

There are two classes of applications where switchback experiments are widely used in practice. The first arises when units interfere with each other either through a network or some more complicated unknown structure. For example, consider a ride-hailing platform that wants to test a new fare pricing algorithm’s effectiveness in a large city. Administering the test version to a subset of drivers can impact their behavior, which, in turn, could change the behavior of drivers that are receiving the old version. Directly comparing the revenue generated by the drivers across the two groups will likely provide a biased estimate of what would happen if everyone were assigned to the new version compared to the old. Instead, practitioners treat the city as a single aggregated unit and use a switchback experiment to estimate the intervention’s effectiveness, thereby alleviating the problem caused by interference. A similar issue often arises in revenue management when, for example, a retailer wants to test the effectiveness of a new

---

1 Many online platforms and retail marketplaces often observe varying levels of interference when conducting experiments. See Chamandy (2016), Cui et al. (2017), Kastelman and Ramesh (2018), Farronato et al. (2018), Glynn et al. (2020), Holtz et al. (2020) for online platforms (e.g., Airbnb, DoorDash, Lyft, Uber), and Caro and Gallien (2012), Ferreira et al. (2016), Cui et al. (2019), Ma et al. (2020) for retail markets (e.g., Amazon, AB InBev, Rue la la, Zara).

2 See Nie et al. (2018), Deshpande et al. (2018), Hadad et al. (2019) for estimating heterogeneous effects.

3 Some literature assumes specific outcome models under interference. Wager and Xu (2019), Johari et al. (2020) both work on experimental design for two-sided online platforms, by assuming that the interference can be captured via mean-field approximation. Glynn et al. (2020) assumes an underlying Markov Chain model and formulates the experimental design problem as estimating the difference between two steady state reward distributions. Some other literature directly models the interference through a network, e.g., Li et al. (2015), Athey et al. (2018), Eckles et al. (2016), Sussman and Airoldi (2017), Basse et al. (2019a), Puelz et al. (2019). In such models, a treatment assigned to one node of the network creates a “spillover effect,” which impacts the outcomes of the neighboring nodes. All of the above methods make specific assumptions on the outcome models. If these assumptions hold, the above methods correctly identify the causal effects (or the model parameters); if these assumptions do not hold, the estimates are likely biased.
promotion planning algorithm (Ferreira et al. 2016). Administering the new version to a subset of stock keeping units (SKU’s) cannibalizes the sales from the other SKU’s. Again comparing the generated revenue across the two groups is unlikely to provide an accurate measure of the promotion’s effectiveness. Instead, practitioners can treat all the SKU’s as a single aggregated unit and use a switchback experiment to obtain accurate estimates of the promotion’s effectiveness. The second application arises when we have a limited number of experimental units, and we believe the effects are likely to be heterogeneous. For example, Bojinov and Shephard (2019) used switchback experiments to make causal claims about the relative effectiveness of algorithms compared with humans at executing large financial trades across a range of financial markets. More generally, psychologists and biostatisticians regularly use switchback experiments whenever studying the effectiveness of an intervention on a single unit, e.g., Lillie et al. (2011) and Boruvka et al. (2018).

There are three significant challenges to using switchback experiments. The first is that causal estimators from switchback experiments have large variances as the precision is a function of the total number of assignments. The second is that past interventions are likely to impact future outcomes; this is often referred to as a carryover effect. Typically, many authors assume that there are no carryover effects (Chamberlain 1982, Athey and Imbens 2018, Imai and Kim 2019), although some recent work has relaxed this assumption (Robins 1986, Sobel 2012, Bojinov et al. 2020a). The third is that standard super population inference — where researchers either assume a model for the outcome, or that the units are sampled from an infinitely large population — requires unrealistic assumptions that fail to capture the problem’s personalized nature (Bojinov and Shephard 2019).

This paper’s main contributions are to address these three challenges and present a framework that allows firms and researchers to run reliable switchback experiments. First, we derive optimal designs for switchback experiments, ensuring that we can select a design that leads to the lowest variance among the most popular class assignment mechanisms. Second, we assume the presence of a carryover effect and show that our estimation and inference are valid both when the order of the carryover effect is correctly specified and misspecified, the later leading to a minor increase in the variance. For practitioners, we also propose a method to identify the order of the carryover effect by running a series of carefully designed switchback experiments. Finally, we take a purely design-based perspective on uncertainty; that is, we treat the outcomes as unknown but fixed (or equivalently, we condition on the set of potential outcomes) and assume that the assignment mechanism is the only source of randomness (Abadie et al. 2020). The main benefit of a design-based perspective is that the inference, and in turn the causal conclusions, do not depend on our ability to correctly specify a model describing the phenomena we are studying, ensuring that our findings are wholly non-parametric and robust to model misspecification (Imbens and Rubin 2015, Chapter 5).
The paper is structured as follows. In Section 2, we define the notations, the assumptions, and the assignment mechanism that we focus on, which we refer to as the *regular switchback experiments*. In Section 3, we discuss how to design an effective regular switchback experiment under the minimax rule. We cast the design problem as a minimax robust optimization problem. We identify the worst-case adversarial strategy, establish structural results, and then explicitly find the optimal design. In Section 4, we discuss how to perform inference and conduct statistical testing based on the results obtained from an optimally designed switchback experiments. We propose an exact test for sharp null hypotheses, and an asymptotic test for testing the average treatment effect. We provide \( p \)-values and construct confidence intervals based on such two hypotheses tests. In Section 5, we discuss cases when the carryover effect is misspecified. We show that our estimation and inference still remain valid. In Section 6, we run simulations to test the correctness and effectiveness of our proposed experiments under various simulation setups. In Section 7, we discuss how to conduct hypothesis testing to identify the true order of the carryover effects and give empirical illustrations on how to conduct a switchback experiment in practice. All technical proofs are in the Appendix.

2. Notations, Assumptions, and Regular Switchback Experiments

2.1. Assignment Paths and Potential Outcomes

We focus our discussion on a single experimental unit. For example, this unit could be a ride-hailing platform testing the effectiveness of a new fare pricing algorithm in a city, or a retailer testing the effectiveness of a new promotion planning algorithm over all its SKU’s. At each time point \( t \in [T] = \{1, 2, ..., T\} \), we assign the unit to receive an intervention \( W_t \in \{0, 1\} \). For example, one experimental period could be several minutes to one hour for a ride-hailing platform or one to two days for a retailer; the intervention could be a new pricing or promotion planning algorithm. In some applications, external factors determine the time horizon, \( T \); however, when \( T \) is not fixed, Section 7.1 provides details for how to choose an appropriate \( T \).

Following convention, we say that the unit is assigned to treatment if \( W_t = 1 \) and control when \( W_t = 0 \); in A/B testing terminology, “A” is control and “B” is treatment. The assignment path is then the collection of assignments and is denoted using a vector notation whose dimensions are specified in the subscript, \( W_{1:T} = (W_1, W_2, ..., W_T) \in \{0, 1\}^T \). We adopt the convention that \( W_{1:T} \) stands for a random assignment path, while \( w_{1:T} \) stands for one realization. Though we focus on binary assignments, our results easily extend to more complex settings.

After administering the assigned intervention, we observed a corresponding outcome. For example, this could be total traffic or total revenue generated during each experimental period. Following the extended potential outcomes framework, at time \( t \in [T] \), we posit that for each possible assignment path \( w_{1:T} \) there exists a corresponding potential outcome denoted by \( Y_t(w_{1:T}) \). The set of all potential outcomes will then be written as \( \mathbb{Y} = \{Y_t(w_{1:T})\}_{t \in [T], w_{1:T} \in \{0, 1\}^T} \).
Figure 1  Illustrator of assignment paths and potential outcomes when $T = 4$. The green path stands for one assignment path $w_{1:4} = (1, 1, 0, 0)$. Following the green path there are four potential outcomes. The two red dots each stands for two potential outcomes that are equal under Assumption 2. And the potential outcomes at the two red dots are equal if Assumption 3 is further assumed.

Example 1. When $T = 4$, there are 16 assignment paths as shown in Figure 1. Associated with each assignment path $w_{1:4}$ are four potential outcomes $Y_1(w_{1:4}), Y_2(w_{1:4}), Y_3(w_{1:4}), Y_4(w_{1:4})$.

Throughout this paper, we do not directly model the potential outcomes or impose a parametric relationship with the assignment path; instead, we treat them as unknown but fixed quantities, or, equivalently, we implicitly condition on $Y$ (Imbens and Rubin 2015, Chapter 5). The benefit of this approach is that it allows us to be completely agnostic to the outcome process, making our causal claims as objective as possible. To make inference possible, we rely on the variation introduced by the random assignment path; this is commonly referred to as finite-sample or design-based perspective. Unlike traditional sampling-based inference, our approach does not require a hypothetical population from which we sampled our experimental units, see Abadie et al. (2020) for a discussion of both.

Since the potential outcomes are unknown but fixed, we can assume that their absolute values are bounded from above (Bai 2019, Li et al. 2020).

Assumption 1 (Bounded Potential Outcomes). The potential outcomes are bounded by some constant, i.e., $\exists B > 0, s.t. \forall t \in [T], \forall w \in \{0, 1\}^T, |Y_t(w)| \leq B,$

or, equivalently, $Y \in [-B, B]^T := \mathcal{Y}$.
Assumption 1 is almost always satisfied, since it only assumes that the potential outcomes are bounded by the same (possibly a large) constant, e.g., the total traffic or revenue generated from each experimental period is always a finite amount. In particular, knowledge about the magnitude of $B$ is not required. The optimal design as we will introduce in Theorem 3 does not depend on $B$.

We further make the following two assumptions that limit the dependence of the potential outcomes on assignment paths. Below let $\{t:t'\} = \{t, t+1, \ldots, t'\}$.

**Assumption 2 (Non-anticipating Potential Outcomes).** For any $t \in [T]$, $w_{1:t} \in \{0,1\}^t$, and for any $w'_{t+1:T}, w''_{t+1:T} \in \{0,1\}^{T-t}$,

$$Y_t(w_{1:t}, w'_{t+1:T}) = Y_t(w_{1:t}, w''_{t+1:T}).$$

Assumption 2 states that the potential outcomes at time $t$ do not depend on future treatments (Bojinov and Shephard 2019, Basse et al. 2019b, Rambachan and Shephard 2019). Since we control the assignment mechanism instead of letting the experimental units to administer future assignments (e.g., at Uber or Lyft, a passenger cannot decide the price in the next hour), the design ensures that this assumption is satisfied.

**Example 2 (Example 1 Continued).** Under Assumption 2, $Y_3(1,1,1,1) = Y_3(1,1,1,0)$. In Figure the red dot at $Y_3(1,1,1)$ stands for both $Y_3(1,1,1,1)$ and $Y_3(1,1,1,0)$. □

**Assumption 3 (No $m$-Carryover Effects).** There exists a fixed and given $m$, such that for any $t \in \{m+1, m+2, \ldots, T\}$, $w_{t-m:T} \in \{0,1\}^{T-t+m+1}$, and for any $w'_{t-m-1:T}, w''_{t-m-1:T} \in \{0,1\}^{t-m-1}$,

$$Y_t(w'_{t-m-1:T}, w_{t-m:T}) = Y_t(w''_{t-m-1:T}, w_{t-m:T}).$$

Assumption 3 restricts the order of the carryover effect (Laird et al. 1992, Senn and Lambrou 1998, Bojinov and Shephard 2019, Basse et al. 2019b). The validity of Assumption 3 depends on the setting and requires practitioners to use their domain knowledge to choose an appropriate $m$; Section 7.2 provides a procedure to correctly identify $m$ with a little more experimental budget. Examples arise in ride-hailing, in which the effect of surge pricing on a ride-hailing platform typically dissipates after one or two hours, depending on the city size (Garg and Nazerzadeh 2019). In beverage drink retailing, a deep promotion may induce consumers to stockpile. Yet more often the stockpiled beverage drinks are consumed within a few days, due to the “pantry effect” (Ailawadi and Neslin 1998, Bell et al. 1999), so the carryover effect lasts no more than a few days. Moreover, assuming an incorrect $m$ will not invalidate the subsequent inference, but will lead to an increase in the variance in estimating most causal estimands (see Section 5 and 6.5).

Assumptions 2 and 3 allow us to simplify notation. For any $t \in \{m+1, \ldots, T\}$ and any two assignment paths $w_{1:T}, w'_{1:T} \in \{0,1\}^{m+1}$, whenever $w_{t-m:t} = w'_{t-m:t}$ this leads to

$$Y_t(w_{1:T}) = Y_t(w'_{1:T}).$$
In the remainder of this paper, we will write \( Y_t(\bm{w}_{t-m:t}) := Y_t(\bm{w}_{1:T}) \). For example, the potential outcomes at the two red dots in Figure 1 are equal, i.e., \( Y_3(1,1) := Y_3(1,1,1,1) = Y_3(1,1,1,0) = Y_3(0,1,1,1) = Y_3(0,1,1,0) \)

2.2. Causal Effects

In the potential outcomes approach to causal inference, any comparison of potential outcomes has a causal interpretation. In this paper, we focus on a special set of causal estimands that measure the relative effectiveness of persistently assigning a unit to treatment as opposed to control. For any \( p \in \{0,1,...,T-1\} \), let \( \mathbf{1}_{p+1} = (1,1,...,1) \) be a vector of \( p + 1 \) ones; let \( \mathbf{0}_{p+1} = (0,0,...,0) \) be a vector of \( p + 1 \) zeros. Define the average lag-\( p \) causal effect of consecutive treatments on the outcome, for any \( p \in \{0,1,...,T-1\} \),

\[
\tau_p(Y) = \frac{1}{T-p} \sum_{t=p+1}^{T} [Y_t(\mathbf{1}_{p+1}) - Y_t(\mathbf{0}_{p+1})].
\]

This estimand captures the effects of permanently deploying a new policy, and has been widely studied in the longitudinal experiments since the early work of Robins (1986).

Remark 1. Although we focus on an average causal effect, all of our results and analysis trivially extend to the total causal effect, which does not normalize, i.e., \((T-p)\tau_p(Y)\). The optimal design as we will show in Section 3 will remain unchanged.

It is worth noting that \( p \) reflects the experimental designer’s knowledge of the order of the carryover effect. See discussion below Assumption 3. Such a knowledge is sometimes correct, which we refer to as the perfect knowledge case \( p = m \); it is sometimes incorrect, which we refer to as the “misspecified” \( m \) case \( p \neq m \). In this section we focus on the \( p = m \) case; Section 5 discusses the \( p \neq m \) case. Section 7.2 introduces a procedure to identify \( m \).

The challenge of causal inference on switchback experiments is that we only observe one assignment path. In other words, for each period \( t \), we observe at most either \( Y_t(\mathbf{1}_{p+1}) \) or \( Y_t(\mathbf{0}_{p+1}) \) (and sometimes neither). After conducting a switchback experiment, the observed data contains \( \bm{w}_{1:T}^{\text{obs}} \) the realized assignment path, and \( Y_t^{\text{obs}} = Y_t(\bm{w}_{1:T}^{\text{obs}}) \) the observed outcome at time \( t \) under the realized assignment path \( \bm{w}_{1:T}^{\text{obs}} \). To link the observed and potential outcomes, we assume there is only one version of the treatment, and that there is no non-compliance.

---

4 What is typical in companies is that after the switchback experiment is finished, managers decide to permanently deploy (or not to deploy) a new policy. So the unit is always exposed to treatment (or control) hereon.

5 Some authors specifically focus on \( p < m \), particularly when \( m \) is of the same order as \( T \) (Bojinov and Shephard 2019).

6 When combined with non-interference if there were multiple units, this is known as the stable unit treatment value assumption (Rubin 1980).
2.3. Regular Switchback Experiments

The design of switchback experiment induces a probabilistic distribution over assignment paths $w_1:T \in \{0, 1\}^T$. Formally, a design of switchback experiment is any $\eta: \{0, 1\}^N \rightarrow [0, 1]$ such that

$$\sum_{w_1:T \in \{0, 1\}^T} \eta(w_1:T) = 1, \quad \eta(w_1:T) \geq 0, \quad \forall w_1:T \in \{0, 1\}^T.$$ 

Explicitly, $\eta(\cdot)$ is the underlying discrete distribution of the random assignment path $W_1:T$.

In this paper, we narrow our scope to the family of regular switchback experiments. This family of experiments are parameterized by $T = \{t_0 = 1 < t_1 < t_2 < ... < t_K\} \subseteq [T]$, where $K \in \mathbb{N}$ belongs to the set of all positive integers, and $T$ contains a total of $K + 1$ integers. For the ease of notations also let $t_{K+1} = T + 1$.

**Definition 1 (Regular Switchback Experiments).** For any $K \in \mathbb{N}$ and any $T = \{t_0 = 1 < t_1 < t_2 < ... < t_K\} \subseteq [T]$, a regular switchback experiment $T$ administers a probabilistic treatment at any time $t$, given by:

$$\Pr(W_t = 1) = \begin{cases} 1/2, & \text{if } t \in T \\ 1\{W_{t-1} = 1\}, & \text{if } t \notin T \end{cases}$$

(2)

In words, the manager decides on a collection of randomization points, which consists of flipping a fair coin at each period $t \in \{t_0, ..., t_K\}$. If the resulting flip at period $t_k$ is heads, then the manager assigns the unit to treatment during periods $(t_k, t_k + 1, ..., t_{k+1} - 1)$; otherwise, if tails, then the manager assigns the unit to control during periods $(t_k, t_k + 1, ..., t_{k+1} - 1)$. The reason behind fair coin flips reflects our limited assumption on the outcome model, and the inherent symmetry in the potential outcomes. Since most firms design the entire experiment before the experiment is launched, the assignment probabilities are typically not updated based on the observed outcomes; therefore, we do not consider adaptively changing the coin flip probabilities.

**Example 3.** When $T = 4$, $T = \{t_0 = 1, t_1 = 3\}$ corresponds to the following design: with probability $1/4$, $W_{1:4} = (1, 1, 1, 1)$; with probability $1/4$, $W_{1:4} = (1, 1, 0, 0)$; with probability $1/4$, $W_{1:4} = (0, 0, 1, 1)$; with probability $1/4$, $W_{1:4} = (0, 0, 0, 0)$. See Figure 2 (left figure).

**Example 4.** Not all switchback experiments are regular. For example, when $T = 4$: with probability $1/4$, $W_{1:4} = (1, 1, 1, 0)$; with probability $1/4$, $W_{1:4} = (1, 0, 0, 0)$; with probability $1/4$, $W_{1:4} = (0, 1, 1, 1)$; with probability $1/4$, $W_{1:4} = (0, 0, 0, 1)$. See Figure 2 (right figure).

For any regular switchback experiment $T$, we refer to the discrete probability distribution using $\eta_T(\cdot)$. For any $T$, there are a total of $2^{K+1}$ many assignment paths, which are uniquely determined by

$^7$ When $t \in T$, the treatment probability that leads to the smallest variance is $1/2$. 

Figure 2  Two designs. The blue lines stand for the possible treatment assignments that a design could administer. Left: regular switchback experiment (Example 3); Right: irregular switchback experiment (Example 4).

the values of \( W_{t_0}, W_{t_1}, \ldots, W_{t_K} \). The assignment path is random, and follows the discrete probability distribution \( \eta_T(\cdot) \):

\[
\eta_T(w_{1:T}) = \begin{cases} 
\frac{1}{2^{K+1}}, & \text{if } \forall k \in \{0, 1, \ldots, K\}, w_{tk} = w_{tk+1} = \ldots = w_{tk+1} - 1, \\
0, & \text{otherwise.}
\end{cases}
\]

(3)

In the remainder of this paper, unless explicitly noted, all probabilities and expectations are taken with respect to this discrete probability distribution \( \eta_T(\cdot) \).

2.4. Estimation

Now that \( \eta_T(\cdot) \) is determined, following any realization of the assignment path \( w_{1:T} \), we use the Horvitz-Thompson estimator to estimate the lag-\( p \) effect:

\[
\hat{\tau}_p(\eta_T, w_{1:T}, Y) = \frac{1}{T-p} \sum_{t=p+1}^{T} \left\{ Y_{obs} \frac{\mathbb{1}\{w_{t-p:t-1} = 1_{p+1}\}}{\Pr(W_{t-p:t-1} = 1_{p+1})} - Y_{obs} \frac{\mathbb{1}\{w_{t-p:t-1} = 0_{p+1}\}}{\Pr(W_{t-p:t-1} = 0_{p+1})} \right\}.
\]

(4)

Since the assignment path \( W_{1:T} \) is random, this Horvitz-Thompson estimator is also random. We emphasize that the estimator \( \hat{\tau}_p(\cdot, \cdot, \cdot) \) depends on (i) the probability distribution that the assignment path is sampled from, (ii) the realization of the assignment path, and (iii) the set of potential outcomes.

Example 5. Suppose \( T = 4, p = m = 1 \). Suppose the assignments are probabilistic and \( \Pr(W_t = 1) = \Pr(W_t = 0) = 1/2, \forall t \in [4] \). With probability 1/16 the green assignment path as in Figure 1 is administered, \( W_{1:4} = (1, 1, 0, 0) \). The estimator is \( \hat{\tau}_1 = \frac{1}{3} \{ 4Y_2(1, 1) + 0 - 4Y_4(0, 0) \} \). □

It is well-known that the Horvitz-Thompson estimator is unbiased if the treatment assignment probabilities are non-zero. Regular switchback experiments naturally satisfy such a probabilistic condition, since the assignment in any period is random, i.e. \( \Pr(W_t = 1) = 1/2, \forall t \in [T] \).

Theorem 1 (Unbiasedness of the Horvitz-Thompson Estimator). In a regular switchback experiment, under Assumptions 2 and 3, the Horvitz-Thompson estimator is unbiased for the average lag-\( p \) causal effect of consecutive treatments on outcome, i.e.,

\[
\mathbb{E}_{W_{1:T} \sim \eta_T}[\hat{\tau}_p(\eta_T, W_{1:T}, Y)] = \tau_p(Y).
\]
The proof to Theorem 1 is standard, by checking the expectations. We defer its proof to Section 5.4 in the Appendix. When \( p \neq m \), the above estimator is still meaningful with causal interpretations. See Section 5.5 for a discussion.

2.5. Evaluation of Experiments: the Decision-Theoretic Framework

To evaluate the quality of a design of experiment, we adopt the decision-theoretic framework (Berger 2013, Bickel and Doksum 2015). When the random design is \( \eta_T(\cdot) \), for any realization of the assignment path \( w_{1:T} \) and any set of potential outcomes \( \mathcal{Y} \), we define the loss function

\[
L(\eta_T, w_{1:T}, \mathcal{Y}) = (\hat{\tau}_p(\eta_T, w_{1:T}, \mathcal{Y}) - \tau_p(\mathcal{Y}))^2
\]

and the risk function

\[
r(\eta_T, \mathcal{Y}) = \mathbb{E}_{W_{1:T} \sim \eta_T(\cdot)}[L(\eta_T, W_{1:T}, \mathcal{Y})] = \sum_{w_{1:T} \in \{0,1\}^T} \eta_T(w_{1:T}) \cdot (\hat{\tau}_p(\eta_T, w_{1:T}, \mathcal{Y}) - \tau_p(\mathcal{Y}))^2
\]

(5)

Such a risk function quantifies the expected squared difference between our estimand and estimator for any design. Since the estimator is unbiased, the risk function also has a second interpretation: the variance of the estimator. A design with a lower risk is also a design whose estimator has a lower variance.

Example 6 (Examples 3 and 5 Revisited). Suppose \( T = 4 \) and \( p = m = 1 \). As in Example 3, \( \mathcal{T} = \{1,3\} \). With probability \( 1/4 \), \( W_{1:4} = (1,1,0,0) \), \( \hat{\tau}_1(\mathcal{T}) = \frac{1}{3}\{2Y_2(1,1) - 2Y_4(0,0)\} \), \( L(\eta_T, w_{1:T}, \mathcal{Y}) = \frac{1}{9}(Y_2(1,1) + Y_2(0,0) - Y_3(1,1) + Y_3(0,0) - Y_4(1,1) - Y_4(0,0))^2 \). As in Example 3, \( \mathcal{\bar{T}} = \{1,2,3,4\} \). With probability \( 1/16 \), \( W_{1:4} = (1,1,0,0) \), \( \hat{\tau}_1(\mathcal{T}) = \frac{1}{3}\{4Y_2(1,1) - 4Y_4(0,0)\} \), \( L(\eta_T, w_{1:T}, \mathcal{Y}) = \frac{1}{9}(3Y_2(1,1) + Y_2(0,0) - Y_3(1,1) + Y_3(0,0) - Y_4(1,1) - 3Y_4(0,0))^2 \). □

Example 6 suggests that, even if the two realizations of the assignment path are the same and the potential outcomes are the same, since the probability distributions \( \eta_T \) and \( \eta_{\bar{T}} \) are distinct, the corresponding estimators \( \hat{\tau}_1(\mathcal{T}) \) and \( \hat{\tau}_1(\mathcal{\bar{T}}) \) could be different, and the corresponding loss functions \( L(\eta_T, w_{1:T}, \mathcal{Y}) \) and \( L(\eta_{\bar{T}}, w_{1:T}, \mathcal{Y}) \) also could be different. This observation suggests that there exists some design \( \eta_T^* \) that has the smallest risk. In the next section we find such a design for the \( p = m \) case.

3. Design of Regular Switchback Experiments under Minimax Rule

The goal of this section is to find the optimal \( \mathcal{T}^* \subseteq [T] \), that is, to select the optimal randomization points. Throughout this section we assume \( m \) is known and we set \( p = m \).

In practice, there is a trade-off between having too few randomization points (corresponding to small \( K \)) and too many (corresponding to large \( K \)). Intuitively, too many decreases the probability
of observing an assignment path $1_{m+1}$ or $0_{m+1}$, which, in turn, decreases the amount of useful data. On the other hand, too few decreases the number of independent observations and reduces our ability to produce reliable results. Both of these scenarios reduce our ability to draw valid causal claims. To make switchback experiments useful in practice, we need to find the optimal subset of randomization points that allows us to draw valid inference while minimizing the risk function.

We formalize this goal through the minimax framework, where we try to derive the best possible design for the worse possible set of potential outcomes.

The minimax decision rule [Berger 2013, Wu 1981] finds an optimal design of experiment, such that the worst-case risk against an adversarial selection of potential outcomes is minimized,

$$
\min_{T \in [T]} \max_{Y \in \mathcal{Y}} r(\eta_T, Y) = \min_{T \in [T]} \max_{Y \in \mathcal{Y}} \sum_{w_{1:T} \in \{0,1\}^T} \eta_T(w_{1:T}) \cdot (\hat{\tau}_p(w_{1:T}, Y) - \tau_p(Y))^2.
$$

(6)

To solve the minimax problem, we start by focusing on the inner maximization part of (6). We characterize the worst-case potential outcomes by identifying two dominating strategies for the adversarial selection of potential outcomes. Denote $\mathcal{Y}^+ = \{Y_t(1_{m+1}) = Y_t(0_{m+1}) = B\}_{t \in \{m+1:T\}}$ and $\mathcal{Y}^- = \{Y_t(1_{m+1}) = Y_t(0_{m+1}) = -B\}_{t \in \{m+1:T\}}$.

**Lemma 1.** Under Assumptions 1–3, $\mathcal{Y}^+$ and $\mathcal{Y}^-$ are the only two dominating strategies for the adversarial selection of potential outcomes. That is, for any $T \subseteq [T]$ and for any $Y \in \mathcal{Y}$,

$$
\begin{align*}
 r(\eta_T, \mathcal{Y}^+) &\geq r(\eta_T, Y); \\
 r(\eta_T, \mathcal{Y}^-) &\geq r(\eta_T, Y).
\end{align*}
$$

Moreover, for any $Y \in \mathcal{Y}$ such that $Y \neq \mathcal{Y}^+, \mathcal{Y} \neq \mathcal{Y}^-$, the above two inequalities are strict.

The proof of Lemma 1 and an implication of Lemma 1 can be found in Sections EC.4.2.2 and EC.4.2.3, respectively.

**Example 7 (Example 3 Continued).** Suppose $T = 4$, $p = m = 1$, and $T = \{1,3\}$. The risk function can be calculated by $r(\eta_T, Y) = \sum_{t=2}^4 [(Y_t(1,1) + Y_t(0,0))^2] + 2Y_3(1,1)^2 + 2Y_3(0,0)^2 + 2 \sum_{t=2}^3 [(Y_t(1,1) + Y_t(0,0))(Y_{t+1}(1,1) + Y_{t+1}(0,0))]$. As Lemma 1 suggests, the risk function is maximized (only) at $Y_t(1,1) = Y_t(0,0) = \pm B$, $\forall t \in \{2:4\}$.

Lemma 1 simplifies the minimax problem in (6), as it allows us to replace $Y$ by either $\mathcal{Y}^+$ or $\mathcal{Y}^-$, and reduce the minimax problem into a minimization problem.

Using Lemma 1 we now establish two structural results that further characterize the class of optimal designs of regular switchback experiments. Lemma 2 states the optimal starting and ending structure; Lemma 3 states the optimal middle-case structure. The proofs to Lemma 2 and Lemma 3 are deferred to Sections EC.4.3.1 and EC.4.3.2 respectively.
**Lemma 2.** When \( Y = Y^+ \) or \( Y = Y^- \), under Assumptions 1–3, any optimal design of experiment \( T \) must satisfy

\[
t_1 \geq m + 2, \quad \text{and} \quad t_K \leq T - m.
\]

Lemma 2 states that the first randomization point on period 1 should be followed by at least \( m \) periods that do not flip a coin, and that the last randomization point should be followed by at least \( m \) periods that do not flip a coin. This guarantees that the assignments during \( \{1 : m + 1\} \) and during \( \{T - m : T\} \) both produce observed data that can be used to estimate the lag-\( m \) effect.

**Lemma 3.** When \( Y = Y^+ \) or \( Y = Y^- \), under Assumptions 1–3, any optimal design of experiment \( T \) must satisfy

\[
t_{k+1} - t_{k-1} \geq m, \ \forall k \in [K].
\]

Lemma 3 suggests that in every consecutive \( m + 1 \) periods, there could be at most 3 randomization points. Intuitively, too many randomization points in every consecutive \( m + 1 \) periods decreases the chance of observing an useful assignment path of \( 1_{m+1} \) or \( 0_{m+1} \). Lemma 3 formalizes such intuition, and suggests that as the persistence of the carryover effect increases, the optimal design randomizes less often.

Lemmas 2 and 3 restrict the space of possible optimal regular switchback experiment to a smaller class of switchback experiments, which we define below.

**Definition 2 (Persistent Switchback Experiments).** We say a regular switchback experiment \( T \) is persistent, if it satisfies the following three conditions,

\[
t_1 \geq m + 2; \quad t_K \leq T - m; \quad t_{k+1} - t_{k-1} \geq m, \ \forall k \in [K].
\]

For persistent switchback experiments, we can explicitly calculate the risk function \( r(\eta_T, Y) \).

**Theorem 2 (Risk Function).** When \( Y = Y^+ \) or \( Y = Y^- \), under Assumptions 1–3, the risk function for any persistent switchback experiment is given by

\[
r(\eta_T, Y) = \frac{1}{(T - m)^2} \left\{ 4 \sum_{k=1}^{K+1} (t_k - t_{k-1})^2 + 8m(t_K - t_1) + 4m^2K - 4m^2 + 4\sum_{k=2}^{K} [(m - t_k + t_{k-1})^+]^2 \right\} B^2 \tag{7}
\]

Theorem 2 explicitly describes the risk function of any optimal design of regular switchback experiments, which lies in the class of persistent switchback experiments. The proof of Theorem 2 is deferred to Section EC.4.4 in the appendix.

To understand the risk function in Theorem 2 we separately examine each term in (7). The first summation of the squares \( \sum_{k=1}^{K+1} (t_k - t_{k-1})^2 \) suggests that the gap between two consecutive
Table 1  An example of the optimal design $T^* = \{1,5,7,9\}$ versus an arbitrary design $\tilde{T} = \{1,4,7,10\}$ when $T = 12$ and $p = m = 2$.

Each checkmark beneath a time period $t$ indicates that $t$ is a randomization point.

randomization points should not be too large. The middle term $8m(t_K - t_1)$ formalizes Lemma 2 suggesting that the second randomization point on period $t_1$ should not be too early and the last randomization point on period $t_K$ should not be too late. The last summation of the squares $\sum_{k=2}^{K} [(m - t_k + t_{k-1})^+]^2$ suggests that the gap should not be too small. Equation 7 formalizes the trade-off that we have described earlier in this section.

**Theorem 3 (Optimal Design).** Under Assumptions 1–3, the optimal solution to the design of regular switchback experiment as we have introduced in (6) is equivalent to the optimal solution to the following subset selection problem.

$$\min_{T \subset [T]} \left\{ 4 \sum_{k=0}^{K} (t_{k+1} - t_k)^2 + 8m(t_K - t_1) + 4m^2K - 4m^2 + 4 \sum_{k=1}^{K-1} [(m - t_{k+1} + t_k)^+]^2 \right\} \tag{8}$$

In particular, when $m = 0$ then $T^* = \{1,2,3,...,T\}$; when $m > 0$, and if there exists $n \geq 4 \in \mathbb{N}$, s.t. $T = nm$, then $T^* = \{1,2m + 1,3m + 1,...,(n-2)m + 1\}$.

The proof of Theorem 3 is deferred to Section EC.4.5.1 in the appendix.

Theorem 3 presents the optimal design in a class of perfect cases when the time horizon splits into several equal-length epochs. See Figure 1 for an example. In practice, when possible, we recommend selecting $T$ that satisfies the condition in Theorem 3. See Section 7.1 for a discussion.

We can also find the optimal design for other imperfect cases when $T$ is not divisible by $m$, by solving (8). However, integrality issues in the subset selection problem make the discussion of optimal design in such imperfect cases rather technical, and so are deferred to Section EC.4.5 in the appendix.

Recall that both the causal estimand and the Horvitz-Thompson estimator involve consecutive treatments or controls for $m + 1$ periods. By contrast, Theorem 3 suggests that the optimal design have epochs of equal length $m$ (ignoring the first and last epoch). At a first sight this is counter-intuitive. Intuitively, each epoch should contain at least $m + 1$ periods so there exist periods that always have consecutive treatments $1_{m+1}$ or $0_{m+1}$ and always generate useful data; e.g., periods $\tilde{t} = 4,7,10$ in the third row of Table 1. However, even if each epoch had $m + 1$ periods, there are still many periods that do not always generate useful data (e.g., periods $\tilde{t} = 5,6,8,9$), thus invalidating this intuition.
To understand Theorem 3, the correct intuition is the existence of a trade-off between too many and too few randomization points. The optimal design of experiment balances randomization frequency between the two extremes. Theorem 3 quantifies this balance.

An important special case arises when experimental designers believe there is very little carryover effect, in which case the optimal designs are almost the same. In particular, Theorem 3 suggests that the optimal design when \( m = 0 \) is \( T^* = \{1, 2, 3, ..., T\} \), and when \( m = 1 \) is \( T^* = \{1, 3, 4, ..., T - 1\} \). This suggests that the minimax optimal design in the absence of a carryover effect is robust to the existence of a short carryover effect.

4. Inference and Statistical Testing

After designing and running the experiment, we obtain two time series. The first is the observed assignment path \( w_{1:T}^{\text{obs}} \) (blue and red dots) and the observed outcomes \( Y_{p+1:T}^{\text{obs}} \) (black curve). The dashed lines are the potential outcomes under consecutive treatments / controls.

![Figure 3](image)

**Figure 3** Illustrator of the observed assignment path \( w_{1:T}^{\text{obs}} \) (blue and red dots) and the observed outcomes \( Y_{p+1:T}^{\text{obs}} \) (black curve). The dashed lines are the potential outcomes under consecutive treatments / controls.

To draw inference from this data we propose two methods, an exact randomization based test and a finite population conservative test that establishes asymptotic result.

Throughout this section we assume perfect knowledge of \( m \), i.e., \( p = m \), and we will write \( \tau_m \) and \( \hat{\tau}_m \) to stand for \( \tau_p \) and \( \hat{\tau}_p \), respectively. When \( p \neq m \), our inference methods are still valid. See Section 5 for a discussion, and see Section 6.5 for a numerical example.
Algorithm 1 Algorithm for performing a sharp-null hypothesis test

Require: Fix $I$, total number of samples drawn.

1: for i in 1 : I do
2: Sample a new assignment path $w_i^{[1:T]}$ according to the assignment mechanism.
3: Hold $Y_{p+1:T}^{\text{obs}}$ unchanged. Compute $\hat{\tau}[i]$ according to (4),
$$\hat{\tau}[i] = \frac{1}{T-m} \sum_{t=m+1}^{T} \left\{ Y_t^{\text{obs}} \frac{1}{\Pr(W_{t-m:t} = 1_{m+1})} - Y_t^{\text{obs}} \frac{1}{\Pr(W_{t-m:t} = 0_{m+1})} \right\}.$$ 
4: end for
5: Compute $\hat{p}_F = I^{-1} \sum_{i=1}^{I} \{ |\hat{\tau}[i]| > |\hat{\tau}| \}$ 
6: return $\hat{p}_F$, the estimated $p$-value. For large $I$, this is exact.

4.1. Exact Inference

We propose an exact non-parametric test for the sharp null of no effect at every time point,
$$H_0 : Y_t(w_{t-m:t}) - Y_t(w'_{t-m:t}) = 0 \quad \text{for all } w_{t-m:t}, w'_{t-m:t}, t \in \{m+1 : T\}. \quad (9)$$

This will be tested against a portmanteau alternative. The sharp null hypothesis implies that $Y_t(w_{t-m:t}^{\text{obs}}) = Y_t(w_{t-m:t})$ for all $w_{t-m:t} \in \{0,1\}^t$. That is, regardless of the assignment path $w_{t-m:t}$ we would have observed the same outcomes.

We can conduct exact tests by using the known assignment mechanism to simulate new assignment paths; see Algorithm 1 for details. The test depends on the observation that, under the sharp null hypothesis of no treatment effect (9), any assignment path $w_i^{[1:T]}$ leads to the same observed outcomes. In particular, in Step 3, we assume the observed outcomes remain unchanged. Thus all treatment paths lead to the same observed outcomes $Y_{m+1:T}^{\text{obs}}$. To obtain a confidence interval, we propose inverting a sequence of exact hypothesis tests to identify the region outside of which (9) is violated at the prespecified nominal level (Imbens and Rubin 2015, Chapter 5).

4.2. Asymptotic Inference

We now introduce a conservative test for the null of no average treatment effect:
$$H_0 : \tau_m = \frac{1}{T-m} \sum_{t=m+1}^{T} [Y_t(1_{m+1}) - Y_t(0_{m+1})] = 0. \quad (10)$$

To test such a null, we derive a finite population central limit theorem to approximate the distribution of the Horvitz-Thompson estimator.

Assume $n = T/m \geq 4$ is an integer, then under the optimal design as shown in Theorem 3, the assignment path is determined by the realizations at $W_1, W_{2m+1}, \ldots, W_{(n-2)m+1}$. To make the dependence on randomization clear, we introduce the following notations. For any $k \in \{0,1,\ldots,n-3\}$,
let \( \hat{Y}_k(1_{m+1}) = \sum_{t=(k+1)m+1}^{(k+2)m} Y_t(1_{m+1}) \) and \( \hat{Y}_k(0_{m+1}) = \sum_{t=(k+1)m+1}^{(k+2)m} Y_t(0_{m+1}) \). Moreover, let \( \hat{Y}_k^{\text{obs}} = \sum_{t=(k+1)m+1}^{(k+2)m} Y_t^{\text{obs}} \) be the sum of observed outcomes.

**Theorem 4 (Variance of the Horvitz-Thompson Estimator).** Under Assumptions 1–3, if \( n = T/m \geq 4 \) is an integer, then under the optimal design as shown in Theorem 3, the variance of the Horvitz-Thompson estimator, \( \text{Var}(\hat{\tau}_m) \), is

\[
\text{Var}(\hat{\tau}_m) = \frac{1}{(T-m)^2} \left\{ \left( \hat{Y}_0(1_{m+1}) \right)^2 + \left( \hat{Y}_0(0_{m+1}) \right)^2 + 2\hat{Y}_0(1_{m+1})\hat{Y}_0(0_{m+1}) + \sum_{k=1}^{n-3} \left[ 3\hat{Y}_k(1_{m+1})^2 + 3\hat{Y}_k(0_{m+1})^2 + 2\hat{Y}_k(1_{m+1})\hat{Y}_k(0_{m+1}) \right] \right. \\
+ \frac{8}{(T-m)^2} \left\{ 6(\hat{Y}_0^{\text{obs}})^2 + \sum_{k=1}^{n-3} 24(\hat{Y}_k^{\text{obs}})^2 \mathbb{I}\{W_{km+1} = W_{(k+1)m+1}\} + 6(\hat{Y}_k^{\text{obs}})^2 \right. \\
\left. + \sum_{k=0}^{n-3} 16\hat{Y}_k^{\text{obs}}\hat{Y}_k^{\text{obs}} \mathbb{I}\{W_{km+1} = W_{(k+1)m+1} = W_{(k+2)m+1}\} \right) \}
\] (11)

Theorem 4 provides the variance of the Horvitz-Thompson estimator. Since we never observe all the potential outcomes, most of the cross-product terms in (11) can not be directly estimated without imposing further assumption. Instead, we provide the following two upper bounds to (11) and propose an unbiased estimator for each.

**Corollary 1.** Under the conditions in Theorem 4 there exist two upper bounds for the variance of the Horvitz-Thompson estimator, \( \text{Var}(\hat{\tau}_m) \leq \text{Var}^{U1}(\hat{\tau}_m) \leq \text{Var}^{U2}(\hat{\tau}_m) \). These two upper bounds \( \text{Var}^{U1}(\hat{\tau}_m) \) and \( \text{Var}^{U2}(\hat{\tau}_m) \) can be estimated by \( \hat{\sigma}^2_{U1} \) and \( \hat{\sigma}^2_{U2} \), respectively, where

\[
\hat{\sigma}^2_{U1} = \frac{1}{(T-m)^2} \left\{ 6(\hat{Y}_0^{\text{obs}})^2 + \sum_{k=1}^{n-3} 24(\hat{Y}_k^{\text{obs}})^2 \mathbb{I}\{W_{km+1} = W_{(k+1)m+1}\} + 6(\hat{Y}_k^{\text{obs}})^2 \right. \\
\left. + \sum_{k=0}^{n-3} 16\hat{Y}_k^{\text{obs}}\hat{Y}_k^{\text{obs}} \mathbb{I}\{W_{km+1} = W_{(k+1)m+1} = W_{(k+2)m+1}\} \right) ,
\]

and

\[
\hat{\sigma}^2_{U2} = \frac{1}{(T-m)^2} \left\{ 8(\hat{Y}_0^{\text{obs}})^2 + \sum_{k=1}^{n-3} 32(\hat{Y}_k^{\text{obs}})^2 \mathbb{I}\{W_{km+1} = W_{(k+1)m+1}\} + 8(\hat{Y}_k^{\text{obs}})^2 \right) .
\]

Moreover, \( \hat{\sigma}^2_{U1} \) and \( \hat{\sigma}^2_{U2} \) are unbiased, i.e., \( \mathbb{E}[\hat{\sigma}^2_{U1}] = \text{Var}^{U1}(\hat{\tau}_m) \), and \( \mathbb{E}[\hat{\sigma}^2_{U2}] = \text{Var}^{U2}(\hat{\tau}_m) \).

Corollary 4 provides the foundation to make conservative inference. In principle, either of the two conservative estimators for the variance leads to valid conservative inference. However, as we show in Section 6.3, although the first variance upper bound is tighter (\( \text{Var}^{U1}(\hat{\tau}_m) \leq \text{Var}^{U2}(\hat{\tau}_m) \)), the estimator for the first one is typically larger in the simulation (\( \hat{\sigma}^2_{U1} \geq \hat{\sigma}^2_{U2} \)).

We make the following technical assumption for the asymptotic normal distribution to hold.
**Assumption 4 (Non-negligible Variance).** Assume that the randomization distribution has a non-negligible variance, i.e.,

\[ \text{Var}(\hat{\tau}_m) \geq \Omega(n^{-1}) \]  

(12)

In particular, one sufficient condition for (12) is to assume that all the potential outcomes are positive, i.e., there exists some constant \( b > 0 \), such that \( \forall t \in [T], \forall w_1:T \in \{0,1\}^T, Y_t(w_1:T) \geq b \).

Intuitively, the key to most central limit theorems is that all the variables roughly have variances of the same order. In other words, there cannot be a small number of variables that compromise the majority of the variance. Since under Assumption 1 the potential outcomes are bounded, each variable contributes to the total variance of order \( O(n^{-2}) \). Assumption 4 suggests that the total variance is large enough, such that it cannot come from only a few of the time periods.

**Theorem 5 (Asymptotic Normality).** Let \( m \) be fixed. For any \( n \geq 4 \in \mathbb{N} \), define an \( n \)-replica experiment such that there are \( T = nm \) time periods. We take the optimal design as in Theorem 3 whose randomization points are at \( T^* = \{1,2m+1,3m+1,...,(n-2)m+1\} \). Under Assumptions 2–3, and under Assumption 4, the limiting distribution of the Horvitz-Thompson estimator in the \( n \)-replica experiment has an asymptotic normal distribution. That is, let \( \text{Var}(\hat{\tau}_m) \) be defined in Theorem 4. As \( n \to +\infty \),

\[ \frac{\hat{\tau}_m - \tau_m}{\sqrt{\text{Var}(\hat{\tau}_m)}} \xrightarrow{D} N(0,1). \]

Theorem 5 is in the spirit of the finite population central limit theorems as in [Li and Ding, 2017]. Note that, Theorem 5 does not require \( \text{Var}(\hat{\tau}_m) \) to converge as \( n \to +\infty \).

To conduct inference, we replace \( \text{Var}(\hat{\tau}_m) \) by \( \hat{\sigma}^2_o \) as provided in Corollary 1. Define the test statistic to be \( z = |\hat{\tau}_m|/\sqrt{\hat{\sigma}^2_o} \). When the alternative hypothesis is two-sided, the estimated \( p \)-value is given by \( \hat{p}_n = 2 - 2\Phi(z) \), where \( \Phi \) is the CDF of a standard normal distribution.

The proofs of Theorem 4, Corollary 1, and Theorem 5 are deferred to Sections EC.5.2, EC.5.3, and EC.5.4 in the Appendix, respectively.

5. A Discussion about Misspecified \( m \)

In Sections 3 and 4, we assumed that we knew the order of the carryover effect \( m \), and set \( p = m \). In practice, we may not know the exact value of the carryover effect, and we have to select \( p \) based on domain knowledge or the procedure we recommend in Section 7.2. In this section, we consider what happens when \( p \neq m \) and show that the estimation and inference are still valid and meaningful, although the design from Theorem 3 is no longer optimal. Below we distinguish the two cases: \( p > m \) and \( p < m \).
5.1. Causal Effects

When \( p > m \), due to Assumption 3, \( Y_t(1_{p+1}) = Y_t(1_{m+1}), \forall t \in \{p+1 : T\} \), so the lag-\( p \) causal effect is essentially the lag-\( m \) causal effect.

When \( p < m \), the lag-\( p \) effect in (1) is not well defined. Instead, we define the \( m \)-misspecified lag-\( p \) causal effect that pads the \( p+1 \) assignments with the earlier observed treatments.

\[
\tau_p^{(m)}(Y) = \frac{1}{T-p} \left\{ \sum_{t=p+1}^{m} \left[ Y_t(\omega^\text{obs}_{1:t-p-1}, 1_{p+1}) - Y_t(\omega^\text{obs}_{1:t-p-1}, 0_{p+1}) \right] + \sum_{t=m+1}^{T} \left[ Y_t(\omega^\text{obs}_{t-m:t-p-1}, 1_{p+1}) - Y_t(\omega^\text{obs}_{t-m:t-p-1}, 0_{p+1}) \right] \right\} .
\] (13)

This is a special case of the weighted lag-\( p \) causal effect introduced in Bojinov and Shephard (2019). Similarly to the average lag-\( p \) causal effect, \( \tau_p^{(m)}(Y) \) captures how administering \( p+1 \) consecutive treatments as opposed to \( p+1 \) consecutive controls impact the outcomes at time \( t \), conditional on the observed assignment path up to time \( t-p-1 \). See Section 6.5 for numerical results.

5.2. Estimator

When \( p > m \), Theorem 1 still holds, i.e., \( \mathbb{E}[\hat{\tau}_p] = \tau_p(Y) = \tau_m(Y) \). When \( p < m \), sometimes we have to slightly augment the results and study the conditional expectation.

Define \( f_T : [T] \to \mathbb{T} \) to be the "determining randomization point of period \( t \)," \( f_T(t) = \max \{j | j \in \mathbb{T}, j \leq t\} \) such that, it is the realization at time \( f_T(t) \) that uniquely determines the assignment at time \( t \), i.e. \( W_t = W_{f_T(t)}, \forall t \in [T] \). See Example 8 for an illustration of \( f_T(\cdot) \). When \( \mathbb{T} \) is clear from the context we drop the subscript and use \( f(\cdot) = f_T(\cdot) \). Depending on if \( f(t-p) \leq t-m \), we establish an analogy of Theorem 1 for the \( p < m \) case.

**Theorem 6 (Conditional Unbiasedness of the Estimator when \( m \) is Misspecified).**

Under Assumptions 2 and 3, for \( p < m \), at each time \( t \geq m+1 \), the Horvitz-Thompson estimator is either unbiased for the lag-\( m \) causal effect when \( f(t-p) \leq t-m \), or conditionally unbiased for the \( m \)-misspecified lag-\( p \) causal effect when \( f(t-p) > t-m \). When \( p+1 \leq t \leq m \), the Horvitz-Thompson estimator is either unbiased for the lag-\( t \) causal effect when \( f(t-p) = 1 \), or conditionally unbiased for the \( m \)-misspecified lag-\( t \) causal effect when \( f(t-p) > 1 \).

To remove the conditional expectation, we can further take an outer loop of expectation averaged over the past assignment paths. Although this is somewhat different from the average lag-\( p \) effect introduced earlier in (1), it does capture the impact of a sequence of treatment relative to a sequence of controls.
All the mathematical expressions of Theorem 6, as well as its proof, are stated in Section EC.6.1 in the Appendix. See Example 8 below for a specific illustration of Theorem 6. For a numerical illustration of the estimand and estimator in more general setups, see Section 6.5.

**Example 8 (Misspecified \( m \)).** Suppose \( T = 4, m = 2, p = 1, T = \{1, 3\} \). Then the determining randomization points are \( f_T(1) = 1, f_T(2) = 1, f_T(3) = 3, f_T(4) = 3 \), and

\[
\begin{align*}
    &\mathbb{E} \left[ Y_{obs}^2 \frac{1 \{ W_{1:2} = (1, 1) \}}{\Pr(W_{1:2} = (1, 1))} - Y_{obs}^2 \frac{1 \{ W_{1:2} = (0, 0) \}}{\Pr(W_{1:2} = (0, 0))} \right] = Y_2(1, 1) - Y_2(0, 0) \\
    &\mathbb{E} \left[ Y_{obs}^3 \frac{1 \{ W_{2:3} = (1, 1) \}}{\Pr(W_{2:3} = (1, 1))} - Y_{obs}^3 \frac{1 \{ W_{2:3} = (0, 0) \}}{\Pr(W_{2:3} = (0, 0))} \right] = Y_3(1, 1, 1) - Y_3(0, 0, 0) \\
    &\mathbb{E} \left[ Y_{obs}^4 \frac{1 \{ W_{3:4} = (1, 1) \}}{\Pr(W_{3:4} = (1, 1))} - Y_{obs}^4 \frac{1 \{ W_{3:4} = (0, 0) \}}{\Pr(W_{3:4} = (0, 0))} \right] = \frac{1}{2} [Y_4(1, 1, 1) + Y_4(0, 1, 1) - Y_4(0, 0, 0) - Y_4(1, 0, 0)]
\end{align*}
\]

Note that this is the 2-misspecified lag-1 causal effect. □

### 5.3. Inference

The exact inference procedure as in Section 4.1 remains valid when \( m \) is misspecified. For the asymptotic inference procedure as in Section 4.2, Theorem 5 still holds when \( m \) is misspecified, as we state in Corollary 2. The proof is deferred to Section EC.6.2 in the Appendix.

**Corollary 2 (Asymptotic Normality when \( m \) is Misspecified).** For any \( n \geq 4 \in \mathbb{N} \), define an \( n \)-replica experiment such that there are \( T = np \) time periods. Take the optimal design as in Theorem 3 whose randomization points are at \( T^* = \{1, 2p + 1, 3p + 1, \ldots, (n - 2)p + 1\} \). We have the following two observations.

i When \( p > m \), under Assumptions 2–3, the variance of the Horvitz-Thompson estimator, \( \text{Var}(\hat{\tau}_p) \), is explicitly given by (11).

ii Furthermore, no matter if \( p > m \) or \( p < m \), under Assumptions 1–3 and assume \( \text{Var}(\hat{\tau}_p) \geq \Omega(n^{-1}) \), the limiting distribution of the Horvitz-Thompson estimator in the \( n \)-replica experiment has an asymptotic normal distribution. That is, as \( n \to +\infty \),

\[
\frac{\hat{\tau}_p - \tau_p}{\sqrt{\text{Var}(\hat{\tau}_p)}} \overset{D}{\to} \mathcal{N}(0, 1).
\]

Corollary 2 together with Theorem 5 is the key to identification of \( m \), the order of the carryover effect. In Section 7.2 we provide a procedure to identify \( m \).

### 6. Simulation Study and Empirical Illustration

There are five goals for this simulation study. First, to illustrate how to conduct a switchback experiment for various outcome models. Second, to show that the optimal design in Theorem 3 has the smallest risk compared against two benchmarks. There are two dimensions for our comparison: the worst-case risk and the risk under a specific outcome model. Third, to verify the asymptotic
normal distribution under a non-asymptotic setup, and to study the quality of the upper bound proposed in Corollary 1. Fourth, to understand the rejection rate and its dependence on the length of time horizon. Fifth, under randomly generated cases, to study the performance of the optimal design under a misspecified $m$, and to compare the difference of the two inference methods proposed in Section 4.

6.1. Outcome Models
The potential outcome framework is flexible. As we will see below, it is easy to use the potential outcome framework to describe many complex relationships between assignments and outcomes.

We start with a simple model which originates from Oman and Seiden (1988):

$$ Y_t(w_{1:t}) = \mu + \alpha_t + \delta w_t + \gamma w_{t-1} + \epsilon_t $$  \hspace{1cm} (14)

where $\mu$ is a fixed effect; $\alpha_t$ is a fixed effect associated to period $t$; $\delta w_t$ is the contemporaneous effect, and $\gamma w_{t-1}$ is the carryover effect from period $t - 1$; $\epsilon_t$ is the random noise in period $t$. Such a model as well as a few very similar ones are widely used in the literature (Hedayat et al. 1978, Jones and Kenward 2014).

A more general variant from the above model is to consider carryover effects of any arbitrary order:

$$ Y_t(w_{1:t}) = \mu + \alpha_t + \delta^{(1)} w_t + \delta^{(2)} w_{t-1} + \ldots + \delta^{(t)} w_1 + \epsilon_t $$ \hspace{1cm} (15)

where $\delta^{(1)}, \delta^{(2)}, \ldots, \delta^{(t)}$ are non-stochastic coefficients. The dotted terms are carryover effects of higher orders. And all the other parameters are as defined in (14). We will run simulations based on this more general model, which enables us to test the performance of our proposed optimal design under a misspecified $m$.

The autoregressive model (Arellano 2003) is even more general: $Y_1(w_1) = \delta_{1,1} w_1 + \epsilon_1$ and $\forall t > 1$

$$ Y_t(w_{1:t}) = \phi_{t,t-1} Y_{t-1}(w_{1:t-1}) + \phi_{t,t-2} Y_{t-2}(w_{1:t-2}) + \ldots + \phi_{t,1} Y_1(w_1) + \delta_{t,t} w_t + \delta_{t,t-1} w_{t-1} + \ldots + \delta_{t,1} w_1 + \epsilon_t $$ \hspace{1cm} (16)

where $\phi_{t,i}$ and $\delta_{t,i}$ are non-stochastic coefficients; the dotted terms are carryover effects of higher orders; $\epsilon_t$ is the random noise in period $t$. We can iteratively replace $Y_t(w_t)$ using a linear combination of $w_t, w_{t-1}, \ldots, w_1$. So the autoregressive model in (16) can be written in a similar form of (15). The only difference is that the coefficients are different and dependent on $t$. 
6.2. Comparison of the Risk Functions

6.2.1. Simulation setup. We consider two setups. The first setup is for the worst-case risk. We consider $T = 120, p = m = 2$ where $m$ is correctly identified, and $Y_t(1_3) = Y_t(0_3) = 10$. We compare three different designs of switchback experiments. The first one is our proposed optimal design as in Theorem 3, such that $T^* = \{1, 5, 7, ..., 117\}$. The second one is the most common and naive switchback experiment, which independently assigns treatment/control in every period with half-half probability. It is parameterized by $T_{H1} = \{1, 2, 3, ..., 120\}$. The third one is the “intuitive” experiment discussed in Table 1, which divides the time horizon into several epochs each with length $m + 1 = 3$. It is parameterized by $T_{H2} = \{1, 4, 7, ..., 118\}$.

Second, we run simulations based on the outcome model as in (15). We consider $T = 120, p = m = 2$ where $m$ is correctly identified. For the outcome model, we consider $\mu = 0, \alpha_t = \log (t)$, and $\epsilon_t \sim N(0, 1)$ are i.i.d. standard normal distributions. For any $t > 3$, let $\delta^{(t)} = 0$. We will vary the values of $\delta^{(1)}, \delta^{(2)}, \delta^{(3)} \in \{1, 2\}$ and conduct experiments under $2^3 = 8$ different scenarios. Again we compare the same three different designs of switchback experiments. $T^* = \{1, 5, 7, ..., 117\}, T_{H1} = \{1, 2, 3, ..., 120\},$ and $T_{H2} = \{1, 4, 7, ..., 118\}$.

We simulate one assignment path at a time, and conduct an experiment following this assignment path. Since the outcome model is prescribed, we can calculate both the causal estimand and the observed outcomes (along the simulated assignment path). Then, we calculate the Horvitz-Thompson estimator based on the simulated assignment path and the simulated observed outcomes. With both the estimand and estimator, we can calculate the loss function. We repeat the above procedure enough (100000) times to obtain an accurate approximation of the risk function.

6.2.2. Simulation results. We calculate the worst-case risk functions via simulation. Notice that even though we could calculate the worst-case risk function explicitly via Theorem 2 we use the simulation to confirm this result. See Table 2 for results.

The causal effect is $\tau_2 = 0$ because $Y_t(1_3) = Y_t(0_3) = 10$. The simulated estimator is $E[\hat{\tau}^*_2] = -0.0291$ for our proposed optimal design, and $E[\hat{\tau}^{H1}_2] = 0.0104$ and $E[\hat{\tau}^{H2}_2] = -0.0478$ for the two benchmarks, respectively. The risk function is $r(\eta_{T^*}) = 26.78$ for our proposed optimal design, and $r(\eta_{T_{H1}}) = 33.67$ and $r(\eta_{T_{H2}}) = 27.85$ for the two benchmarks, respectively. Such simulation results suggest that our proposed optimal design have the smallest risk, under the worst case outcome model.

The optimal design $T^*$ as suggested in Theorem 3 yields the smallest risk.
We also calculate the risk functions based on the outcome model in (15). See Table 3. As we vary
the values of $\delta(1)$, $\delta(2)$ and $\delta(3)$, the total lag-2 causal effect is being changed. All three estimators
are able to reflect the change as the estimand changes. The risk function can be simulated and we
see that the risk function associated with the first benchmark $T_H^1$ is $28\% \sim 32\%$ larger than the
optimal design; and the second benchmark $T_H^2$ is $1\% \sim 2\%$ larger. Such simulation results suggest
again that our proposed optimal design have the smallest risk. Moreover, as $r(\eta_{TH})$ is close to

</table>

For each row, the random seed that generates the simulation setup is fixed. The optimal design $T^*$ as suggested in Theorem 3, though solved from a minimax program, still yields the smallest risk for the outcome model in (15).

$r(\eta_{TH})$ and both are much smaller than $r(\eta_{pH})$, our results suggest that when $m$ is unknown, it is
better to select $p$ to be slightly larger than the true $m$ as opposed to significantly smaller.

As the magnitude of treatment effects increase, the associated risk functions also increase. The
relative difference between risk functions of $r(\eta_{pH})$ and $r(\eta_{TH})$ increases, while the relative difference
between $r(\eta_{pH})$ and $r(\eta_{TH})$ decreases. This coincides with the intuitions discussed in Section 3.

6.3. Asymptotic Normality

6.3.1. Simulation setup. We run simulations based on the outcome model in (15), with $T = 120$ and $m = 2$. We will consider three cases: (i) $m$ is correctly specified so $p = 2$; (ii) $p = 3$, and
we estimate lag-3 causal estimand as in (1); (iii) $p = 1$, and we pretend as if we estimated the lag-1 causal estimand. However, as the lag-1 causal estimand is not well defined, we instead estimate the
2-misspecified lag-1 causal estimand as in (13).

For the outcome model, we consider $\mu = 0$, $\alpha = \log (t)$, and $\epsilon_t \sim N(0, 1)$ are i.i.d. standard normal
distributions. For any $t > 3$, let $\delta(t) = 0$. For simplicity, let $\delta(1) = \delta(2) = \delta(3) = \delta$. We vary $\delta \in \{1, 2, 3\}$
and conduct experiments under 3 different scenarios.

We simulate one assignment path at a time, and conduct experiment following this assignment
path. Since the outcome model is prescribed, we calculate the observed outcomes based on the simu-
lated assignment path. Then we calculate the Horvitz-Thompson estimator, and two conservative
estimators of the randomization variance (Corollary [1]), both based on the simulated assignment.
path and the simulated observed outcomes. On the other hand, the lag-$p$ causal estimand is easy
to calculate once the outcome model is prescribed. Yet the $m$-misspecified lag-$p$ causal estimand
has to be calculated in conjunction with the simulated assignment path. By repeating the above
procedure enough (100000) times we obtain a distribution of the estimator, and we calculate the
mean value of the estimator (and the $m$-misspecified lag-$p$ causal estimand).

6.3.2. Simulation results. Figure 4 shows approximate normality of the randomization dis-
tribution, under all 9 cases. There are three specifications of $p$. And there are three specifications
of $\delta \in \{1, 2, 3\}$. In all 9 cases, the distributions are all centered around the red vertical lines, which
are the mean values of the randomization distributions. Specifically, Figures (a) – (c) show that
Theorem 5 holds for moderate values of $T$, and Figures (d) – (i) show that Corollary 2 holds for
moderate values of $T$, as well.

For all the above cases, see Table 4 for the expected values and the variances of the randomization
distributions, as well two conservative estimators of the randomization variances. Note that the
three cases all have the same underlying outcome model. It is the different knowledge of $m$ that
leads to three different designs.

</tbody>
</table>

The randomization distribution is unbiased in all 9 cases (when $p < m$ it is unbiased for the $m$-misspecified average lag-1
causal effect). The conservative estimation of the variance upper bound from Corollary 1 is close to the true variance.

From Table 4 we make the following two observations. (i) **Unbiasedness of the Horvitz-Thompson estimator.** When $m$ is correctly specified, $\mathbb{E}[\hat{\tau}_p]$ is very close to $\tau_p$, verifying the
unbiasedness of the estimator. When $m = 2, p = 3$, the estimand remains unchanged, and the
estimator remains unbiased. But the variance of the estimator is larger. When $m = 2, p = 1$, the
estimand is the $m$-misspecified estimand, and the estimator is unbiased for this $m$-misspecified
estimand.

(ii) **Quality of Corollary 1** As we increase $\delta$, the variance of the randomization distribution
also increases. The two conservative estimators of the randomization variance are very close to
the true variance, which suggests that Corollary 1 approximates the true variance quite well. Even
(a) \( m = 2, p = 2, \delta = 1 \).
(b) \( m = 2, p = 2, \delta = 2 \).
(c) \( m = 2, p = 2, \delta = 3 \).
(d) \( m = 2, p = 3, \delta = 1 \).
(e) \( m = 2, p = 3, \delta = 2 \).
(f) \( m = 2, p = 3, \delta = 3 \).
(g) \( m = 2, p = 1, \delta = 1 \).
(h) \( m = 2, p = 1, \delta = 2 \).
(i) \( m = 2, p = 1, \delta = 3 \).

Figure 4  Approximate normality of the randomization distributions in all 9 cases. The red vertical lines are the expected values of the randomization distributions.

though the second upper bound \( \text{Var}^{U2}(\hat{\tau}_p) \) is larger than the first one \( \text{Var}^{U1}(\hat{\tau}_p) \), its estimator \( \hat{\sigma}_{U2}^2 \) turns out to be smaller than \( \hat{\sigma}_{U1}^2 \) in most cases.
6.4. Rejection Rates

6.4.1. Simulation setup. We run simulations based on the outcome model as in (15). We vary $T \in \{60, 120, 180, \ldots, 600\}$. We consider $p = m = 2$ where $m$ is correctly specified. Similar to Section 6.3, we consider the same parameterization and conduct experiments under 3 different scenarios $\delta \in \{1, 2, 3\}$.

We simulate one assignment path at a time, and conduct experiment following this assignment path. We first calculate the observed outcomes and the Horvitz-Thompson estimator. Then we conduct the two inference methods as proposed in Section 4 (for the asymptotic inference method, we plug in the second upper bound $\hat{\sigma}_U^2$) and obtain two estimated $p$-values. We reject the corresponding null hypothesis when the $p$-value is smaller than 0.1. By repeating the above procedure enough (in this simulation, 1000) times we obtain the frequency of a null hypothesis being rejected, which we refer to as the rejection rate.

6.4.2. Simulation Results. We calculate the rejection rates via simulation, and plot Figure 5. In all the simulations, $\delta \neq 0$, $\tau_p \neq 0$, so ideally we would wish to reject the null hypothesis (whether if it is (9) or (10)).

From Figure 5, we make the following three observations. (i) **Dependence on $T/m$.** The rejection rates increase as the length of the horizon increases – more specifically, as $T/m$ the total number of epochs increases. In practice, when firms have choose the length of $T$ and decide how much experimental budgets to allocate, they can refer to Figure 5 to choose $T$ properly. Also see discussion in Section 7.1.

(ii) **Between two inference methods.** In all three cases, the rejection rate from testing a sharp null hypothesis (9) is slightly higher than that from testing the Neyman’s null (10). This
coincides with our intuition that a sharp null is more likely to be rejected. We discuss this in Section 6.5.2 together with the associated p-values.

(iii) Dependence on the signal-to-noise ratio. The rejection rates all increase as \( \delta \) increases from 1 to 3 (while holding the noise from the model fixed). This suggests that when the treatment effect is relatively larger, we do not require a long experimental horizon to achieve a desired rejection rate.

6.5. Estimation under a Misspecified \( m \)

6.5.1. Simulation setup. We run simulations based on the outcome model as in (15). We consider \( T = 120, m = 2 \). We consider three cases: (i) \( m \) correctly specified so \( p = 2 \); (ii) \( p = 3 \), and we estimate the lag-3 causal estimand as in (1); (iii) \( p = 1 \), and we pretend as if we estimated the lag-1 causal estimand. However, the lag-1 causal estimand is not well defined. Instead, we estimate the 2-misspecified lag-1 causal estimand as in (13).

For the outcome model, we consider the same parameterization as in Section 6.3 and conduct experiments under 3 different scenarios \( \delta \in \{1, 2, 3\} \).

We only simulate one assignment path. Since the outcome model is prescribed, we calculate the observed outcomes. There is only one time series of such observed outcomes. We calculate the Horvitz-Thompson estimator based on the simulated assignment path and the simulated observed outcomes. We calculate the lag-\( p \) causal estimand directly, and also the \( m \)-misspecified lag-\( p \) causal estimand in conjunction with the simulated assignment path. Finally, we perform the two inference methods from Section 4 and report their associated estimated p-values. The conservative sampling variance we take is \( \hat{\sigma}_{U2}^2 \). We choose \( I = 100000 \) to be the number of samples drawn in the exact inference method as shown in Algorithm 1.

6.5.2. Simulation results. Notice this is only one experiment under one simulated experimental setup from one simulated assignment path. So the estimators \( \hat{\tau}_p \) we derive are different from \( \tau_p \). But they are still following the true causal effects which they estimate. See Table 5.

From Table 5 we see that both our estimator and the estimated variance are well defined in all the cases when \( p = m \), \( p > m \), and \( p < m \). In each case, as \( \delta \) increases from 1 to 3, the associated p-values exhibit decreasing trends, suggesting a stronger rejection rate against the null hypothesis. Moreover, the p-values suggested by the exact inference is always slightly smaller than the p-values suggested by the asymptotic inference. This coincides with our intuition that: (i) the exact inference method possesses a stronger null hypothesis which implies the null hypothesis of (10); (ii) in the asymptotic inference we replaced the true randomization variance by its conservative upper bound, which further leads to a larger p-value.
Table 5  Simulation results for correctly specified \(m\) case, and two misspecified \(m\) cases.

| \(m = 2, p = 2\) | \(\delta = 1\) | 3 | \(\tau_t^{(u)}\) | 1.35 | \(\tau_p\) | 8.81 | \(\hat{p}_F\) | 0.626 | \(\hat{p}_N\) | 0.648 |
| \(\delta = 2\) | 6 | - | 4.30 | 15.16 | 0.231 | 0.269 |
| \(\delta = 3\) | 9 | - | 7.25 | 23.88 | 0.101 | 0.138 |
| \(m = 2, p = 3\) | \(\delta = 1\) | 3 | - | 1.77 | 14.26 | 0.606 | 0.639 |
| \(\delta = 2\) | 6 | - | 5.00 | 24.69 | 0.262 | 0.314 |
| \(\delta = 3\) | 9 | - | 8.23 | 39.00 | 0.136 | 0.188 |
| \(m = 2, p = 1\) | \(\delta = 1\) | - | 2 | -1.03 | 3.87 | 0.590 | 0.599 |
| \(\delta = 2\) | - | 4 | 0.41 | 6.28 | 0.866 | 0.870 |
| \(\delta = 3\) | - | 6 | 1.86 | 9.47 | 0.530 | 0.547 |

The simulation setup for the three \(\delta = 1\) cases is the same; so are the \(\delta = 2\) cases and \(\delta = 3\) cases. The estimated \(p\)-values \(\hat{p}_F\) derived from the exact inference are slightly smaller than the \(p\)-values \(\hat{p}_N\) derived from the asymptotic inference.

7. Practical Implications

When a firm decided to use a switchback experiment for the evaluation of a new product or initiative, they have to make multiple decisions to ensure that the results are reliable, practical, and replicable. First, the firm must determine an appropriate outcome(s) that adequately captures the relative effectiveness of the change. In practice, this requires substantive domain knowledge combined with an understanding of the likely impact of the change; see [Kohavi et al. (2020a)] for an in-depth discussion of metric definition strategies. Second, as part of the design of the experiment, the firm often have control over the length of the test and the time between consecutive randomization steps. In Section 7.1, we provide practical advice for selecting the length of the experiment because, as we showed earlier, the variance and, in turn, the reliability of the conclusions depend on \(T\). Third, the firm must decide an appropriate value for the order of the carryover effect; this, again, requires substantive domain knowledge. Section 7.2 provides a data-driven approach to identify a possible value for the carryover effect by running multiple experiments. Finally, using the first three steps, the firm decide the collection of randomization points and samples the assignment path from the appropriate randomization distribution. This final step has already been discussed at length, as we showed in Section 3 the optimal design is obtained from Theorem 3. After designing the experiment, the firm can use the data collected from the test to draw causal conclusions about the new innovation’s performance using the methods in Section 4.

7.1. Choosing the Granularity and the Length of Horizon

The selection of \(T\) depends on the following two components: the granularity of a single period and the number of total epochs \(T/p\) included in the time horizon.

A single period’s granularity refers to how long a single experimental time period (i.e., \(t_k - t_{k-1}\)) corresponds to in the physical world. As long as each time period is smaller than the length of the carryover effect and the length of the carryover effect is divisible by the length of one time unit, the selection of granularity makes no difference to the optimal design and analysis of switchback experiments. See Example 9.
Example 9 (Two Granularity Levels). In the ride-sharing application, suppose the firm has two options to either treat one single time period as 15 minutes, or as 30 minutes. See Figure 6. Each small time period stands for 15 minutes, and the carryover effect lasts for 1 hour. In the time granularity as shown in blue, each time period lasts for 15 minutes, and the carryover effect lasts for $m = 4$ time periods. In the time granularity as shown in red, each time period lasts for 30 minutes, and the carryover effect lasts for $m = 2$ time periods.

![Illustrator of two granularity levels. Blue: each period is 15 minutes; Red: each period is 30 minutes.](image)

From Theorem 3, the optimal design exhibits an optimal structure that randomizes once every $m$ time periods (except for the first and last epoch, which lasts for $2m$ time periods each). In both cases, the optimal design would randomize once every hour. Furthermore, from Theorem 1 we know that under both cases the mean value of the Horvitz-Thompson estimator remains unchanged. From Theorem 4, the variance consists of terms such as $\bar{Y}_k(1_{m+1}) = \sum_{t=(k+1)m+1}^{(k+2)m} Y_t(1_{m+1})$, which are the sum across all the outcomes within 1 hour. So under both cases the variance of the estimator remains unchanged. □

On the other hand, setting each period’s length longer than the carryover effect will lead to a loss in precisions. Consider an extreme case where the carryover effect is 1 minute, while each period is selected to be an hour. Had we set each period to be a minute, we would have collected order of magnitude more useful data. Hence, we suggest that each period’s length be smaller than the carryover effect duration.

After selecting an appropriate granularity, we can use the procedures from Section 7.2 to identify $m$. After selecting $m$, the firm usually set $p = m$ and control the overall duration of the experiment $n = T/p = T/m$. We suggest choosing $n$ by referring to the rejection rate curve, as shown in Section 6.4; intuitively, this procedure resembles a typical power analysis. We begin with selecting our inference method, as described in Section 4. We then use our domain knowledge to estimate the expected signal-to-noise ratio; this could be done by looking at historical experiments or through dummy experiments, as described in the next section. Finally, we choose the desired rejection rate and find out the length of the horizon required.
7.2. Identifying the Order of the Carryover Effect

We borrow Theorem 5 and Corollary 2 to define a procedure, which, combined with a searching method, estimates the order of the carryover effect. This method is in the spirit of the Hausman test.

To build intuition, suppose we have access to two comparable experimental units. The two experimental units could be two separate units or two time epochs on one experimental unit such that the two epochs are far enough such that the carryover effect from one does not affect the outcomes of the other. Suppose, on the first experimental unit, we design an optimal experiment under \( p = p_1 \) and on the second unit, we use \( p = p_2 \); without loss of generality let \( p_1 < p_2 \).

After running the experiment and collecting the results, consider the following two statistics. For the first unit, we calculate \( \hat{\tau}_{p_1} \), the sampling average, and \( \hat{\sigma}^2_{p_1} \), the conservative sampling variance as suggested by Corollary 1. For the second unit, we calculate \( \hat{\tau}_{p_2} \) and \( \hat{\sigma}^2_{p_2} \).

Define a procedure that tests the following null hypothesis:

\[
H_0: m \leq p_1
\]  

(17)

Under the null hypothesis (17), \( \tau_{p_1} = \tau_{p_2} \). Furthermore, given that the two experimental units are independent, the difference between the two sample means should be a normal distribution centered around zero, i.e., \((\hat{\tau}_{p_1} - \hat{\tau}_{p_2})/\sqrt{\text{Var}(\hat{\tau}_{p_1}) + \text{Var}(\hat{\tau}_{p_2})} \overset{D}{\to} \mathcal{N}(0,1)\). To test the null hypothesis (17), define the test statistic to be \( z = |\hat{\tau}_{p_1} - \hat{\tau}_{p_2}|/\sqrt{\hat{\sigma}^2_{p_1} + \hat{\sigma}^2_{p_2}} \). The estimated p-value is given by \( \hat{p} = 2 - 2\Phi(z) \), where \( \Phi \) is the CDF of a standard normal distribution.

The above procedure enables us to test the null hypothesis (17). We can combine such a procedure with any searching method to identify \( m \).

For example, suppose we are running an experiment based on the setup described in Section 6.5 with \( \delta = 3 \). Suppose we have narrowed down the range of the order of the carryover effect to be \( m \leq 3 \). In the first round, we use our procedure to test a null hypothesis \( m \leq 2 \). Then we would observe row 3 and 6 from Table 5 with \( \hat{\tau}_2 = 7.25, \hat{\sigma}^2_2 = 23.88; \hat{\tau}_3 = 8.23, \hat{\sigma}^2_3 = 39.00 \). So the estimated p-value for the null hypothesis \( m \leq 2 \) is estimated to be \( \hat{p} = 0.902 \), which is too large to reject the null hypothesis. In the second round, we consult the procedure to test a null hypothesis \( m \leq 1 \). Then we would observe row 3 and 9 from Table 5 with \( \hat{\tau}_1 = 1.86, \hat{\sigma}^2_3 = 9.47; \hat{\tau}_2 = 7.25, \hat{\sigma}^2_2 = 23.88 \). The estimated p-value for the null hypothesis \( m \leq 1 \) is estimated to be \( \hat{p} = 0.350 \). This is still rather big, yet a significant difference from the previous 0.902.

We conduct a few more numerical simulations with different time periods. The setup is the same as in Section 6.5 except that \( T \) takes values in \( T \in \{210, 1020, 2010\} \). When \( T = 210 \), in the first

\(^8\) The values of \( T \) were selected such that they were both divisible by 2 and 3, the possible values of the carryover effect.
round the estimated $p$-value for the null hypothesis $m \leq 2$ is estimated to be $\hat{p} = 0.956$; in the second round the estimated $p$-value for the null hypothesis $m \leq 1$ is estimated to be $\hat{p} = 0.182$. When $T = 1020$, in the first round the estimated $p$-value for the null hypothesis $m \leq 2$ is estimated to be $\hat{p} = 0.869$; in the second round the estimated $p$-value for the null hypothesis $m \leq 1$ is estimated to be $\hat{p} = 0.163$. When $T = 2010$, in the first round the estimated $p$-value for the null hypothesis $m \leq 2$ is estimated to be $\hat{p} = 0.760$; in the second round the estimated $p$-value for the null hypothesis $m \leq 1$ is estimated to be $\hat{p} = 0.037$. In practice, we suggest increasing the horizon’s length to a degree such that $T/p > 100$.

8. Concluding Remarks, Limitations and Future Work

We studied the design and analysis of switchback experiments. We formulated and solved a minimax problem for the design of optimal switchback experiments. We then analyzed our proposed optimal design and proposed two inferential methods. In particular, we showed asymptotic normality of the randomization distribution. We discussed cases when the order of the carryover effect, $m$, is misspecified and detailed a method to identify the order of the carryover effect. We gave empirical suggestions that it is better to select $p$ to be slightly larger than the true $m$ as opposed to significantly smaller.

We point out two limitations of our paper. First, when $m$, the order of the carryover effect is as large as comparable to $T$ the horizon’s length, our method, though still unbiased in theory, incurs a large variance that typically prohibits the experimental designer from making meaningful inference. This is because our method is general and requires the minimum amount of modeling assumptions. If we have strong domain knowledge about the outcome model, we can incorporate them to improve the design. Second, our method only considers flipping independent coins before the experiment even begins. We do not consider adaptively changing the coin flip probabilities, as it requires further assumptions about the outcome model.

Finally, we do encourage empirical researchers who apply our method to use domain knowledge to narrow down $m$ first, before using the procedure in Section 7.2 to identify $m$. This is because, in theory, when $m$ is relatively large compared to $T$, this procedure could accept (not reject) the null hypothesis simply due to insufficient statistical power. So this procedure could require too many testing periods. And in practice, each procedure to identify (17) needs to consume experimental resources at the scale of $T/m > 100$ to distinguish two candidate values, which could be luxurious when the resource is scarce.

Online Appendix

EC.1. Recap of Notations

Within this paper, let $\mathbb{N}, \mathbb{N}_0$ be the set of positive integers and non-negative integers, respectively. For any $T \in \mathbb{N}$, let $[T] = \{1, \ldots, T\}$ be the set of positive integers no larger than $T$. For any $t < t' \in \mathbb{N}$, let $\{t : t'\} = \{t, t+1, \ldots, t'\}$ be the set of integers between (including) $t$ and $t'$. For any $m \in \mathbb{N}$, let $1_m = (1, 1, \ldots, 1)$ be a vector of $m$ ones; let $0_m = (0, 0, \ldots, 0)$ be a vector of $m$ zeros. We use parentheses for probabilities, i.e., $\text{Pr}(\cdot)$; brackets for expectations, i.e., $\mathbb{E}[\cdot]$; and curly brackets for indicators, i.e., $1\{\cdot\}$. For any $a \in \mathbb{R}$, let $(a)^+ = \max\{a, 0\}$.

EC.2. Theorems Used

We summarize here the results that we have directly used in our proofs.

**Definition EC.1 (φ-Dependent Random Variables, Hoeffding and Robbins (1948)).** For any sequence $\{X_1, X_2, \ldots\}$, if there exists $\phi$ such that for any $s - r > \phi$, the two sets $(X_1, X_2, \ldots, X_r), (X_s, X_{s+1}, \ldots, X_n)$ are independent, then the sequence is said to be $\phi$-dependent.

**Lemma EC.1 (Romano and Wolf (2000), Theorem 2.1).** Let $\{X_{n,i}\}$ be a triangular array of zero-mean random variables. Let $\phi \in \mathbb{N}$ be a fixed constant. For each $n = 1, 2, \ldots$, let $d = d_n$, and suppose that $X_{n,1}, X_{n,2}, \ldots, X_{n,d}$ is an $\phi$-dependent sequence of random variables. Define

$$B_{n,k,a}^2 = \text{Var}\left(\sum_{i=a}^{a+k-1} X_{n,i}\right), \quad B_n^2 = B_{n,d,1}^2 = \text{Var}\left(\sum_{i=1}^{d} X_{n,i}\right)$$

For some $\delta > 0$ and $-1 \leq \gamma \leq 1$, if the following conditions hold:
1. $\mathbb{E}|X_{n,i}|^{2+\delta} \leq \Delta_n$, for all $i$;
2. $B_{n,k,a}^2/k^{1+\gamma} \leq K_n$, for all $a$ and $k \geq \phi$;
3. $B_n^2/(d\phi^\gamma) \geq L_n$;
4. $K_n/L_n = O(1)$;
5. $\Delta/L_n^{2+\delta/2} = O(1)$,

then

$$\frac{\sum_{i=1}^{d} X_{n,i}}{B_n} \overset{D}{\to} \mathcal{N}(0, 1).$$

We explain Lemma EC.1. The $\overset{D}{\to}$ notation stands for convergence in distribution. The definition of a sequence of $\phi$-dependent random variables is given in Definition EC.1. To check if the conditions in Lemma EC.1 hold, we will first calculate $B_{n,k,a}^2$ for any $k$ and $a$, and then construct some proper $\Delta_n, K_n$, and $L_n$. 
EC.3. Proof from Section 2

The only proof from Section 2 is the unbiasedness of the Horvitz-Thompson estimator. We prove by checking the expectations.

Proof of Theorem 1. First observe that for regular switchback experiments, both \(0 < \Pr(W_{t-p}: t = 0_{p+1}) = 1_{p+1})\) and \(\Pr(W_{t-p}: t = 0_{p+1}) = 0_{p+1})\) hold. So for any \(t \in \{p+1 : T\}\), with probability \(\Pr(W_{t-p}: t = 1_{p+1}) \neq 0\), \(\Pr(W_{t-p}: t = 0_{p+1}) = 1\), and \(Y_{t} = Y_{t}(1_{p+1})\). So \(\frac{Y_{t} \mathbb{1}_{W_{t-p}: t = 1_{p+1}}}{\Pr(W_{t-p}: t = 1_{p+1})} = Y_{t}(1_{p+1})\). Similarly \(\frac{Y_{t} \mathbb{1}_{W_{t-p}: t = 0_{p+1}}}{\Pr(W_{t-p}: t = 0_{p+1})} = Y_{t}(0_{p+1})\). Sum them up for any \(t \in \{p+1 : T\}\) we finish the proof.

\[\square\]

EC.4. Proofs and Discussions from Section 3

In Section 3 we focus on the case when \(p = m\). Throughout this section in the appendix, we use only \(m\) instead of \(p\).

EC.4.1. Extra Notations Used in the Proofs from Section 3

For any \(t \in \{m+1 : T\}\), denote

\[
1_{t}(T, Y) = Y_{t}(1_{m+1}) \left[ \mathbb{1}_{W_{t-m:t} = (1_{m+1})} \cdot 2 \prod_{l=1}^{m} 2^{1_{t-l+1 \in T}} - 1 \right] - Y_{t}(0_{m+1}) \left[ \mathbb{1}_{W_{t-m:t} = (0_{m+1})} \cdot 2 \prod_{l=1}^{m} 2^{1_{t-l+1 \in T}} - 1 \right] \quad \text{(EC.1)}
\]

where we use \(2 \prod_{l=1}^{m} 2^{1_{t-l+1 \in T}}\) to calculate the inverse propensity score. When \(T\) and \(Y\) are clear from the context we omit them and use \(1_{t}\) for \(1_{t}(T, Y)\).

Using the above notation, we could re-write

\[
\hat{\tau}_{m} - \tau_{m} = \frac{1}{T - m} \sum_{t=m+1}^{T} 1_{t}(T, Y)
\]

Note that \(\forall t \in \{m+1, m+2, ..., T\}\),

\[
\mathbb{E}[1_{t}(T, Y)] = 0. \quad \text{(EC.2)}
\]

Recall that any regular switchback experiment can be represented by \(T = \{t_{0}, t_{1}, ..., t_{K}\} \subseteq [T]\). Define \(f_{T} : [T] \to T\) to be the “determining randomization point of period \(t\)”, i.e.

\[
f_{T}(t) = \max \{j | j \in T, j \leq t\}
\]

such that \(W_{f_{T}(t)}\) uniquely determines the distribution of \(W_{t}\), i.e. \(W_{t} = W_{f_{T}(t)}\). When \(T\) is clear from the context we also omit the subscript and use \(f(t)\) for \(f_{T}(t)\).
Similarly, we define $f^m_T(t) : [T] \to \{0,1\}^T$, which maps a time period to a subset of the set $T$, to be the “determining randomization points of periods $\{t - m, t - m + 1, ..., t\}$”, i.e.

$$f^m_T(t) = \{j \mid \exists i \in \{t - m, ..., t\}, \text{s.t.} j = f_T(i)\}$$

such that $f^m_T(t) \subseteq T \subseteq [T]$. And $f^m_T(t)$ contains all the time periods whose coin flips determine the distributions of $W_{t-m}, W_{t-m+1}, ..., W_t$. Denote $|f^m_T(t)| = J$. We keep in mind that $J$ depends on $m, t$ and $T$, yet they are all omitted for brevity. Since $W_{t-m}, W_{t-m+1}, ..., W_t$ are determined by at least one randomization point $f(t-m)$, we know that $f^m_T(t) \neq \emptyset$ is non-empty, i.e.,

$$|f^m_T(t)| = J \geq 1. \quad \text{(EC.3)}$$

Finally, define “overlapping randomization points of periods $\{t - m, t - m + 1, ..., t\}$ and $\{t' - m, t' - m + 1, ..., t'\}$” to be

$$O_T(t, t') = f^m_T(t) \cap f^m_T(t')$$

Denote $|O_T(t, t')| = J^o$. We keep in mind that $J^o$ depends on $m, t, t'$ and $T$, yet they are all omitted for brevity.

EC.4.2. Lemma 1] Adversarial Selection of Potential Outcomes

EC.4.2.1. Preliminaries. We first introduce two Lemmas for the proof of Lemma 1.

**Lemma EC.2.** Under Assumptions 2, 3 for any $t \in [T]$, let $|f^m_T(t)| = J$.

$$\mathbb{E}[1]^2 = (2^J - 1)\mathbb{E}(1_{m+1})^2 + 2\mathbb{E}(1_{m+1})\mathbb{E}(0_{m+1}) + (2^J - 1)\mathbb{E}(0_{m+1})^2. \quad \text{(EC.4)}$$

**Proof of Lemma EC.2.** Denote $|f^m_T(t)| = J$. Let the elements be $f^m_T(t) = \{u_1, u_2, ..., u_J\}$. Let $u_1 < u_2 < ... < u_J$.

Using the notations defined earlier in Section EC.4

$$\mathbb{E}[1]^2 = \mathbb{E}(W_{t-m, t} = 1_{m+1}) \cdot (2^{J} \cdot 1_{m+1} - Y_t(1_{m+1})(2^{J} \cdot 0_{m+1}))^2$$

$$+ \mathbb{E}(W_{t-m, t} = 0_{m+1}) \cdot (2^{J} \cdot 0_{m+1} - Y_t(0_{m+1})(2^{J} \cdot 1_{m+1}))^2$$

$$+ \mathbb{E}(W_{t-m, t} \neq 1_J \text{ or } 0_J) \cdot (2^{J} \cdot 0_{m+1} - Y_t(0_{m+1})(2^{J} \cdot 1_{m+1}))^2$$

$$= \mathbb{E}((W_{u_1}, ..., W_{u_J}) = 1_J) \cdot (2^{J} - 1)Y_t(1_{m+1} + Y_t(0_{m+1}))^2$$

$$+ \mathbb{E}((W_{u_1}, ..., W_{u_J}) = 0_J) \cdot (2^{J} - 1)Y_t(0_{m+1})^2$$

$$+ \mathbb{E}((W_{u_1}, ..., W_{u_J}) \neq 1_J \text{ or } 0_J) \cdot (2^{J} - 1)Y_t(1_{m+1} + Y_t(0_{m+1}))^2$$

$$= (2^{J} - 1)Y_t(1_{m+1})^2 + 2Y_t(1_{m+1})Y_t(0_{m+1}) + (2^{J} - 1)Y_t(0_{m+1})^2$$

which finishes the proof. \qed
LEMMA EC.3. Under Assumptions 3, for any \( t < t' \in [T] \), when \(|O_t(t, t')| = J^o = 0\),
\[
\mathbb{E}[1_t 1_{t'}] = 0.
\] (EC.5)

When \(|O_t(t, t')| = J^o \geq 1\),
\[
\mathbb{E}[1_t 1_{t'}] = (2^{J^o} - 1)Y_t(1_{m+1})Y_{t'}(1_{m+1}) + Y_t(0_{m+1})Y_{t'}(0_{m+1})
\]
\[+ Y_t(0_{m+1})Y_{t'}(1_{m+1}) + (2^{J^o} - 1)Y_t(0_{m+1})Y_{t'}(0_{m+1}). \] (EC.6)

Proof of Lemma EC.3. Denote \( |f_T^o(t)| = J, |f_T^o(t')| = J', \) and \(|O_t(t, t')| = J^o\). Let the elements be \( f_T^o(t) = \{u_1, u_2, ..., u_J\}, f_T^o(t') = \{u'_1, u'_2, ..., u'_{J'}\}, \) and \( O_T(t, t') = \{u_1^o, u_2^o, ..., u_{J^o}\}. \) Let \( u_1 < u_2 < \ldots < u_J, u'_1 < u'_2 < \ldots < u'_{J'}, \) and \( u_1^o < u_2^o < \ldots < u_{J^o}. \)

One time period could have different numberings in \( f_T^o(t), f_T^o(t'), \) and \( O_T(t, t'). \) For example, \( u_{J-J^o+1} = u'_1 = u_1^o, \) and \( u_J = u'_{J'} = u_{J^o}^o. \) See Table EC.1 for an illustrator of the determining randomization points and the overlapping randomization points.

<table>
<thead>
<tr>
<th>( u_1 )</th>
<th>( u_2 )</th>
<th>\ldots</th>
<th>( u_{J-J^o+1} )</th>
<th>\ldots</th>
<th>( u_J )</th>
</tr>
</thead>
</table>
| \( u'_1 \) | \( \ldots \) | \( u'_{J'} \) | \ldots | \( u'_{J^o+1} \) | \ldots | \( u'_{J'} \)

Each column stands for one time period. The first row stands for the determining randomization points of \( f_T^o(t); \) the second row for the overlapping randomization points of \( O_T(t, t'); \) and the third row for the determining randomization points of \( f_T^o(t'). \)

First, when \( J^o = 0 \), this implies that \( 1_t \) and \( 1_{t'} \) are independent. Then \( \mathbb{E}[1_t 1_{t'}] = \mathbb{E}[1_t] \mathbb{E}[1_{t'}] = 0, \) where the second equality is due to (EC.2).

When \( J^o \geq 1 \), this implies that \( 1_t \) and \( 1_{t'} \) are correlated. Using the notations defined above,
\[
\mathbb{E}[1_t 1_{t'}] = \mathbb{E}_{W_{u_1}^o, \ldots, W_{u_J}^o} \left[ \mathbb{E}_{W_{u_1}^o, \ldots, W_{u_J}^o} \left[ 1_t 1_{t'} \mid W_{u_1}^o, \ldots, W_{u_J}^o \right] \right] \]
\[
= \Pr \left( (W_{u_1}^o, \ldots, W_{u_J}^o) = 1_{J^o} \right) \mathbb{E}[1_t 1_{t'} \mid (W_{u_1}^o, \ldots, W_{u_J}^o) = 1_{J^o}]
\]
\[+ \Pr \left( (W_{u_1}^o, \ldots, W_{u_J}^o) = 0_{J^o} \right) \mathbb{E}[1_t 1_{t'} \mid (W_{u_1}^o, \ldots, W_{u_J}^o) = 0_{J^o}]
\]
\[+ \Pr \left( (W_{u_1}^o, \ldots, W_{u_J}^o) \neq 1_{J^o} \text{ or } 0_{J^o} \right) \mathbb{E}[1_t 1_{t'} \mid (W_{u_1}^o, \ldots, W_{u_J}^o) \neq 1_{J^o} \text{ or } 0_{J^o}]. \] (EC.7)

Next we go over the three cases of \( (W_{u_1}^o, \ldots, W_{u_J}^o) \) as decomposed above. Note that conditional on \( (W_{u_1}^o, \ldots, W_{u_J}^o), 1_t \text{ and } 1_{t'} \) are independent, i.e.,
\[
\mathbb{E}[1_t 1_{t'} \mid W_{u_1}^o, \ldots, W_{u_J}^o] = \mathbb{E}[1_t \mid W_{u_1}^o, \ldots, W_{u_J}^o] \mathbb{E}[1_{t'} \mid W_{u_1}^o, \ldots, W_{u_J}^o].\]
(1) With probability $1/2^j$, $(W_{u^j_1},...,W_{u^j_o}) = 1_{j^o}$, in which case

$$
\mathbb{E} \left[ 1_t \mid W_{u^j_1},...,W_{u^j_o} \right] = \Pr (W_{t-m:t} = 1_{m+1}) \cdot \left\{ Y_t(1_{m+1})(2^J \cdot 1 - 1) + Y_t(0_{m+1}) \right\} \\
+ \Pr (W_{t-m:t} \neq 1_{m+1}) \cdot \left\{ Y_t(1_{m+1})(2^J \cdot 0 - 1) + Y_t(0_{m+1}) \right\} \\
= \Pr \left( (W_{u^j_1},W_{u^j_2},...,W_{u^j_o}) = 1_{j^o} \right) \cdot \left\{ Y_t(1_{m+1})(2^J - 1) + Y_t(0_{m+1}) \right\} \\
+ \Pr \left( (W_{u^j_1},W_{u^j_2},...,W_{u^j_o}) \neq 1_{j^o} \right) \cdot \left\{ -Y_t(1_{m+1}) + Y_t(0_{m+1}) \right\} \\
= \frac{1}{2^{j^o}} \cdot \left\{ Y_t(1_{m+1})(2^J - 1) + Y_t(0_{m+1}) \right\} + \left( 1 - \frac{1}{2^{j^o}} \right) \cdot \left\{ -Y_t(1_{m+1}) + Y_t(0_{m+1}) \right\} \\
= (2^j - 1)Y_t(1_{m+1}) + Y_t(0_{m+1})
$$

where the third equality is due to (2). Similarly,

$$
\mathbb{E} \left[ 1_{t'} \mid W_{u^j_1},...,W_{u^j_o} \right] = \Pr (W_{t'-m':t'} = 1_{m+1}) \cdot \left\{ Y_{t'}(1_{m+1})(2^J' \cdot 1 - 1) + Y_{t'}(0_{m+1}) \right\} \\
+ \Pr (W_{t'-m':t'} \neq 1_{m+1}) \cdot \left\{ Y_{t'}(1_{m+1})(2^J' \cdot 0 - 1) + Y_{t'}(0_{m+1}) \right\} \\
= \Pr \left( (W_{u'^j_{j^o+1}},W_{u'^j_{j^o+2}},...,W_{u'^j_o}) = 1_{j^o} \right) \cdot \left\{ Y_{t'}(1_{m+1})(2^J' - 1) + Y_{t'}(0_{m+1}) \right\} \\
+ \Pr \left( (W_{u'^j_{j^o+1}},W_{u'^j_{j^o+2}},...,W_{u'^j_o}) \neq 1_{j^o} \right) \cdot \left\{ -Y_{t'}(1_{m+1}) + Y_{t'}(0_{m+1}) \right\} \\
= \frac{1}{2^{j^o}} \cdot \left\{ Y_{t'}(1_{m+1})(2^J' - 1) + Y_{t'}(0_{m+1}) \right\} + \left( 1 - \frac{1}{2^{j^o}} \right) \cdot \left\{ -Y_{t'}(1_{m+1}) + Y_{t'}(0_{m+1}) \right\} \\
= (2^j - 1)Y_{t'}(1_{m+1}) + Y_{t'}(0_{m+1})
$$

(2) With probability $1/2^j$, $(W_{u^j_1},...,W_{u^j_o}) = 0_{j^o}$, in which case

$$
\mathbb{E} \left[ 1_t \mid W_{u^j_1},...,W_{u^j_o} \right] = \Pr (W_{t-m:t} = 0_{m+1}) \cdot \left\{ -Y_t(1_{m+1}) - Y_t(0_{m+1})(2^J \cdot 1 - 1) \right\} \\
+ \Pr (W_{t-m:t} \neq 1_{m+1}) \cdot \left\{ -Y_t(1_{m+1}) - Y_t(0_{m+1})(2^J \cdot 0 - 1) \right\} \\
= \frac{1}{2^{j^o}} \cdot \left\{ -Y_t(1_{m+1}) - Y_t(0_{m+1})(2^J - 1) \right\} + \left( 1 - \frac{1}{2^{j^o}} \right) \cdot \left\{ -Y_t(1_{m+1}) + Y_t(0_{m+1}) \right\} \\
= -Y_t(1_{m+1}) - (2^j - 1)Y_t(0_{m+1})
$$

$$
\mathbb{E} \left[ 1_{t'} \mid W_{u^j_1},...,W_{u^j_o} \right] = \Pr (W_{t'-m':t'} = 0_{m+1}) \cdot \left\{ -Y_{t'}(1_{m+1}) - Y_{t'}(0_{m+1})(2^J' \cdot 1 - 1) \right\} \\
+ \Pr (W_{t'-m':t'} \neq 1_{m+1}) \cdot \left\{ -Y_{t'}(1_{m+1}) - Y_{t'}(0_{m+1})(2^J' \cdot 0 - 1) \right\} \\
= \frac{1}{2^{j^o}} \cdot \left\{ -Y_{t'}(1_{m+1}) - Y_{t'}(0_{m+1})(2^J' - 1) \right\} + \left( 1 - \frac{1}{2^{j^o}} \right) \cdot \left\{ -Y_{t'}(1_{m+1}) + Y_{t'}(0_{m+1}) \right\} \\
= -Y_{t'}(1_{m+1}) - (2^j - 1)Y_{t'}(0_{m+1})
$$

(3) With probability $1 - 2 \cdot (1/2^j)$, $(W_{u^j_1},...,W_{u^j_o}) \neq 1_{j^o}$ or $0_{j^o}$, in which case

$$
\mathbb{E} \left[ 1_t \mid W_{u^j_1},...,W_{u^j_o} \right] = -Y_t(1_{m+1}) + Y_t(0_{m+1})
$$

$$
\mathbb{E} \left[ 1_{t'} \mid W_{u^j_1},...,W_{u^j_o} \right] = -Y_{t'}(1_{m+1}) + Y_{t'}(0_{m+1})
$$
Finally, putting all above together into (EC.7), we have

\[
\mathbb{E}[\mathbf{1}_t \mathbf{1}_{t'}] = \frac{1}{2 \rho_o} \cdot \left\{ (2^\rho_o - 1)Y_t(1_{m+1}) + Y_t(0_{m+1}) \right\} \cdot \left\{ (2^\rho_o - 1)Y_{t'}(1_{m+1}) + Y_{t'}(0_{m+1}) \right\} \\
+ \frac{1}{2} \cdot \left\{ -Y_t(1_{m+1}) - (2^\rho_o - 1)Y_t(0_{m+1}) \right\} \cdot \left\{ -Y_{t'}(1_{m+1}) - (2^\rho_o - 1)Y_{t'}(0_{m+1}) \right\} \\
+ \left\{ 1 - \frac{2}{2^\rho_o} \right\} \cdot \left\{ -Y_t(1_{m+1}) + Y_t(0_{m+1}) \right\} \cdot \left\{ -Y_{t'}(1_{m+1}) + Y_{t'}(0_{m+1}) \right\} \\
= (2^\rho_o - 1)Y_t(1_{m+1})Y_{t'}(1_{m+1}) + Y_t(1_{m+1})Y_t(0_{m+1}) + Y_t(0_{m+1})Y_{t'}(1_{m+1}) + (2^\rho_o - 1)Y_t(0_{m+1})Y_{t'}(0_{m+1})
\]

which finishes the proof. \(\Box\)

EC.4.2.2. Proof of Lemma 1. The proof of Lemma 1 is through careful expansion of the risk function, the expected square loss.

Proof of Lemma 1. From Lemma EC.2 and Lemma EC.3, all the terms are quadratic, and all the coefficients are non-negative. That is, after multiplying the constant \((T - m)^2\), for any \(T \in [T], \forall \in \mathcal{Y}\) we can express in canonical form the following:

\[
(T - m)^2 \cdot \mathbb{E}_{W_1 \sim \eta(\cdot)} \left[ (\hat{\tau}_m(W_{1:T}, \forall) - \tau_m(\forall))^2 \right] \\
= \sum_{t = m + 1}^{T} \{ a_t(11) Y_t(1_{m+1})^2 + a_t(10) Y_t(1_{m+1}) Y_t(0_{m+1}) + a_t(00) Y_t(0_{m+1})^2 \} \\
+ \sum_{m + 1 \leq t < t' \leq T} \{ b_{tt'}(11) Y_t(1_{m+1}) Y_{t'}(1_{m+1}) + b_{tt'}(10) Y_t(1_{m+1}) Y_{t'}(0_{m+1}) \}
+ \sum_{m + 1 \leq t < t' \leq T} \{ b_{tt'}(01) Y_t(0_{m+1}) Y_{t'}(1_{m+1}) + b_{tt'}(00) Y_t(0_{m+1}) Y_{t'}(0_{m+1}) \}
\]

Combining Lemma EC.2 and inequality EC.3, \(a_t(11), a_t(10), a_t(00)\) are all strictly positive. From Lemma EC.3 \(b_{tt'}(11), b_{tt'}(10), b_{tt'}(01), b_{tt'}(00)\) are all non-negative.

For the squared terms, \(y^2 \leq B^2\), where the inequality is due to convexity. For the cross-product terms, \(y_1 \cdot y_2 \leq (y_1^2 + y_2^2)/2 \leq B^2\) where the first inequality is due to Cauchy-Schwarz, and the second inequality is due to convexity. Combining that fact that all coefficients are non-negative, \(r(\eta_T, \forall) \leq r(\eta_T, \forall^+) = r(\eta_T, \forall^-)\).

Moreover, for any \(\forall \in \mathcal{Y}\) such that \(\forall \neq \forall^+\) or \(\forall^-\), if \(\exists t \in \{m + 1, \ldots, T\}\) such that \(-B < Y_t(1_{m+1}) < B\). Then from inequality EC.3, \(a_t(11) > 0\), so the inequality is strict. Similarly, if \(\exists t \in \{m + 1, \ldots, T\}\) such that \(-B < Y_t(0_{m+1}) < B\), then combine \(a_t(00) > 0\), so the inequality is strict. \(\Box\)

EC.4.2.3. Implications of Lemma 1. Lemma 1 simplifies the minimax problem in (6). Instead of thinking it as a minimax problem, we can now replace \(\forall\) by either \(\forall^+\) or \(\forall^-\), and solve only a minimization problem.

Here we state Lemma EC.4 that is a direct implication of Lemma 1. It will be frequently used later on.
Lemma EC.4. When $Y = Y^+$ or $Y = Y^-$, under Assumptions 2, 3 for any $t \in [T]$,

$$E[1^2] = 2^{J+1}B^2.$$  

For any $t < t' \in [T]$, when $|O_T(t, t')| = J^o = 0$,

$$E[1_1 1_{t'}] = 0$$

When $|O_T(t, t')| = J^o \geq 1$,

$$E[1_1 1_{t'}] = 2^{J^o + 1}B^2$$

Proof of Lemma EC.4. Replace $Y_t(1_{m+1}) = Y_t(0_{m+1})$ by $B$ or $-B$, into the expressions in Lemmas EC.2 and EC.3. □

EC.4.3. Structural Results of the Optimal Design

First note that when we focus on the optimal design, we treat $T$ and $m$ both as constants. So the constant of $1/(T - m)$ in the expression of the risk function does not affect the optimal design.

Proof of Lemma 2. We prove the two parts separately, both by contradiction.

(1) Suppose there exists an optimal design $T = \{t_0 = 1, t_1, t_2, ..., t_K\}$ such that $t_1 \leq m + 1$. Then we try to construct another design $\tilde{T}$, such that $|\tilde{T}| = K = |T| - 1$. And the $K$ elements are $\tilde{T} = \{\tilde{t}_0 = 1, \tilde{t}_1 = t_2, \tilde{t}_2 = t_3, ..., \tilde{t}_{K-1} = t_K\}$.

Table EC.2 An example of two regular switchback experiments $T$ and $\tilde{T}$ when $m = 4$ and $t_1 = 3$.

<table>
<thead>
<tr>

</tr>
</tbody>
</table>

Each checkmark beneath a number indicates that this number is within that set; and each dash beneath a number indicates that this number is not within that set. For example, the checkmark ✓ beneath number 3 indicates that $3 \in T$; and the dash – beneath number 3 indicates that $3 \notin T$.

Next we argue that when $Y = Y^+$ or $Y = Y^-$,

$$r(T, Y) > r(\tilde{T}, Y),$$

which suggests that $T$ is not the optimal design.

First, focus on the squared terms. For any $m + 1 \leq t \leq t_1 + m - 1$, $t_1 \in f^m_T(t)$, $t_1 \neq f^m_T(t)$. Moreover, $t - m \leq t_1 - 1$, so that $t_0 \in f^m_T(t)$. So $f^m_T(t) - \{t_1\} = f^m_T(t)$, and $|f^m_T(t)| \geq 1$. As a result,

$$E[1_t(\tilde{T})^2] - E[1_t(\tilde{T})^2] \geq (2^{2+1} - 2^{1+1})B^2 = 4B^2.$$
For any \( t \geq t_1 + m \), either (i) \( f_T(t - m) = t_1 \), in which case \( f_{\tilde{T}}(t - m) = t_0 \). This is the only difference between \( f^n_T(t) \) and \( f^n_{\tilde{T}}(t) \), i.e., \( f^n_T(t) - \{ t_1 \} = f^n_{\tilde{T}}(t) - \{ t_0 \} \). So \( |f^n_T(t)| = |f^n_{\tilde{T}}(t)| \). The second case is (ii) \( f_T(t - m) \geq t_2 \), in which case \( f^n_T(t) = f^n_{\tilde{T}}(t) \). Both cases suggest that
\[
E[I_t(T)]^2 - E[I_t(\tilde{T})]^2 = 0.
\]

So we have
\[
\sum_{t = m + 1}^{T} E[I_t(T)]^2 - \sum_{t = m + 1}^{T} E[I_t(\tilde{T})^2] = \sum_{t = m + 1}^{t_1 + m - 1} \left( E[I_t(T)]^2 - E[I_t(\tilde{T})^2] \right) + \sum_{t = t_1 + m}^{T} \left( E[I_t(T)]^2 - E[I_t(\tilde{T})^2] \right) \\
\geq \sum_{t = m + 1}^{t_1 + m - 1} (4B^2) + 0 \\
= 4(t_1 - 1)B^2 > 0.
\]

Second, focus on the cross product terms. For any \( t \) and \( t' \) such that \( m + 1 \leq t < t' \leq t_1 + m - 1 \), \( t_1 \in O_T(t, t'), t_1 \neq O_{\tilde{T}}(t, t') \). Moreover, \( t - m \leq t_1 - 1 \), so that \( t_0 \in O_T(t, t') \). So \( O_T(t, t') - \{ t_1 \} = O_{\tilde{T}}(t, t') \), and \( |O_T(t, t')| \geq 1 \). As a result,
\[
E[I_t(T)I_{t'}(T)] - E[I_t(\tilde{T})I_{t'}(\tilde{T})] \geq (2^{2+1} - 2^{1+1})B^2 = 4B^2 > 0.
\]

For any \( m + 1 \leq t < t' \leq T \) such that \( t' \geq t_1 + m \), either (i) \( f_T(t' - m) = t_1 \), in which case \( f_{\tilde{T}}(t' - m) = t_0 \). So \( O_T(t, t') - \{ t_1 \} = O_{\tilde{T}}(t, t') - \{ t_0 \} \). So \( |O_T(t, t')| = |O_{\tilde{T}}(t, t')| \). The second case is (ii) \( f_T(t' - m) \geq t_2 \), in which case \( O_T(t, t') = O_{\tilde{T}}(t, t') \). Both cases suggest that
\[
E[I_t(T)I_{t'}(T)] - E[I_t(\tilde{T})I_{t'}(\tilde{T})] = 0.
\]

So we have
\[
\sum_{m + 1 \leq t < t' \leq T} E[I_t(T)I_{t'}(T)] - \sum_{m + 1 \leq t < t' \leq T} E[I_t(\tilde{T})I_{t'}(\tilde{T})] \\
= \sum_{m + 1 \leq t < t' \leq t_1 + m - 1} \left( E[I_t(T)I_{t'}(T)] - E[I_t(\tilde{T})I_{t'}(\tilde{T})] \right) + \sum_{m + 1 \leq t < t' \leq T} \left( E[I_t(T)I_{t'}(T)] - E[I_t(\tilde{T})I_{t'}(\tilde{T})] \right) \\
\geq 0.
\]

Combine both square terms and cross-product terms we know that
\[
r(T, Y) > r(\tilde{T}, Y).
\]

(2) Suppose there exists an optimal design \( T = \{ t_0 = 1, t_1, t_2, ..., t_K \} \) such that \( t_K \geq T - m + 1 \). Then we try to construct another design \( \tilde{T} \), such that \( |\tilde{T}| = K = |T| - 1 \). And the \( K \) elements are \( \tilde{T} = \{ \tilde{t}_0 = 1, \tilde{t}_1 = t_1, \tilde{t}_2 = t_2, ..., \tilde{t}_{K-1} = t_{K-1} \} \).
Table EC.3  An example of two regular switchback experiments $T$ and $\tilde{T}$ when $m = 4$ and $t_K = T - 2$.

<table>
<thead>
<tr>
<th></th>
<th>$T - 5$</th>
<th>$T - 4$</th>
<th>$T - 3$</th>
<th>$T - 2$</th>
<th>$T - 1$</th>
<th>$T$</th>
</tr>
</thead>
<tbody>
<tr>
<td>$T$</td>
<td>...</td>
<td>✓</td>
<td>−</td>
<td>✓</td>
<td>✓</td>
<td>−</td>
</tr>
<tr>
<td>$\tilde{T}$</td>
<td>...</td>
<td>✓</td>
<td>−</td>
<td>✓</td>
<td>−</td>
<td>−</td>
</tr>
</tbody>
</table>

Each checkmark beneath a number indicates that this number is within that set; and each dash beneath a number indicates that this number is not within that set. For example, the checkmark ✓ beneath number $T - 2$ indicates that $T - 2 \in T$; and the dash − beneath number $T - 2$ indicates that $T - 2 \notin \tilde{T}$.

Next we argue that when $Y = Y^+$ or $Y = Y^-$,

$$r(T, Y) > r(\tilde{T}, Y),$$

which suggests that $T$ is not the optimal design.

First focus on the squared terms. For any $m + 1 \leq t \leq t_K - 1$, $f_{\tilde{T}}^m(t) = f_T^m(t)$ is totally unchanged.

$$\mathbb{E}[\mathbbm{1}_t(T)^2] - \mathbb{E}[\mathbbm{1}_t(\tilde{T})^2] = 0.$$  

For any $t_K \leq t \leq T$, $t_K \notin f_{\tilde{T}}^m(t), t_K \in f_T^m(t)$. And all the other determining randomization points are unchanged. So $f_{\tilde{T}}^m(t) \subset f_T^m(t)$ and $f_{\tilde{T}}^m(t) - \{t_K\} = f_T^m(t)$ and $|f_{\tilde{T}}^m(t)| \geq 1$.

$$\mathbb{E}[\mathbbm{1}_t(T)^2] - \mathbb{E}[\mathbbm{1}_t(\tilde{T})^2] \geq (2^{2+1} - 2^{1+1})B^2 = 4B^2.$$  

So we have

$$\sum_{t=m+1}^{T} \mathbb{E}[\mathbbm{1}_t(T)^2] - \sum_{t=m+1}^{T} \mathbb{E}[\mathbbm{1}_t(\tilde{T})^2] = \sum_{t=m+1}^{t_K-1} \left( \mathbb{E}[\mathbbm{1}_t(T)^2] - \mathbb{E}[\mathbbm{1}_t(\tilde{T})^2] \right) + \sum_{t=t_K}^{T} \left( \mathbb{E}[\mathbbm{1}_t(T)^2] - \mathbb{E}[\mathbbm{1}_t(\tilde{T})^2] \right)$$

$$\geq \sum_{t=t_K}^{T} (4B^2) + 0$$

$$= 4(T - t_K + 1)B^2$$

$$> 0$$

Next we focus on the cross-product terms. For any $m + 1 \leq t < t' \leq T$ such that $t \leq t_K - 1$, $O_T(t, t') = O_{\tilde{T}}(t, t')$ is totally unchanged.

$$\mathbb{E}[\mathbbm{1}_t(T)\mathbbm{1}_{t'}(T)] - \mathbb{E}[\mathbbm{1}_t(\tilde{T})\mathbbm{1}_{t'}(\tilde{T})] = 0.$$  

For any $t_K \leq t < t' \leq T$, since $t' - m \leq T - m \leq t_K - 1$, so $f_{\tilde{T}}(t' - m) < t_K$ and $|O_{\tilde{T}}(t, t')| \geq 1$ must contain an element. Moreover, $O_{\tilde{T}}(t, t') \in O_{\tilde{T}}(t', t')$. So

$$\mathbb{E}[\mathbbm{1}_t(T)\mathbbm{1}_{t'}(T)] - \mathbb{E}[\mathbbm{1}_t(\tilde{T})\mathbbm{1}_{t'}(\tilde{T})] \geq (2^{2+1} - 2^{1+1})B^2 \geq 4B^2 > 0.$$
So we have
\[
\sum_{m+1 \leq t < t' \leq T} E[1_t(T)1_{t'}(T)] - \sum_{m+1 \leq t < t' \leq T} E[1_t(\tilde{T})1_{t'}(\tilde{T})] = \sum_{m+1 \leq t < t' \leq T} \left( E[1_t(T)1_{t'}(T)] - E[1_t(\tilde{T})1_{t'}(\tilde{T})] \right) \geq 0
\]

Combine both square terms and cross-product terms we know that
\[
r(T, Y) > r(\tilde{T}, Y).
\]

\[\square\]

**EC.4.3.2. Proof of Lemma 3.**

Proof of Lemma 3. Recall that we denote \( t_0 = 1 \) and \( t_{K+1} = T + 1 \). First, from Lemma 2, \( t_1 \geq m + 2 \), \( t_{K} \leq T - m \). So \( k = 1 \) and \( k = K \) cases both hold. Next, when \( 2 \leq k \leq K - 1 \), we prove by contradiction.

Suppose there exists some optimal design \( T \), such that \( \exists 2 \leq k \leq K - 1, \text{s.t.} t_{k+1} - t_{k-1} \leq m - 1 \). Denote
\[
\mathbb{K} = \{ k \in \{2 : K - 1\} | t_{k+1} - t_{k-1} \leq m - 1 \}.
\]

Since \( \mathbb{K} \neq \emptyset \), pick \( j = \max \mathbb{K} \) to be the largest element in \( \mathbb{K} \). Apparently \( j \leq K - 1 \) since \( j \in \{2 : K - 1\} \). We also know that \( t_{j+2} \geq t_j + m \), because otherwise \( j + 1 \in \mathbb{K} \), which contradicts the maximality of \( j \).

We now construct another design \( \tilde{T} \) such that \( |\tilde{T}| = |T| - 1 \), and the \( K \) elements are \( \tilde{T} = \{ \tilde{t}_0 = 1, \tilde{t}_1 = t_1, \ldots, \tilde{t}_{j-1} = t_{j-1}, \tilde{t}_j = t_{j+1}, \ldots, \tilde{t}_{K-1} = t_K \} \).

| Table EC.4 | An example of two regular switchback experiments \( T \) and \( \tilde{T} \) when \( m = 4 \) and \( t_j = t_{j+1} - 1 = t_{j+2} \). |
|-----|-----|-----|-----|-----|-----|-----|-----|
| \( T \) | \( t_{j-1} \) | \( t_{j-1} + 1 \) | \( t_j \) | \( t_{j+1} \) | \( t_{j+1} + 2 \) | \( t_{j+2} \) | \( ... \) |
| \( \tilde{T} \) | \( ... \) | \( \checkmark \) | \( - \) | \( \checkmark \) | \( - \) | \( - \) | \( \checkmark \) |

Each checkmark beneath a number indicates that this number is within that set; and each dash beneath a number indicates that this number is not within that set. For example, the checkmark \( \checkmark \) beneath number \( t_j \) indicates that \( t_j \in T \); and the dash \( - \) beneath number \( t_j \) indicates that \( t_j \notin \tilde{T} \).

Next we argue that when \( Y = Y^+ \) or \( Y = Y^- \),
\[
r(T, Y) > r(\tilde{T}, Y),
\]
which suggests that \( T \) is not the optimal design.
First focus on the squared terms. When $t \leq t_j - 1$, $f_T^n(t) = f_T^n(t)$ is totally unchanged.

$$E[1_t(T)^2] - E[1_t(\tilde{T})^2] = 0.$$ 

When $t_j \leq t \leq t_j + m - 1$, this suggests that $t - m \leq t_j - 1$ so that $f_T(t) \leq f_T(t_j)$. So $f_T(t) \not\in f_T^n(t_j)$. And all the other determining randomization points are unchanged. So $f_T^n(t) \subseteq f_T^n(t_j)$ and $f_T^n(t_j \setminus \{t_j\}) = f_T^n(t_j)$ and $|f_T^n(t_j)| \geq 1$.

$$E[1_t(T)^2] - E[1_t(\tilde{T})^2] \geq (2^{2+1} - 2^{1+1})B^2 = 4B^2.$$ 

When $t_j + m \leq t \leq T$, either (i) $f_T(t - m) = t_j$, in which case $f_T(t - m) = t_{j-1}$. This is the only difference between $f_T^n(t)$ and $f_T^n(t)$, i.e., $f_T^n(t) \setminus \{t_j\} = f_T^n(t - m) \setminus \{t_{j-1}\}$. So $|f_T^n(t)| = |f_T^n(t)|$. The second case is (ii) $f_T(t - m) \geq t_j + 1$, in which case $f_T^n(t) = f_T^n(t)$. Both cases suggest that

$$E[1_t(T)^2] - E[1_t(\tilde{T})^2] = 0.$$

So we have

$$\sum_{t=m+1}^{T} E[1_t(T)^2] - \sum_{t=m+1}^{T} E[1_t(\tilde{T})^2] = \sum_{t=m+1}^{t_j-1} \left( E[1_t(T)^2] - E[1_t(\tilde{T})^2] \right) + \sum_{t=t_j}^{t_j+m-1} \left( E[1_t(T)^2] - E[1_t(\tilde{T})^2] \right) + \sum_{t=t_j+m}^{T} \left( E[1_t(T)^2] - E[1_t(\tilde{T})^2] \right) \geq 0 + \sum_{t=t_j}^{t_j+m-1} (4B^2) + 0 = 4(m-1)B^2 > 0$$

Next we focus on the cross-product terms. Let $m + 1 \leq t < t' \leq T$. There are many cases which we summarize in Table EC.5.

**Table EC.5** Summary of the differences between cross-product terms under two regular switchback experiments $T$ and $\tilde{T}$.

</tbody>
</table>

We explain Table EC.5.
When \( m + 1 \leq t \leq t_{j-1}, t < t' \leq T \), all the overlapping randomization points are earlier than \( t_{j-1} - 1 \), i.e., \( \forall a \in O_{\bar{T}}(t,t'), a \leq t_{j-1} - 1; \forall a \in O_{\bar{\bar{T}}}(t,t'), a \leq t_{j-1} - 1 \). So \( t_j \notin O_{\bar{T}}(t,t') \), and the overlapping randomization points are unchanged, i.e., \( O_{\bar{T}}(t,t') = O_{\bar{\bar{T}}}(t,t') \).

When \( t_{j-1} \leq t \leq t_j - 1, t < t' \leq t_j + m - 1 \), all the overlapping randomization points are earlier than \( t_{j-1} \), i.e., \( \forall a \in O_{\bar{T}}(t,t'), a \leq t_{j-1}; \forall a \in O_{\bar{\bar{T}}}(t,t'), a \leq t_{j-1} \). So \( t_j \notin O_{\bar{T}}(t,t') \), and the overlapping randomization points are unchanged, i.e., \( O_{\bar{T}}(t,t') = O_{\bar{\bar{T}}}(t,t') \).

When \( t_{j-1} \leq t \leq t_j - 1, t_j + m \leq t' \leq t_{j+1} + m - 1 \), changing from \( T \) to \( \tilde{T} \) increases the expected values. This is because \( t' - m \geq t_j > t \). So first, \( O_{\bar{T}}(t,t') = \emptyset \). But \( f_{\bar{T}}(t' - m) = t_{j-1} \) and \( t_{j-1} \in f_{\bar{T}}^m(t) \), which suggests that \( t_{j-1} \in O_{\bar{\bar{T}}}(t,t') \). Also, \( \forall a \in f_{\bar{T}}^m(t'), a \geq t_{j-1}; \forall a \in f_{\bar{T}}^m(t), a \leq t_{j-1} \), which suggests that \( t_{j-1} \) is the only overlapping element. So, \( O_{\bar{\bar{T}}}(t,t') = \{ t_{j-1} \} \). In this case,

\[
E[1_{\bar{T}}(T)1_{t'}(\bar{T})] - E[1_{\bar{T}}(\tilde{T})1_{t'}(\tilde{T})] = (0 - 2^{1+1})B^2 = -4B^2.
\]

When \( t_{j-1} \leq t \leq t_j - 1, t_j + m \leq t' \leq T \), since \( t' - m \geq t_{j+1} > t \), \( O_{\bar{T}}(t,t') = O_{\bar{\bar{T}}}(t,t') = \emptyset \).

When \( t_j \leq t < t' \leq t_j + m - 1 \), \( t_j \in O_{\bar{T}}(t,t') \) and \( t_j \notin O_{\bar{\bar{T}}}(t,t') \). And all the other overlapping randomization points are unchanged, so \( O_{\bar{T}}(t,t') - \{ t_j \} = O_{\bar{\bar{T}}}(t,t') \) and \( |O_{\bar{\bar{T}}}(t,t')| \geq 1 \). In this case,

\[
E[1_{\bar{T}}(T)1_{t'}(\bar{T})] - E[1_{\bar{T}}(\tilde{T})1_{t'}(\tilde{T})] \geq (2^{2+1} - 2^{1+1})B^2 = 4B^2.
\]

When \( t_j \leq t \leq t_j + m - 1, t_j + m \leq t' \leq T \), either (i) \( f_{\bar{T}}^m(t' - m) = t_j \), in which case \( f_{\bar{T}}(t' - m) = t_{j-1} \). This is the only difference between \( O_{\bar{T}}(t,t') \) and \( O_{\bar{\bar{T}}}(t,t') \), i.e., \( O_{\bar{T}}(t,t') - \{ t_j \} = O_{\bar{\bar{T}}}(t,t') - \{ t_{j-1} \} \). \(|O_{\bar{T}}(t,t')| = |O_{\bar{\bar{T}}}(t,t')|\). The second case is (ii) \( f_{\bar{T}}(t' - m) \geq t_{j+1} \), in which case \( O_{\bar{T}}(t,t') = O_{\bar{\bar{T}}}(t,t') \) is unchanged. Both cases suggest that \( E[1_{\bar{T}}(T)1_{t'}(\bar{T})] - E[1_{\bar{T}}(\tilde{T})1_{t'}(\tilde{T})] = 0 \).

When \( t_j + m \leq t < t' \leq T \), either (i) \( f_{\bar{T}}^m(t' - m) = t_j \), in which case \( f_{\bar{T}}(t' - m) = t_{j-1} \). This is the only difference between \( O_{\bar{T}}(t,t') \) and \( O_{\bar{\bar{T}}}(t,t') \), i.e., \( O_{\bar{T}}(t,t') - \{ t_j \} = O_{\bar{\bar{T}}}(t,t') - \{ t_{j-1} \} \). \(|O_{\bar{T}}(t,t')| = |O_{\bar{\bar{T}}}(t,t')|\). The second case is (ii) \( f_{\bar{T}}(t' - m) \geq t_{j+1} \), in which case \( O_{\bar{T}}(t,t') = O_{\bar{\bar{T}}}(t,t') \) is unchanged. Both cases suggest that \( E[1_{\bar{T}}(T)1_{t'}(\bar{T})] - E[1_{\bar{T}}(\tilde{T})1_{t'}(\tilde{T})] = 0 \).

So we have

\[
\sum_{t+1 \leq t' \leq T} E[1_{\bar{T}}(T)1_{t'}(\bar{T})] - \sum_{t+1 \leq t' \leq T} E[1_{\bar{T}}(\tilde{T})1_{t'}(\tilde{T})] = \sum_{t_{j-1} \leq t' \leq t_j - 1} \left( E[1_{\bar{T}}(T)1_{t'}(\bar{T})] - E[1_{\bar{T}}(\tilde{T})1_{t'}(\tilde{T})] \right) + \sum_{t_j \leq t' \leq t_{j+1} + m - 1} \left( E[1_{\bar{T}}(T)1_{t'}(\bar{T})] - E[1_{\bar{T}}(\tilde{T})1_{t'}(\tilde{T})] \right)
\]

\[
\geq \sum_{t_{j-1} \leq t' \leq t_j - 1} (-4B^2) + \sum_{t_j \leq t' \leq t_{j+1} + m - 1} (4B^2)
\]

\[
= -(t_j - t_{j-1})(t_{j+1} - t_j)4B^2 + \frac{m(m-1)}{2}4B^2
\]

\[
\geq 0
\]
where the last inequality is because \( j \in \mathbb{K}, t_{j+1} - t_{j-1} \leq m - 1 \), so \( (t_j - t_{j-1})(t_{j+1} - t_j) \leq \frac{(m-1)^2}{4} \leq \frac{m(m-1)}{2} \).

Combine both square terms and cross-product terms we know that
\[
 r(T, \mathcal{Y}) > r(\mathcal{T}', \mathcal{Y}).
\]

\( \square \)

**EC.4.4. Proof of Theorem 2**

**Proof of Theorem 2.** Think of \( E[1^2] \) as \( E[1,1] \), so that
\[
 r(\eta_T, \mathcal{Y}) = \sum_{t=m+1}^{T} \sum_{t' = m+1}^{T} E[1,1].
\]

Then we can decompose the risk function to be
\[
 (T-m)^2 \cdot r(\eta_T, \mathcal{Y}) = \sum_{m+1 \leq t,t' \leq T} E[1,1] + \sum_{k=1}^{K-1} \left( \sum_{t_k \leq t,t' \leq T} E[1,1] \right) + \sum_{t_K \leq t,t' \leq T} E[1,1].
\]

(EC.8)

The core of this proof is to carefully count how many values can each \( E[1,1] \), \( \forall t,t' \in \{m+1:T\} \) take. See Table EC.6 for an illustration.

</table>

In the second line, each checkmark beneath number \( t \) indicates that period \( t \in T \), i.e. there is a randomization point at period \( t \). This table illustrates different values of \( E[1,1] \) when \( t,t' \in \{m+1,T\} \), where the zero values are omitted. The \( B^2 \) magnitudes are also omitted.

First we calculate the first block from equation [EC.8]. Because \( t_1 \geq m + 2 \), for any \( t,t' \) such that \( m + 1 \leq \min\{t,t'\} \leq t_1 - 1 \), \( m + 1 \leq \max\{t,t'\} \leq t_1 + m - 1 \), we know that the only overlapping
randomization point is \( t_0 \). So \( E[\mathbb{1}_t \mathbb{1}_{t'}] = 4B^2 \). For any \( t, t' \) such that \( m + 1 \leq \min\{t, t'\} \leq t_1 - 1 \), \( t_1 + m \leq \max\{t, t'\} \leq T \), there is no overlapping randomization point so \( E[\mathbb{1}_t \mathbb{1}_{t'}] = 0 \).

\[
\sum_{\substack{m+1 \leq t, t' \leq T \\quad \min\{t, t'\} \leq t_1 - 1}} E[\mathbb{1}_t \mathbb{1}_{t'}] = B^2 \left( 4 \cdot ((t_1 - 1)^2 - m^2) \right)
\]

Then we calculate the second block from equation (EC.8). For any \( k \in [K - 1] \), consider \( t_k - t_{k-1} \) and \( t_{k+1} - t_k \), which jointly determine the values of \( E[\mathbb{1}_t \mathbb{1}_{t'}] \) for any \( t, t' \), such that \( t_k \leq \min\{t, t'\} \leq t_{k+1} - 1 \) and \( t_k \leq \max\{t, t'\} \leq T \). We will go over each of the four cases below.

1. When \( t_k - t_{k-1} \geq m, t_{k+1} - t_k \geq m \). Due to Lemma [EC.4] for all \( t, t' \in \{t_k : t_k + m - 1\} \), \( E[\mathbb{1}_t \mathbb{1}_{t'}] = 8B^2 \), because both \( t_{k-1} \leq t - m \leq t_k - 1 \) and \( t_{k-1} \leq t' - m \leq t_k - 1 \), and both \( t_{k-1} \) and \( t_k \) are overlapping randomization points. For all \( t, t' \) such that \( t_k \leq \min\{t, t'\} \leq t_{k+1} - 1 \) and \( t_k + m \leq \max\{t, t'\} \leq t_{k+1} + m - 1 \), \( E[\mathbb{1}_t \mathbb{1}_{t'}] = 4B^2 \), because \( t_k \leq \min\{t, t'\} \leq t_{k+1} - 1 \) and \( t_k \leq \max\{t, t'\} - m \leq t_{k+1} - 1 \) so only \( t_k \) is the overlapping randomization point. For all \( t, t' \) such that \( t_k \leq \min\{t, t'\} \leq t_{k+1} - 1 \) and \( t_{k+1} + m \leq \max\{t, t'\} \leq T \), \( E[\mathbb{1}_t \mathbb{1}_{t'}] = 0 \).

In this case,

\[
\sum_{\substack{t_k \leq t, t' \leq T \\quad \min\{t, t'\} \leq t_{k+1} - 1}} E[\mathbb{1}_t \mathbb{1}_{t'}] = B^2 \left( 8 \cdot m^2 + 4 \cdot ((m + t_{k+1} - t_k)^2 - 2m^2) \right)
\]

2. When \( t_k - t_{k-1} \geq m, t_{k+1} - t_k < m \). Due to Lemma [EC.4] for all \( t, t' \) such that \( t_k \leq \min\{t, t'\} \leq t_{k+1} - 1 \), \( t_k \leq \max\{t, t'\} \leq t_{k+1} + m - 1 \), \( E[\mathbb{1}_t \mathbb{1}_{t'}] = 8B^2 \), because both \( t_{k-1} \leq t - m \leq t_k - 1 \) and \( t_{k-1} \leq t' - m \leq t_k - 1 \), and both \( t_{k-1} \) and \( t_k \) are overlapping randomization points. For all \( t, t' \) such that \( t_k \leq \min\{t, t'\} \leq t_{k+1} - 1 \) and \( t_k + m \leq \max\{t, t'\} \leq t_{k+1} + m - 1 \), \( E[\mathbb{1}_t \mathbb{1}_{t'}] = 4B^2 \), because \( t_k \leq \min\{t, t'\} \leq t_{k+1} - 1 \) and \( t_k \leq \max\{t, t'\} - m \leq t_{k+1} - 1 \) so only \( t_k \) is the overlapping randomization point. For all \( t, t' \) such that \( t_k \leq \min\{t, t'\} \leq t_{k+1} - 1 \) and \( t_{k+1} + m \leq \max\{t, t'\} \leq T \), \( E[\mathbb{1}_t \mathbb{1}_{t'}] = 0 \).

In this case,

\[
\sum_{\substack{t_k \leq t, t' \leq T \\quad \min\{t, t'\} \leq t_{k+1} - 1}} E[\mathbb{1}_t \mathbb{1}_{t'}] = B^2 \left( 8 \cdot (m^2 - (m - t_{k+1} + t_k)^2) + 4 \cdot ((m + t_{k+1} - t_k)^2 - 2m^2 + (m - t_{k+1} - t_k)^2) \right)
\]

3. When \( t_k - t_{k-1} < m, t_{k+1} - t_k \geq m \). Due to Lemma [EC.4] for all \( t, t' \in \{t_k : t_k + m - 1\} \), \( E[\mathbb{1}_t \mathbb{1}_{t'}] = 16B^2 \), because \( t - m \leq t_{k-1} - 1 \leq t_k \leq t \) and \( t' - m \leq t_{k-1} - 1 \leq t_k \leq t' \) so \( t_{k-2}, t_{k-1}, t_k \) are three determining randomization points. Also \( t_k - t_{k-2} \geq m \) so \( t_{k-2} \leq \min\{t, t'\} - m \) and \( t_{k-3} \) is not a determining randomization point. For all \( t, t' \) such that \( t_k \leq \min\{t, t'\} \leq t_k + m - 1, t_{k-1} + m \leq \max\{t, t'\} \leq t_k + m - 1 \), \( E[\mathbb{1}_t \mathbb{1}_{t'}] = 8B^2 \), because \( \min\{t, t'\} - m \leq t_k - 1 \) and \( t_{k-1} \leq \max\{t, t'\} - m \leq t_k - 1 \) so \( t_{k-1} \) and \( t_k \) are two determining randomization points. For all \( t, t' \) such that \( t_k \leq \min\{t, t'\} \leq t_k + m - 1 \) and \( t_{k-1} + m \leq \max\{t, t'\} \leq t_k + m - 1 \), \( E[\mathbb{1}_t \mathbb{1}_{t'}] = 4B^2 \), because \( \min\{t, t'\} - m \leq t_k - 1 \) and \( t_{k-1} \leq \max\{t, t'\} - m \leq t_k - 1 \) so \( t_{k-1} \) and \( t_k \) are two determining randomization points. For all \( t, t' \) such that \( t_k \leq \min\{t, t'\} \leq t_k + m - 1 \) and \( t_{k-1} + m \leq \max\{t, t'\} \leq t_k + m - 1 \), \( E[\mathbb{1}_t \mathbb{1}_{t'}] = 0 \).
\[ t_{k+1} - 1, t_k + m \leq \max\{t, t'\} \leq t_{k+1} + m - 1, \quad \mathbb{E}[\mathbf{1}_t \mathbf{1}_{t'}] = 4B^2, \] because \( t_k \leq \max\{t, t'\} - m \) so \( t_k \) is the only determining randomization point. For all \( t, t' \) such that \( t_k \leq \min\{t, t'\} \leq t_{k+1} - 1, t_{k+1} + m \leq \max\{t, t'\} \leq T, \quad \mathbb{E}[\mathbf{1}_t \mathbf{1}_{t'}] = 0. \]

In this case,
\[ \sum_{\substack{t_k \leq t, t' \leq T \\ \min\{t, t'\} \leq t_{k+1} - 1}} \mathbb{E}[\mathbf{1}_t \mathbf{1}_{t'}] = B^2 \left( 16 \cdot (m - t_k + t_{k-1})^2 + 8 \cdot (m^2 - (m - t_k + t_{k-1})^2) \right) + 4 \cdot ((m + t_{k+1} - t_k)^2 - 2m^2) \]

(4) When \( t_k - t_{k-1} < m, t_{k+1} - t_k < m \). Due to Lemma EC.4, for all \( t, t' \in \{t_k : t_{k-1} + m - 1\}, \quad \mathbb{E}[\mathbf{1}_t \mathbf{1}_{t'}] = 16B^2, \) because \( t - m \leq t_{k-1} - 1 \leq t_k \leq t \) and \( t' - m \leq t_{k-1} - 1 \leq t_k \leq t' \) so \( t_{k-2}, t_{k-1}, t_k \) are three determining randomization points. Also \( t_k - t_{k-2} \geq m \) so \( t_{k-2} \leq \min\{t, t'\} - m \) and \( t_{k-3} \) is not a determining randomization point. For all \( t, t' \) such that \( t_k \leq \min\{t, t'\} \leq t_{k+1} - 1, t_{k+1} + m \leq \max\{t, t'\} \leq t_k + m - 1, \quad \mathbb{E}[\mathbf{1}_t \mathbf{1}_{t'}] = 8B^2, \) because \( \min\{t, t'\} - m < t_k - 1 \) and \( t_{k-1} \leq \max\{t, t'\} - m \leq t_k - 1 \) so \( t_{k-1} \) and \( t_k \) are two determining randomization points. For all \( t, t' \) such that \( t_k \leq \min\{t, t'\} \leq t_k + 1, t_k + m \leq \max\{t, t'\} \leq t_k + 1 + m - 1, \quad \mathbb{E}[\mathbf{1}_t \mathbf{1}_{t'}] = 4B^2, \) because \( t_k \leq \max\{t, t'\} - m \) so \( t_k \) is the only determining randomization point. For all \( t, t' \) such that \( t_k \leq \min\{t, t'\} \leq t_{k+1} - 1, t_{k+1} + m \leq \max\{t, t'\} \leq T, \quad \mathbb{E}[\mathbf{1}_t \mathbf{1}_{t'}] = 0. \]

In this case,
\[ \sum_{\substack{t_k \leq t, t' \leq T \\ \min\{t, t'\} \leq t_{k+1} - 1}} \mathbb{E}[\mathbf{1}_t \mathbf{1}_{t'}] = B^2 \left( 16 \cdot (m - t_k + t_{k-1})^2 + 8 \cdot (m^2 - (m - t_k + t_{k-1})^2) \right) + 4 \cdot ((m + t_{k+1} - t_k)^2 - 2m^2 + (m - t_k + t_{k-1})^2) \]

Finally we calculate the third block from equation [EC.8]. Observe that \( T - t_K \geq m \). (1) When \( t_K - t_{K-1} \geq m \). Due to Lemma EC.4, for all \( t, t' \in \{t_K : t_{K-1} + m - 1\}, \quad \mathbb{E}[\mathbf{1}_t \mathbf{1}_{t'}] = 8B^2, \) because both \( t_{K-1} \leq t - m \leq t_K - 1 \) and \( t_{K-1} \leq t' - m \leq t_K - 1 \), and both \( t_{K-1} \) and \( t_K \) are overlapping randomization points. For all \( t, t' \) such that \( t_K \leq \min\{t, t'\} \leq T, t_K + m \leq \max\{t, t'\} \leq T, \quad \mathbb{E}[\mathbf{1}_t \mathbf{1}_{t'}] = 4B^2, \) because \( t_K \leq \max\{t, t'\} - m \) so \( t_K \) is the only determining randomization point.

In this case,
\[ \sum_{t_K \leq t, t' \leq T} \mathbb{E}[\mathbf{1}_t \mathbf{1}_{t'}] = B^2 \left( 8 \cdot m^2 + 4 \cdot ((T + 1 - t_K)^2 - m^2) \right) \]

(2) When \( t_K - t_{K-1} < m \). Due to Lemma EC.4, for all \( t, t' \in \{t_K : t_{K-1} + m - 1\}, \quad \mathbb{E}[\mathbf{1}_t \mathbf{1}_{t'}] = 16B^2, \) because \( t - m \leq t_{K-1} - 1 \leq t_K \leq t \) and \( t' - m \leq t_{K-1} - 1 \leq t_K \leq t' \) so \( t_{K-2}, t_{K-1}, t_K \) are three determining randomization points. Also \( t_K - t_{K-2} \geq m \) so \( t_{K-2} \leq \min\{t, t'\} - m \) and \( t_{K-3} \) is not a determining randomization point. For all \( t, t' \) such that \( t_K \leq \min\{t, t'\} \leq t_K + m - 1, t_K + m \leq \max\{t, t'\} \leq T, \quad \mathbb{E}[\mathbf{1}_t \mathbf{1}_{t'}] = 0. \]
max\{t, t'\} \leq t_K + m - 1, \ E[\mathbb{I}_t \mathbb{I}_{t'}] = 8B^2,$

because $\min\{t, t'\} - m \leq t_K - 1$ and $t_K - 1 \leq \max\{t, t'\} - m \leq t_K - 1$ so $t_{K-1}$ and $t_K$ are two determining randomization points. For all $t, t'$ such that $t_K \leq \min\{t, t'\} \leq T, t_K + m \leq \max\{t, t'\} \leq T, \ E[\mathbb{I}_t \mathbb{I}_{t'}] = 4B^2,$

because $t_K \leq \max\{t, t'\} - m$ so $t_K$ is the only determining randomization point.

In this case,

$$\sum_{t_K \leq t, t' \leq T} E[\mathbb{I}_t \mathbb{I}_{t'}] = B^2 \left(16 \cdot (m - t_K + t_K - 1)^2 + 8 \cdot (m^2 - (m - t_K + t_K - 1)^2) + 4 \cdot ((T + 1 - t_K)^2 - m^2)\right)$$

Now we combine all above together.

Note that whenever there exists $k \in \{2 : K\}$ such that $(t_k - t_{k-1}) < m,$ this suggests that in

$$\sum_{\min\{t, t'\} \leq t_{K-1} - 1} t_k \leq t, t' \leq T} E[\mathbb{I}_t \mathbb{I}_{t'}]$$

there is a $16(m - t_k + t_{k-1})^2$; but in $\sum_{\min\{t, t'\} \leq t_{K-1} - 1} t_k \leq t, t' \leq T} E[\mathbb{I}_t \mathbb{I}_{t'}]$ there is a $8(-(m - t_k + t_{k-1})^2).$ So when we sum them up, we break $16(m - t_k + t_{k-1})^2$ into two $8(m - t_k + t_{k-1})^2,$ which cancels in two summations. By telescoping,

$$(T - m)^2 \cdot r(\eta_T, Y) = \sum_{m+1 \leq t, t' \leq T} E[\mathbb{I}_t \mathbb{I}_{t'}] + \sum_{k=1}^{K-1} \left( \sum_{t_k \leq t, t' \leq T} E[\mathbb{I}_t \mathbb{I}_{t'}] \right) + \sum_{t_K \leq t, t' \leq T} E[\mathbb{I}_t \mathbb{I}_{t'}]$$

$$= 4B^2 \cdot (t_1 - 1)^2 - m^2) + \sum_{k=1}^{K-1} B^2 \cdot \left( 8m^2 + 4 \left((m + t_{k+1} - t_k)^2 - 2m^2 + ((m - t_{k+1} + t_k)^2)\right)\right)$$

$$+ B^2 \cdot \left( 8m^2 + 4 \left((T + 1 - t_K)^2 - m^2)\right)\right)$$

$$= B^2 \left\{ 4 \sum_{k=0}^{K} (t_{k+1} - t_k)^2 + 8m(t_K - t_1) + 4m^2K - 4m^2 + \sum_{k=1}^{K-1} (m - t_{k+1} + t_k)^2 \right\}$$

which finishes the proof. □

EC.4.5. Optimal Solutions to the Subset Selection Problem in Theorem \ref{thm:subset_selection_pf}

EC.4.5.1. Proof of Theorem \ref{thm:subset_selection_pf}

Proof of Theorem \ref{thm:subset_selection_pf}. Consider the problem as we have introduced in \cite{6}. Due to Lemma \ref{lem:subset_selection_pf},

$$Y^+ = \{Y_t(1_{m+1}) = Y_t(0_{m+1}) = B\}_{t \in \{m + 1 : T\}} \text{ and } Y^- = \{Y_t(1_{m+1}) = Y_t(0_{m+1}) = -B\}_{t \in \{m + 1 : T\}}$$

are the only two dominating strategies for the adversarial selection of potential outcomes.

Then due to Lemma \ref{lem:subset_selection_pf} and Lemma \ref{lem:subset_selection_pf} the optimal design of switchback experiment must satisfy the following three conditions.

$$t_1 \geq m + 2, \quad t_K \leq T - m \quad t_{k+1} - t_{k-1} \geq m, \ \forall k \in [K].$$

Due to Theorem \ref{thm:subset_selection_pf}, the risk function of the optimal design of experiment is given by

$$r(\eta_T, Y) = \frac{1}{(T - m)^2} \left\{ 4 \sum_{k=1}^{K_2} (t_k - t_{k-1})^2 + 8m(t_K - t_1) + 4m^2K - 4m^2 + \sum_{k=2}^{K} (m - t_k + t_{k-1})^2 \right\} B^2$$
So if we further take minimum over $T \subset [T]$ in the above risk function, we find the optimal solution to the original problem introduced in [6]. Note that $B^2$ is a constant and irrelevant to our decisions, and that $T$ and $m$ are inputs. So we solve, for any given $T$ and $m$, the following subset selection problem:

$$
\min_{T \subset [T]} \left\{ 4 \sum_{k=0}^{K} (t_{k+1} - t_k)^2 + 8m(t_K - t_1) + 4m^2K - 4m^2 + 4 \sum_{k=1}^{K-1} [(m-t_{k+1}+t_k)^+]^2 \right\},
$$

as stated in [8].

In particular, if there exists some constant $n \in \mathbb{N}, n \geq 4$, such that $T = nm$, we can explicitly find the optimal design of experiment. Take the continuous relaxation of this problem, such that for any $K$, $\{1 < t_1 < t_2 < ... < t_K < T + 1\} \in [1, T+1]^K$.

$$
\min_{K \in \mathbb{N}, \{1 < t_1 < t_2 < ... < t_K < T + 1\} \in [1, T+1]^K} \left\{ 4 \sum_{k=0}^{K} (t_{k+1} - t_k)^2 + 8m(t_K - t_1) + 4m^2K - 4m^2 + 4 \sum_{k=1}^{K-1} [(m-t_{k+1}+t_k)^+]^2 \right\}
$$

The relaxed problem provides a lower bound to the original subset selection problem as stated in [8]. We will argue later that it is a lucky coincidence that the optimal solution to this relaxed problem is also an integer solution.

First we argue that $t_1 - t_0 = t_{K+1} - t_K$. This is because otherwise if $t_1 - t_0 \neq t_{K+1} - t_K$ then denote $a = \frac{t_1 - t_0 + t_{K+1} - t_K}{2}$. We could always pick for any $k \in \{1 : K\}$, $\tilde{t}_k = t_k + a - t_1 + 1$, such that $t_{k+1} - t_k$ is unchanged for any $k \in \{1 : K - 1\}$. The only change in the objective value comes from

$$
(2a^2) - ((t_1 - t_0) + (t_{K+1} - t_K))^2 < 0,
$$

which suggests that $t_1 - t_0 \neq t_{K+1} - t_K$ is not optimal.

Second, similarly, we argue that for any $k' < k'' \in [K - 1]$, $t_{k'+1} - t_{k'} = t_{k''+1} - t_{k''}$ This is because otherwise if $t_{k'+1} - t_{k'} \neq t_{k''+1} - t_{k''}$ then denote $b = \frac{t_{k'+1} - t_{k'} + t_{k''+1} - t_{k''}}{2}$. We could always pick for any $k \in \{k'+1 : k''\}$, $\tilde{t}_k = t_k + b - (t_{k'+1} - t_{k'})$, such that $t_{k+1} - t_k$ is unchanged for any $k \in \{k'+1 : k'' - 1\}$. The only change in the objective value comes from

$$
(2b^2 + 2((m-b)^+)^2) - (t_{k'+1} - t_{k'}) + (t_{k''+1} - t_{k''})^2 + ((m-t_{k'+1} + t_{k'})^+)^2 + ((m-t_{k''+1} + t_{k''})^+)^2 < 0,
$$

where $x^2 + ((m-x)^+)^2$ is convex and the inequality holds due to Jensen’s Inequality. This inequality suggests that $t_{k'+1} - t_{k'} \neq t_{k''+1} - t_{k''}$ is not optimal.

With the above two structural results, we can assume that there exists $a, b > 0$, such that $t_1 - t_0 = t_{K+1} - t_K = a$, and $t_{k+1} - t_k = b, \forall k \in [K - 1]$. Also, it must be satisfied that $2a + (K-1)b = T$. Next we replace $K-1 = \frac{T-2a}{b}$ into the relaxed problem, to have

$$
\min_{a, b > 0} \left\{ 4(2a^2 + (K-1)b^2) + 8m(K-1)b + 4m^2(K-1) + 4(K-1)((m-b)^+)^2 \right\} = \min_{a, b > 0} \left\{ 8a^2 + 4(T-2a)b + 8m(T-2a) + 4m^2 \frac{T-2a}{b} + 4 \frac{T-2a}{b} ((m-b)^+)^2 \right\}
$$
Either when \( b \geq m \), the above is to minimize
\[
\min_{a,b>0} \left\{ 8a^2 + 4(T - 2a)b + 8m(T - 2a) + 4m^2 \frac{T - 2a}{b} \right\}
\]
Note that
\[
8a^2 + 4(T - 2a)b + 8m(T - 2a) + 4m^2 \frac{T - 2a}{b} = 8a^2 + 8m(T - 2a) + 4(T - 2a) \left( b + \frac{m^2}{b} \right)
\]
\[
\geq 8a^2 + 16m(T - 2a)
\]
\[
= 8(a - 2m)^2 + 16mT - 32m^2
\]
\[
\geq 16mT - 32m^2
\]
where the first inequality takes equality if and only if \( b = \frac{m^2}{b} \), which suggests \( b = m \); the second inequality takes equality if and only if \( a = 2m \).

Or when \( b \leq m \), the above is to minimize
\[
\min_{a,b>0} \left\{ 8a^2 + 4(T - 2a)b + 8m(T - 2a) + 4m^2 \frac{T - 2a}{b} + 4 \frac{T - 2a}{b} (m - b)^2 \right\}
\]
Note that
\[
8a^2 + 4(T - 2a)b + 8m(T - 2a) + 4m^2 \frac{T - 2a}{b} + 4 \frac{T - 2a}{b} (m - b)^2 = 8a^2 + 8(T - 2a) \left( b + \frac{m^2}{b} \right)
\]
\[
\geq 8a^2 + 16m(T - 2a)
\]
\[
= 8(a - 2m)^2 + 16mT - 32m^2
\]
\[
\geq 16mT - 32m^2
\]
where the first inequality takes equality if and only if \( b = \frac{m^2}{b} \), which suggests \( b = m \); the second inequality takes equality if and only if \( a = 2m \).

Combining both cases, the optimal solution is when \( a = 2m \) and \( b = m \), which happens to be an integer solution, thus optimal for the subset selection problem. Translating into \( t_1, \ldots, t_K \) this suggests that \( t_1 = 2m + 1, t_2 = 3m + 1, \ldots, t_K = (n - 2)m + 1 \).

\[\square\]

**EC.4.5.2. Solutions in the Imperfect Cases.** It is always worth noting that we are taking a design of experiments perspective. So when practically we have control of \( T \), we can pick \( T \) to be some multiples of \( m \), which fits our Theorem perfectly. If we do not have control of \( T \), we can always pick a smaller \( T' \) such that \( T' = \lfloor T/m \rfloor \cdot m \) is some multiples of \( m \).

Nonetheless, from an optimization perspective, we establish the following optimal structure for the subset selection problem as in [8]. Recall that \( t_{K+1} = T + 1 \).
Lemma EC.5. Under Assumptions 1-3, the optimal design of regular switchback experiment must satisfy the following two conditions,

\[ |(t_1 - t_0) - (t_{K+1} - t_K)| \leq 1, \quad |(t_{j+1} - t_j) - (t_{j'+1} - t_{j'})| \leq 1, \forall 1 \leq j, j' \leq K - 1. \]

Proof of Lemma EC.5. Prove by contradiction.

Case 1. Suppose there exists some optimal design \( \mathbb{T} \), such that \( (t_1 - t_0) - (t_{K+1} - t_K) \geq 2 \). We now construct another design \( \tilde{\mathbb{T}} \), such that \( |\tilde{\mathbb{T}}| = K = |\mathbb{T}| \), and the K elements are \( \tilde{\mathbb{T}} = \{\tilde{t}_0 = 1, \tilde{t}_1 = t_1 - 1, \tilde{t}_2 = t_2 - 1, \ldots, \tilde{t}_K = t_K - 1\} \). Now check the expression as in (8). Note that \( \tilde{t}_{k+1} - \tilde{t}_k = t_{k+1} - t_k \) is unchanged for any \( k \in [K - 1] \); \( \tilde{t}_K - \tilde{t}_1 = t_K - t_1 \) is unchanged; and \( m - \tilde{t}_{k+1} - \tilde{t}_k = m - t_{k+1} - t_k \) in unchanged for any \( k \in [K - 1] \). But \( (\tilde{t}_1 - \tilde{t}_0)^2 + (\tilde{t}_K - \tilde{t}_{K-1})^2 = (t_1 - t_0 - 1)^2 + (t_K - t_{K-1} + 1)^2 \leq (t_1 - t_0)^2 + (t_{K+1} - t_K)^2 \), because \( (t_1 - t_0) - (t_{K+1} - t_K) \geq 2 \) and due to convexity.

Similarly, if there exists some optimal design \( \mathbb{T} \), such that \( (t_{K+1} - t_K) - (t_1 - t_0) \geq 2 \), then construct another design \( \tilde{\mathbb{T}} = \{\tilde{t}_0 = 1, \tilde{t}_1 = t_1 + 1, \tilde{t}_2 = t_2 + 1, \ldots, \tilde{t}_K = t_K + 1\} \).

Case 2. Suppose there exists some optimal design \( \mathbb{T} \), and there exists \( 1 \leq j < j' \leq K - 1 \) such that \( (t_{j+1} - t_j) - (t_{j'+1} - t_{j'}) \geq 2 \). We now construct another design \( \tilde{\mathbb{T}} \), such that \( |\tilde{\mathbb{T}}| = K = |\mathbb{T}| \), and the K elements are \( \tilde{\mathbb{T}} = \{\tilde{t}_0 = 1, \tilde{t}_1 = t_1, \ldots, \tilde{t}_j = t_j, \tilde{t}_{j+1} = t_{j+1} - 1, \ldots, \tilde{t}_j' = t_j' - 1, \tilde{t}_{j'+1} = t_{j'+1}, \ldots, \tilde{t}_K = t_K\} \).

Now check the expression as in (8). Note that \( \tilde{t}_{k+1} - \tilde{t}_k = t_{k+1} - t_k \) is unchanged for any \( k \in \{0 : K\} \) except \( j \) and \( j' \); \( \tilde{t}_K - \tilde{t}_1 = t_K - t_1 \) is unchanged; and \( m - \tilde{t}_{k+1} - \tilde{t}_k = m - t_{k+1} - t_k \) in unchanged for any \( k \in [K - 1] \) except \( j \) and \( j' \). Now focus on \( j \) and \( j' \).

\[
(t_{j+1} - t_j)^2 + (t_{j'+1} - t_{j'})^2 + [(m - t_{j+1} + t_j)^+]^2 + [(m - t_{j'+1} + t_{j'})^+]^2
\leq (t_{j+1} - t_j)^2 + (t_{j'+1} - t_{j'})^2 + [(m - t_{j+1} + t_j + 1)^+]^2 + [(m - t_{j'+1} + t_{j'} - 1)^+]^2
\]

To see why this inequality holds, define \( g(x) = x^2 + [(m - x)^+]^2 \) and note that \( g(x) \) is a univariate convex function. The inequality holds due to \( (t_{j+1} - t_j) - (t_{j'+1} - t_{j'}) \geq 2 \) and convexity.

Similarly, if there exists some optimal design \( \mathbb{T} \), and there exists \( 1 \leq j < j' \leq K - 1 \) such that \( (t_{j'+1} - t_{j'}) - (t_{j+1} - t_j) \geq 2 \). Then construct another design \( \tilde{\mathbb{T}} = \{\tilde{t}_0 = 1, \tilde{t}_1 = t_1, \ldots, \tilde{t}_j = t_j, \tilde{t}_{j+1} = t_{j+1} + 1, \ldots, \tilde{t}_j' = t_j' + 1, \tilde{t}_{j'+1} = t_{j'+1}, \ldots, \tilde{t}_K = t_K\} \).

Combine both cases we finish the proof. \( \Box \)

EC.5. Proofs and Discussions from Section 4

In Section 4 we focus on the case when \( p = m \). Throughout this section in the appendix, we use only \( m \) instead of \( p \).
EC.5.1. Extra Notations Used in the Proofs from Section 4

For any \( t \in \{ m + 1 : T \} \), we use the notations of \( 1_t \) as defined in (EC.1). Denote

\[
\begin{align*}
\bar{1}_0 &= \sum_{t=m+1}^{2m} 1_t, \\
\bar{1}_k &= \sum_{t=(k+1)m+1}^{(k+2)m} 1_t, \\
\bar{1}_{K+1} &= \sum_{t=(K+2)m+1}^{(K+3)m} 1_t,
\end{align*}
\]

\( \forall k \in [K] \)

It is worth noting that under the optimal design as suggested by Theorem 3, when \( T/m = n \in \mathbb{N} \) is an integer, we have \( K = n - 3 \). So \( (K + 3)m = T \). See Example EC.1 below.

**Example EC.1 (An Optimal Design and Its \( \bar{1}_k \) Notations).** When \( T = 12 \), \( p = m = 2 \), the optimal design of regular switchback experiment is \( T^* = \{1, 5, 7, 9\} \), and \( K = 3 \). The \( \bar{1}_k \) notations are defined below. Each \( \bar{1}_k \) spans \( m = 2 \) periods. See Table EC.7.

\[
\begin{array}{cccccccccccc}
& 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 & 9 & 10 & 11 & 12 \\
T^* & \checkmark & - & - & - & \checkmark & - & \checkmark & - & - & - & - & - \\
\{\bar{1}_k\}_{k=0}^{K+1} & - & \bar{1}_0 & \bar{1}_1 & \bar{1}_2 & \bar{1}_3 & \bar{1}_4 \\
\end{array}
\]

Using the above notation, we could write

\[
\hat{\tau}_m - \tau_m = \frac{1}{T - m} \sum_{k=0}^{K+1} \bar{1}_k,
\]

and so

\[
\text{Var}(\hat{\tau}_m) = \frac{1}{(T - m)^2} \text{Var} \left( \sum_{k=0}^{K+1} \bar{1}_k \right).
\]

EC.5.2. Proof of Theorem 4

The proof of Theorem 4 resembles the proof of Lemmas EC.2 and EC.3. The trick here is to observe that for any \( k \in [K] \), the values of all the variables \( 1_t \), where \( (k+1)m+1 \leq t \leq (k+2)m \), are all determined by the randomization at time \( km + 1 \) and \( (k+1)m + 1 \). Since they are all correlated, we can use \( \bar{1}_k \) to stand for \( \sum_{t=(k+1)m+1}^{(k+2)m} 1_t \) for short.

**Proof of Theorem 4.** First observe that \( \bar{1}_k \) has zero mean for each \( k \in \{0 : K + 1\} \). So we can decompose the variance into squared terms and cross-product terms,

\[
(T - m)^2 \text{Var}(\hat{\tau}_m) = \text{Var} \left( \sum_{k=0}^{K+1} \bar{1}_k \right) = \sum_{k=0}^{K+1} E \left[ \bar{1}_k^2 \right] + \sum_{0 \leq k < k' \leq K+1} 2E[\bar{1}_k \bar{1}_k'].
\]
We focus on the variance of the squared terms first,
\[
E \left[ \bar{\tilde{k}}^2 \right] = \begin{cases} 
Y_0(1_{m+1})^2 + Y_0(0_{m+1})^2 + 2Y_0(1_{m+1})Y_0(0_{m+1}), & \text{if } k = 0 \\
3Y_k(1_{m+1})^2 + 3Y_k(0_{m+1})^2 + 2Y_k(1_{m+1})Y_k(0_{m+1}), & \text{if } 1 \leq k \leq K \\
Y_{K+1}(1_{m+1})^2 + Y_{K+1}(0_{m+1})^2 + 2Y_{K+1}(1_{m+1})Y_{K+1}(0_{m+1}), & \text{if } k = K + 1
\end{cases}
\]
This is because when \( k = 0 \) or \( k = K + 1 \), then with probability 1/2, \( \tilde{k} = Y_0(1_{m+1}) + Y_0(0_{m+1}) \); with probability 1/2, \( \tilde{k} = Y_0(1_{m+1}) - Y_0(0_{m+1}) \). When \( k \in [K] \), with probability 1/4, \( \tilde{k} = 3Y_0(1_{m+1}) + Y_0(0_{m+1}) \); with probability 1/4, \( \tilde{k} = -Y_0(1_{m+1}) + Y_0(0_{m+1}) \); with probability 1/4, \( \tilde{k} = -Y_0(1_{m+1}) - 3Y_0(0_{m+1}) \).

Then for the cross-product terms, if \( k' - k \geq 2 \), then \( \tilde{k} \) and \( \tilde{k}' \) are independent, i.e., \( E[\tilde{k}\tilde{k}'] = 0 \). If \( k' - k = 1 \), then
\[
E \left[ \tilde{k} \tilde{k} \right] = (Y_k(1_{m+1}) + Y_k(0_{m+1}))(Y_{k+1}(1_{m+1}) + Y_{k+1}(0_{m+1}))
\]
This is because the values of \( \tilde{k} \) and \( \tilde{k} \) are determined by the realization at 3 randomization points, \( W_{k+1}, W(1_{m+1}), W(0_{m+1}) \). With probability 1/8, \( \tilde{k} = Y_k(1_{m+1}) \cdot (3Y_k(1_{m+1}) + Y_k(0_{m+1})) ; \text{with} \) probability 1/8, \( \tilde{k} = Y_k(1_{m+1}) \cdot (3Y_k(1_{m+1}) + Y_k(0_{m+1})) \cdot (Y_k(1_{m+1}) + Y_k(0_{m+1})) ; \text{with} \) probability 1/8, \( \tilde{k} = Y_k(1_{m+1}) \cdot (3Y_k(1_{m+1}) + Y_k(0_{m+1})) \cdot (Y_k(1_{m+1}) + Y_k(0_{m+1})) \). Combining the squared terms and the cross-product terms we finish the proof. 

EC.5.3. Discussions and proof of Corollary 1

We first provide the details of the two variance upper bounds here.
\[
\text{Var}^U_1(\hat{\tau}_m) = \frac{1}{(T - m)^2} \left\{ \begin{array}{l}
3 [Y_0(1_{m+1})^2 + Y_0(0_{m+1})^2] + \sum_{k=1}^{n-3} 6 [Y_k(1_{m+1})^2 + Y_k(0_{m+1})^2] \\
+ 4 [Y_{n-2}(1_{m+1})^2 + Y_{n-2}(0_{m+1})^2] + \sum_{k=0}^{n-3} 2 [Y_k(1_{m+1}) \cdot Y_{k+1}(1_{m+1}) + Y_k(0_{m+1}) \cdot Y_{k+1}(0_{m+1})]
\end{array} \right\},
\]
and
\[
\text{Var}^U_2(\hat{\tau}_m) = \frac{1}{(T - m)^2} \left\{ \begin{array}{l}
4 [Y_0(1_{m+1})^2 + Y_0(0_{m+1})^2] + \sum_{k=1}^{n-3} 8 [Y_k(1_{m+1})^2 + Y_k(0_{m+1})^2] \\
+ 4 [Y_{n-2}(1_{m+1})^2 + Y_{n-2}(0_{m+1})^2]
\end{array} \right\}.
\]
We prove Corollary 1 using the basic inequality that $2xy \leq x^2 + y^2$. Such an inequality is commonly used to find a conservative upper bound of the variance.

**Proof of Corollary 1.** From Theorem 4, the variance of the estimator is given by

$$(T - m)^2 \text{Var}(\hat{\tau}_m)$$

$$\leq 2 \left\{ \bar{Y}_0(1_{m+1})^2 + \bar{Y}_0(0_{m+1})^2 \right\} + \sum_{k=1}^{n-3} 4 \left\{ \bar{Y}_k(1_{m+1})^2 + \bar{Y}_k(0_{m+1})^2 \right\} + 2 \left\{ \bar{Y}_{n-2}(1_{m+1})^2 + \bar{Y}_{n-2}(0_{m+1})^2 \right\}$$

$$+ \sum_{k=0}^{n-3} 2 \left[ \bar{Y}_k(1_{m+1}) + \bar{Y}_k(0_{m+1}) \right] : \left[ \bar{Y}_{k+1}(1_{m+1}) + \bar{Y}_{k+1}(0_{m+1}) \right]$$

$$\leq 2 \left\{ \bar{Y}_0(1_{m+1})^2 + \bar{Y}_0(0_{m+1})^2 \right\} + \sum_{k=1}^{n-3} 4 \left\{ \bar{Y}_k(1_{m+1})^2 + \bar{Y}_k(0_{m+1})^2 \right\} + 2 \left\{ \bar{Y}_{n-2}(1_{m+1})^2 + \bar{Y}_{n-2}(0_{m+1})^2 \right\}$$

$$+ \sum_{k=0}^{n-3} \left\{ 2\bar{Y}_k(1_{m+1})\bar{Y}_{k+1}(1_{m+1}) + 2\bar{Y}_k(0_{m+1})\bar{Y}_{k+1}(0_{m+1}) + \bar{Y}_k(1_{m+1})^2 + \bar{Y}_k(0_{m+1})^2 + \bar{Y}_{k+1}(1_{m+1})^2 + \bar{Y}_{k+1}(0_{m+1})^2 \right\}$$

$$\leq 3 \left\{ \bar{Y}_0(1_{m+1})^2 + \bar{Y}_0(0_{m+1})^2 \right\} + \sum_{k=1}^{n-3} 6 \left\{ \bar{Y}_k(1_{m+1})^2 + \bar{Y}_k(0_{m+1})^2 \right\} + 3 \left\{ \bar{Y}_{n-2}(1_{m+1})^2 + \bar{Y}_{n-2}(0_{m+1})^2 \right\}$$

$$+ \sum_{k=0}^{n-3} \left\{ \bar{Y}_k(1_{m+1})^2 + \bar{Y}_k(0_{m+1})^2 + \bar{Y}_{k+1}(1_{m+1})^2 + \bar{Y}_{k+1}(0_{m+1})^2 \right\}$$

$$= 4 \left\{ \bar{Y}_0(1_{m+1})^2 + \bar{Y}_0(0_{m+1})^2 \right\} + \sum_{k=1}^{n-3} 8 \left\{ \bar{Y}_k(1_{m+1})^2 + \bar{Y}_k(0_{m+1})^2 \right\} + 4 \left\{ \bar{Y}_{n-2}(1_{m+1})^2 + \bar{Y}_{n-2}(0_{m+1})^2 \right\}$$

where the first inequality suggests $\text{Var}(\hat{\tau}_m) \leq \text{Var}^{\text{U}1}(\hat{\tau}_m)$, and the last inequality suggests $\text{Var}^{\text{U}1}(\hat{\tau}_m) \leq \text{Var}^{\text{U}2}(\hat{\tau}_m)$.

The unbiasedness part is due to the estimator of the variances being Horvitz-Thompson type estimators. □

**EC.5.4. Proof of Theorem 5**

We prove Theorem 5 by using Lemma 1. In particular, we derive $B^2_{n,k,a}$, and then construct some proper $\Delta_n, K_n$, and $L_n$.

**Proof of Theorem 5**. In the $n$-replica experiment, $\hat{\tau}_m - \tau_m = \frac{1}{(n-1)m} \sum_{k=0}^{n-2} \bar{I}_k$, and $\text{Var}(\hat{\tau}_m) = \frac{1}{(n-1)^2 m^2} \text{Var}(\sum_{k=0}^{n-2} \bar{I}_k)$. To use the language from Lemma 1, denote $d = n - 1$. Denote for any $i \in [n-1]$, $X_{n,i} = \frac{1}{(n-1)m} \bar{I}_{i-1}$ so we know that $\phi = 1$, i.e., $\{X_{n,1}, X_{n,2}, \ldots\}$ is a sequence of 1-dependent random variables.

First note that $B^2_n = \text{Var}(\hat{\tau}_m)$, and we calculate $B^2_{n,k,a}$ as follows.

$$B^2_{n,k,a} = \frac{1}{(n-1)^2 m^2} \text{Var} \left( \sum_{i=a}^{a+k-1} \bar{I}_{i-1} \right)$$

$$\leq \frac{1}{(n-1)^2 m^2} \left\{ \sum_{i=a}^{a+k-1} \left[ 3\bar{Y}_{i-1}(1_{m+1})^2 + 3\bar{Y}_{i-1}(0_{m+1})^2 + 2\bar{Y}_{i-1}(1_{m+1})\bar{Y}_{i-1}(0_{m+1}) \right] \right\}$$
In Section 5 we discuss the cases when \( m \) is misspecified. Throughout this section in the appendix, we use both \( p \) and \( m \). Recall that \( m \) is the order of the carryover effect, and \( p \) is the experimenter’s knowledge of \( m \).

### EC.6. Proofs and Discussions from Section 5

In Section 5 we discuss the cases when \( m \) is misspecified. Throughout this section in the appendix, we use both \( p \) and \( m \). Recall that \( m \) is the order of the carryover effect, and \( p \) is the experimenter’s knowledge of \( m \).

#### EC.6.1. Unbiasedness of the Horvitz-Thompson Estimator when \( m \) is Misspecified

We state here the omitted mathematics in Theorem 6.

Under Assumptions 2 and 3 for \( p < m \), at each time \( t \geq m + 1 \), the Horvitz-Thompson estimator is either unbiased for the lag-\( m \) causal effect when \( f(t - p) \leq t - m \), i.e.,

\[
\\begin{align*}
\mathbb{E}_{W_{i, t} \sim \eta_t} & \left[ Y_{t, \text{obs}} \frac{1}{\Pr(W_{t - p:t} = 1_{p+1})} - Y_{t, \text{obs}} \frac{1}{\Pr(W_{t - p:t} = 0_{p+1})} \right] = Y_t(1_{m+1}) - Y_t(0_{m+1}),
\end{align*}
\\end{align*}
\]

or conditionally unbiased for the \( m \)-misspecified lag-\( p \) causal effect when \( f(t - p) > t - m \), i.e.,

\[
\\begin{align*}
\mathbb{E}_{W_{i, t} \sim \eta_t} \left[ \left\{ Y_{t, \text{obs}} \frac{1}{\Pr(W_{t - p:t} = 1_{p+1})} - Y_{t, \text{obs}} \frac{1}{\Pr(W_{t - p:t} = 0_{p+1})} \right\} - \left\{ Y_t(w_{t - m:f(t-p)-1}^{\text{obs}}, 1_{t-f(t-p)+1}) - Y_t(w_{t - m:f(t-p)-1}^{\text{obs}}, 0_{t-f(t-p)+1}) \right\} \bigg| W_{t - m:f(t-p)-1} = w_{t - m:f(t-p)-1}^{\text{obs}} \right] = 0.
\end{align*}
\]
When \( p + 1 \leq t \leq m \), the Horvitz-Thompson estimator is either unbiased for the lag-\( t \) causal effect when \( f(t - p) = 1 \), i.e.,

\[
\mathbb{E}_{W_1:T \sim \eta_t} \left[ Y_t \Pr(\{W_{t-p:t} = 1_{p+1}\}) \Pr(W_{t-p:t} = 1_{p+1}) - Y_t \Pr(\{W_{t-p:t} = 0_{p+1}\}) \Pr(W_{t-p:t} = 0_{p+1}) \right] = Y_t(1_t) - Y_t(0_t),
\]

or conditionally unbiased for the \( m \)-misspecified lag-\( t \) causal effect when \( f(t - p) > 1 \), i.e.,

\[
\mathbb{E}_{W_1:T \sim \eta_t} \left[ \left\{ Y_t \Pr(\{W_{t-p:t} = 1_{p+1}\}) \Pr(W_{t-p:t} = 1_{p+1}) - Y_t \Pr(\{W_{t-p:t} = 0_{p+1}\}) \Pr(W_{t-p:t} = 0_{p+1}) \right\} - \\
Y_t(w_{obs}^{1:f(t-p)-1}, 1_t-f(t-p)+1) - Y_t(w_{obs}^{1:f(t-p)-1}, 0_t-f(t-p)+1) \right| W_{1:f(t-p)-1} = w_{obs}^{1:f(t-p)-1} = 0.
\]

To remove the conditional expectation, we can further take an outer loop of expectation averaged over the past assignment paths. So the estimator is estimating a weighted average of lag-\( p \) effects. When \( t \geq m + 1 \),

\[
\sum_{w_{1:m:f(t-p)-1}} \Pr(W_{t-m:f(t-p)-1} = w_{1:m:f(t-p)-1}) (Y_t(w_{t-m:f(t-p)-1}, 1_t-f(t-p)+1) - Y_t(w_{t-m:f(t-p)-1}, 0_t-f(t-p)+1)),
\]

and when \( p + 1 \leq t \leq m \),

\[
\sum_{w_{1:f(t-p)-1}} \Pr(W_{1:f(t-p)-1} = w_{1:f(t-p)-1}) (Y_t(w_{1:f(t-p)-1}, 1_t-f(t-p)+1) - Y_t(w_{1:f(t-p)-1}, 0_t-f(t-p)+1)).
\]

We prove Theorem 6 as follows.

**Proof of Theorem 6.** Focus on any specific \( t \in \{m + 1 : T\} \).

When \( f(t - p) \leq t - m \), both \( 0 < \Pr(W_{t-p:t} = 1_{p+1}), \Pr(W_{t-p:t} = 0_{p+1}) < 1 \). With probability \( \Pr(W_{t-p:t} = 1_{p+1}) \neq 0, 1 \{W_{t-p:t} = 1_{p+1}\} = 1 \), and \( Y_{t}^{obs} = Y_{t}(1_{m+1}) \). So \( \mathbb{E} \left[ Y_t \Pr(\{W_{t-p:t} = 1_{p+1}\}) \right] = Y_t(1_{m+1}) \). Similarly \( \mathbb{E} \left[ Y_t \Pr(\{W_{t-p:t} = 0_{p+1}\}) \right] = Y_t(0_{m+1}) \). So

\[
\mathbb{E}_{W_1:T \sim \eta_t} \left[ \left\{ Y_t \Pr(\{W_{t-p:t} = 1_{p+1}\}) \Pr(W_{t-p:t} = 1_{p+1}) - Y_t \Pr(\{W_{t-p:t} = 0_{p+1}\}) \Pr(W_{t-p:t} = 0_{p+1}) \right\} \right] = Y_t(1_{m+1}) - Y_t(0_{m+1}).
\]

When \( f(t - p) > t - m \), both \( 0 < \Pr(W_{t-p:t} = 1_{p+1}) \left| W_{t-m:f(t-p)-1} = w_{obs}^{t-m:f(t-p)-1} \right. < 1 \) and \( 0 < \Pr(W_{t-p:t} = 0_{p+1}) \left| W_{t-m:f(t-p)-1} = w_{obs}^{t-m:f(t-p)-1} \right. < 1 \). Conditional on \( W_{t-m:f(t-p)-1} = w_{obs}^{t-m:f(t-p)-1} \), we know that with probability \( \Pr(W_{t-p:t} = 1_{p+1}) \left| W_{t-m:f(t-p)-1} = w_{obs}^{t-m:f(t-p)-1} \right. \neq 0, 1 \{W_{t-p:t} = 1_{p+1}\} = 1 \), and \( Y_{t}^{obs} = Y_{t}(w_{obs}^{t-m:f(t-p)-1}, 1_t-f(t-p)+1) \). So

\[
\mathbb{E}_{W_1:T \sim \eta_t} \left[ Y_t \Pr(\{W_{t-p:t} = 1_{p+1}\}) \right] - Y_t(w_{obs}^{t-m:f(t-p)-1}, 1_t-f(t-p)+1) \left| W_{t-m:f(t-p)-1} = w_{obs}^{t-m:f(t-p)-1} \right. = 0.
\]

Similarly, we have

\[
\mathbb{E}_{W_1:T \sim \eta_t} \left[ Y_t \Pr(\{W_{t-p:t} = 0_{p+1}\}) \right] - Y_t(w_{obs}^{t-m:f(t-p)-1}, 0_t-f(t-p)+1) \left| W_{t-m:f(t-p)-1} = w_{obs}^{t-m:f(t-p)-1} \right. = 0,
\]

which finishes the proof. □
EC.6.2. Asymptotic Normality when $m$ is Misspecified

The proof of Corollary 2 consists of two parts: $p > m$ and $p < m$. When $p > m$ we consult Theorems 4 and 5. When $p < m$ we prove Corollary 2 by using Lemma EC.1. In particular, we derive $B^2_{n,k,a}$ and then construct some proper $\Delta_n, K_n,$ and $L_n$.

Proof of Corollary 2. The proof consists of two parts: $p > m$ and $p < m$. First, when $p > m$, we know that $\hat{\tau}_p = \bar{\tau}_m, \tau_p = \tau_m, \text{Var}(\hat{\tau}_p) = \text{Var}(\bar{\tau}_m)$. Due to Theorems 4 we prove part (i) the expression in (11). Due to Theorem 5 we know that

$$\frac{\hat{\tau}_p - \tau_p}{\sqrt{\text{Var}(\hat{\tau}_p)}} = \frac{\bar{\tau}_m - \tau_m}{\sqrt{\text{Var}(\bar{\tau}_m)}} \xrightarrow{D} N(0, 1).$$

Second, when $p < m$, then we follow the same trick as in Theorem 5. In the $n$-replica experiment, $\bar{\tau}_p - \mathbb{E}[\bar{\tau}_p] = \frac{1}{(n-1)p} \sum_{k=0}^{m-2} \bar{1}_k,$ and $\text{Var}(\bar{\tau}_p) = \frac{1}{(n-1)p^2} \text{Var}\left(\sum_{k=0}^{m-2} \bar{1}_k\right)$. To use the language from Lemma EC.1 denote $d = n - 1$. Denote for any $i \in [n-1], X_{n,i} = \frac{1}{(n-1)p} \bar{1}_{i-1}$. We know that $\phi = \lceil m/p \rceil$, so that $\{X_{n,1}, X_{n,2}, \ldots\}$ is a sequence of $\phi$-dependent random variables. See Table EC.8 for an illustration of $\phi$.

<td>$\bar{1}_{14}$</td>
<td>$\bar{1}_{15}$</td>
</tr>
</tbody>
</table>

In this example $\phi = \lceil m/p \rceil = 2$. The arrow above numbers 17 through 22 means that the assignment on period 17 affects the outcome on period 22. So that $\bar{1}_4$ and $\bar{1}_6$ are correlated, but $\bar{1}_3$ and $\bar{1}_5$ are independent.

First note that $B^2_n = \text{Var}(\hat{\tau}_p)$, and we calculate $B^2_{n,k,a}$ as follows. Note that $k \geq \phi + 1$.

$$B^2_{n,k,a} = \frac{1}{(n-1)^2p^2} \text{Var}\left(\sum_{i=a}^{a+k-1} \bar{1}_{i-1}\right) \leq \frac{1}{(n-1)^2p^2} \left(\sum_{i=a}^{a+k-1} \mathbb{E}[\bar{1}_{i-1}^2] + \sum_{i=a}^{a+k-2} 2\mathbb{E}[\bar{1}_{i-1}\bar{1}_i] + \ldots + \sum_{i=a}^{a+k-1+\phi} 2\mathbb{E}[\bar{1}_{i-1}\bar{1}_{i-1+\phi}]\right) \leq C\frac{p^2B^2}{(n-1)^2p^2} \cdot (k + (k - 1) + \ldots + (k - \phi)) \leq \frac{(\phi + 1)CB^2}{(n-1)^2}$$

where $C$ is some constant bounding the number of terms in each cross-product expectation $2\mathbb{E}[\bar{1}_{i-1}\bar{1}_i], \ldots, 2\mathbb{E}[\bar{1}_{i-1}\bar{1}_{i-1+\phi}]$; and $\phi + 1$ is a constant as well.

Pick $\gamma = 0, \delta = 1$, then $\Delta_n = B^3/(n-1)^3, K_n = (\phi + 1)CB^2/(n-1)^2,$ and $L_n = \text{Var}(\bar{\tau}_m)/(n-1)$.

We check that all the five conditions from Lemma EC.1 are satisfied.
1. $\mathbb{E} |X_{n,i}|^3 \leq \Delta_n = B^3/(n-1)^3$, because all the potential outcomes are bounded by $B$, so that $X_{n,i} \leq B/(n-1)$.

2. $B^2_{n,k,a}/k \leq K_n = (\phi + 1)CB^2/(n-1)^2$.

3. $B^2_n/(n-1) \geq L_n = \text{Var}(\hat{\tau}_m)/(n-1)$.

4. $K_n/L_n = (\phi + 1)CB^2/(n-1)\text{Var}(\hat{\tau}_m) = O(1)$, where the last equality is due to Assumption 4.

5. $\Delta_n/L_n^{3/2} = B^3/(n-1)^{3/2}\text{Var}(\hat{\tau}_m)^{3/2} = O(1)$, where the last equality is due to Assumption 4.

Due to Lemma 1:

$$\frac{\hat{\tau}_p - \tau_p}{\sqrt{\text{Var}(\hat{\tau}_p)}} \xrightarrow{D} \mathcal{N}(0,1).$$
