Learning-Based Distributionally Robust Model Predictive Control of Markovian Switching Systems with Guaranteed Stability and Recursive Feasibility

Mathijs Schuurmans and Panagiotis Patrinos

Abstract—We present a data-driven model predictive control scheme for chance-constrained Markovian switching systems with unknown switching probabilities. Using samples of the underlying Markov chain, ambiguity sets of transition probabilities are estimated which include the true conditional probability distributions with high probability. These sets are updated online and used to formulate a time-varying, risk-averse optimal control problem. We prove recursive feasibility of the resulting MPC scheme and show that the original chance constraints remain satisfied at every time step. Furthermore, we show that under sufficient decrease of the confidence levels, the resulting MPC scheme renders the closed-loop system mean-square stable with respect to the true-but-unknown distributions, while remaining less conservative than a fully robust approach.

I. INTRODUCTION

Stochasticity is inherent to processes emerging in a multitude of applications. Nevertheless, we are often required to performantly control such systems, using only the limited information that is available. Over the past decades, the decreasing cost of data acquisition, transmission and storage has caused a surge in research interest in data-driven approaches towards control. More recently, as the focus in research is gradually shifting towards real-life, safety-critical approaches towards control. More recently, as the focus in research is gradually shifting towards real-life, safety-critical applications, there has been an increasing concern for safe ty

Many of these approaches, however, require knowledge of the transition kernel governing the switching behavior of these systems, although in practice, such information is typically unavailable. Although recently, data-driven methods have been proposed to address this problem [5], [6], relatively little attention has gone to providing a priori guarantees on stability and constraint satisfaction.

Leveraging the framework of risk-averse model predictive control (MPC) [7]–[9] and its connection to distributionally robust (DR) optimization [10], we propose a learning-based DR MPC scheme, which is provably stable, recursively feasible and uses data gathered during operation to improve performance, rendering it less conservative than more traditional robust approaches [11]. Despite its growing popularity [9], [12]–[15], this approach has remained relatively unexplored for chance-constrained stochastic optimal control problems with ambiguity in the estimation of conditional distributions, in particular for Markovian switching dynamics.

We summarize our contributions as follows. (i) We propose a general data-driven, DR MPC scheme for Markov switching systems with unknown transition probabilities, which is compatible with the recently developed framework of risk-averse MPC [7], [8]. The resulting closed-loop system satisfies the (chance) constraints of the original stochastic problem and allows for online improvement of performance based on observed data. (ii) We state the problem in terms of an augmented state vector of constant dimension, which summarizes the available information at every time. This idea, which is closely related to that of sufficient statistics [16, Ch. 5] and belief states in partially-observed Markov decision processes [17] allows us to formulate the otherwise time-varying optimal control problem as a dynamic programming recursion. (iii) We provide sufficient conditions for recursive feasibility and mean-square stability of the proposed MPC scheme, with respect to the true-but-unknown probability distributions.

A. Notation

Let \( \mathbb{N} \) denote the set of natural numbers and \( \mathbb{N}_{>0} := \mathbb{N} \setminus \{0\} \). For two naturals \( a, b \in \mathbb{N}, a \leq b \), we denote \( \mathbb{N}_{[a,b]} := \{n \in \mathbb{N} \mid a \leq n \leq b\} \) and similarly, we introduce the shorthand \( \mathcal{W}_{[a,b]} := (w_i)_{i=a}^b \) to denote a sequence of variables. We denote the extended real line by \( \mathbb{R} := \mathbb{R} \cup \{\pm \infty\} \) and the set of nonnegative (extended) real numbers by \( \mathbb{R}_+ \) (and \( \mathbb{R}_+ \)). The cardinality of a (finite) set \( W \) is denoted by \( |W| \). We write \( f : X \to Y \) to denote that \( f \) is a set-valued mapping from \( X \) to \( Y \). Given a matrix \( P \in \mathbb{R}^{n \times m} \), we denote its \( (i,j) \)’th element by \( P_{ij} \) and its \( i \)’th row as \( P_i \in \mathbb{R}^m \). The \( i \)’th element of a vector \( x \) is denoted \( x^i \) whenever confusion with time indices is possible. \( \text{vec}(M) \) denotes the vertical concatenation of the columns of a matrix \( M \). We denote the vector in \( \mathbb{R}^k \) with all elements one as \( 1_k := (1)_{1 \leq j \leq k} \) and the probability simplex of dimension \( k \) as \( \Delta_k := \{p \in \mathbb{R}_+^k \mid p^\top 1_k = 1\} \). We define the indicator function as \( 1_{x=y} = 1 \) if \( x = y \) and 0 otherwise.
the characteristic function \( \delta_X : \mathbb{R}^n \to \mathbb{R} \) of a set \( X \subseteq \mathbb{R}^n \) is defined by \( \delta_X(x) = 0 \) if \( x \in X \) and \( \infty \) otherwise.

II. Problem statement

We consider discrete time Markovian switching systems with dynamics of the form

\[
x_{t+1} = f(x_t, u_t, w_{t+1}),
\]

where \( x_t \in \mathbb{R}^{n_x} \), \( u_t \in \mathbb{R}^{n_u} \) are the state and control action at time \( t \), respectively, and \( w_{t+1} : \Omega \to W \) is a random variable drawn from a discrete-time, time-homogeneous Markov chain \( \mathbf{w} := (w_t)_{t \in \mathbb{N}} \) defined on a probability space \( (\Omega, \mathcal{F}, \mathbb{P}) \) and taking values on \( W := \mathbb{N}_{[1,M]} \). We refer to \( w_t \) as the mode of the Markov chain at time \( t \). The transition kernel governing the Markov chain is denoted by \( P = (P_{ij})_{i,j \in W} \), where \( P_{ij} = \mathbb{P}[w_t = j \mid w_{t-1} = i] \). As such, the probability space can be constructed by taking the sample space \( \Omega = W^\infty \), \( \mathcal{F} = 2^\Omega \) and for any \( (w_t)_{t \in \mathbb{N}} \in \Omega \), \( \mathbb{P}(\omega_t)_{t \in \mathbb{N}} = \prod_{t \in \mathbb{N}} \mathbb{P}^t \), where \( \mathbb{P}^t \) is the initial distribution. For simplicity, we will assume that the initial mode is known to be \( w \), so \( \mathbb{P}_0 = (1_{i=w})_{i \in W} \). We assume that the state \( x_t \) and mode \( w_t \) are observable at time \( t \).

For a given state-mode pair \((x,w)\) in \( \mathbb{R}^{n_x} \times W \), we constrain the control action \( u \) to the set \( U(x,w) \), defined through \( n_g \) chance constraints of the form

\[
U(x,w) := \{ u \in \mathbb{R}^{n_u} : \mathbb{P}[g_t(x, u, w, v) > 0 \mid x, w] \leq \alpha_i, \forall i \in [1,n_g] \}, (2)
\]

where \( v \sim P_w \) is randomly drawn from the Markov chain \( \mathbf{w} \) in mode \( w \), and \( g_t : \mathbb{R}^{n_x} \times \mathbb{R}^{n_u} \times W^2 \to \mathbb{R} \) are constraint functions with corresponding constraint violation rates \( \alpha_i \). By appropriate choices of \( \alpha_i \) and \( g_t \), constraint (2) can be used to encode robust constraints (\( \alpha_i = 0 \) or chance constraints (\( 0 < \alpha_i < 1 \)) on the state, the control action, or both. Note that the formulation (2) additionally covers chance constraints on the successor state \( f(x,u,v) \) under input \( u \), conditioned on the current values \( x \) and \( w \).

Ideally, our goal is to synthesize \( \beta \)-optimal controllers - controllers that minimize the following stochastic optimal control problem (OCP).

**Definition II.1 (Stochastic OCP).** For a given state-mode pair \((x,w)\), the optimal cost of the stochastic OCP is

\[
V^*_N(x,w) = \min_{\pi} V^*_N(x,w), \quad (4a)
\]

subject to

\[
x_0 = x, w_0 = w, \pi = (\pi_k)_{k=0}^{N-1}, \quad (4b)
\]

\[
x_{k+1} = f(x_k, \pi_k(x_k, w_k), w_{k+1}), \quad (4c)
\]

\[
\pi_k(k, w_k) \in U(x_k, w_k), \quad \forall k \in [0,N-1]. \quad (4d)
\]

We denote by \( \Pi_N(x,w) \) the corresponding set of minimizers.

Let \( \pi^*_k(x,w)_{k=0}^{\infty} \in \Pi_N(x,w) \), so that the stochastic MPC control law is given by \( \kappa_N(x,w) = \pi^*_0(x,w) \). Sufficient conditions on the terminal cost \( \bar{V}_T \) and its effective domain \( \bar{V}_T = \mathcal{X}_T \) to ensure mean-square stability of the closed-loop system, have been studied for a similar problem set-up in [3], among others.

Both designing and computing such a stochastic MPC law requires knowledge of the probability distribution governing the state dynamics (1), or equivalently, of the transition kernel \( P \). In reality, \( P \) is typically not known but rather estimated from a finitely-sized sequence \( w_{0:T} \) of observed values. Therefore, they are subject to some level of misestimation, commonly referred to as ambiguity. The goal of the proposed MPC scheme is to model this ambiguity explicitly, in order to be resilient against it, without disregarding available statistical information. To do so, we introduce the notion of a learner state, which is very similar in spirit to the concept of a belief state, commonly used in control of partially observed Markov decision processes [17]. It can be regarded as an internal state of the controller that stores all the information required to build a set of possible conditional distributions over the next state, given the observed data. We formalize this in the following assumption.

**Assumption II.2 (Learning system).** Given a sequence \( w_{[0,t]} \) sampled from the Markov chain \( \mathbf{w} \), we can compute (i) a statistic \( s_t : W^{t+1} \to \mathcal{S} \subseteq \mathbb{R}^{n_S} \), accompanied by a vector of confidence parameters \( \beta_t \in \mathcal{I} := [0,1]^{n_S} \), which admit recursive update rules \( s_{t+1} = \mathcal{L}(s_t, w_{t+1}) \) and \( \beta_{t+1} = \mathcal{C}(\beta_t), \ t \in \mathbb{N} \); and (ii) an ambiguity set \( \mathcal{A} : \mathcal{S} \times \mathcal{W} \times [0,1] \Rightarrow \mathcal{M}_S : \{s, \omega, \beta\} \to A_S(s, \omega) \), mapping \( s_t, \omega_t \) and an element \( \beta_t \) to a convex subset of the \( M \)-dimensional probability simplex \( \Delta_M \) such that for all \( t \in \mathbb{N} \),

\[
\mathbb{P}(P_{w_t} \in A_{S,t}(s_t, w_t)) \geq 1 - \beta_t^i. \quad (5)
\]

We will refer to \( s_t \) and \( \beta_t \) as the state of the learner and the confidence vector at time \( t \), respectively.

**Remark II.3 (Confidence levels).** Two points of clarification are in order. First, we consider a vector of confidence levels, rather than a single value. This is motivated by the fact that one would often wish to assign separate confidence levels to ambiguity sets corresponding to the \( n_g \) individual chance constraints as well as the cost function of the data-driven OCP (defined in Definition III.3 below). Accordingly, we will assume that \( n_\beta = n_g + 1 \).

Second, the confidence levels are completely exogenous to the system dynamics and can in principle be chosen to be any time-varying sequence satisfying the technical conditions discussed further (see Proposition III.1 and Assumption II.4). The requirement that the sequence \( (\beta_t)_{t \in \mathbb{N}} \) can be written as
the trajectory of a time-invariant dynamical system serves to facilitate theoretical analysis of the proposed scheme through dynamic programming. Meanwhile, it covers a large class of sequences one may reasonably choose, as illustrated in Example II.5.

We will additionally invoke the following assumption on the confidence levels when appropriate.

**Assumption II.4.** The confidence dynamics $\beta_{t+1} = C(\beta_t)$ is chosen such that $\sum_{i=0}^{\infty} \beta_i^t < \infty, \forall i \in \mathbb{N}_{[1, n_\beta]}$.

In other words, we will assume that the probability of obtaining an ambiguity set that contains the true conditional distribution (expressed by (5)) increases sufficiently fast. This assumption will be of crucial importance in showing stability (see Section IV-C).

To fix ideas, consider the following example of a learning system satisfying the requirements of Assumption II.2.

**Example II.5 (Transition counts and $\ell_1$-ambiguity).** A natural choice for the learner state is to take $s_t = \text{vec}(m(t))$, where $m(t) = (m_{wv}(t))_{w,v \in \mathcal{W}} \in \mathbb{N}^{M \times M}$ contains the mode transition counts at time $t$. That is, $m_{wv}(t) = \{\tau \in \mathbb{N}_{[0, t]} : w_{\tau-1} = w, w_{\tau} = v\}$, for all $w, v \in \mathcal{W}$. Thus, since,

$$m_{wv}(t+1) = \begin{cases} m_{wv}(t) + 1 & \text{if } w_t = w, w_{t+1} = v \\ m_{wv}(t) & \text{otherwise,} \end{cases}$$

it is clear that we can indeed write $s_{t+1} = \mathcal{L}(s_t, w_t, w_{t+1})$. Furthermore, following [18], we can uniquely obtain ambiguity sets parametrized as

$$A_{\beta_t}^i(s_t, w_t) := \{ p \in \Delta_M : \|p - \hat{p}_{w_t}\|_1 \leq r_{w_t}(s_t, \beta_t^i) \},$$

for $i \in \mathbb{N}_{[1, n_\beta]}$, where $\hat{p}_{w_t}$ is the empirical estimate of the $w_t$th row of the transition kernel (initialized to the uniform distribution if no transitions in mode $w_t$ have been observed) and the radii $r_{w_t}(s_t, \beta_t^i)$ are chosen to satisfy (5) by means of basic concentration inequalities, yielding a closed-loop expression $O(\sqrt{-m_{wv}(t)-1}\ln(\beta_t^i))$, with $m_{wv} = \sum_{u \in \mathcal{W}} m_{wuv}$. Both of these quantities depend solely on the learner state $s_t$, the confidence level $\beta_t$ and the current mode $w_t$. Finally, the sequence of the confidence levels $\beta_t$ remains to be selected. One particular family of sequences satisfying the additional requirement of Assumption II.4 is $\beta_t = b e^{-n^t}$, with some arbitrarily chosen parameters $0 \leq b \leq 1$ and $\tau > 0$. Alternatively, if a slower decay rate is preferred, one may choose a sequence of the form $\beta_t = b(1 + t)^{-1}$, with parameters $0 \leq b \leq 1$, $q > 1$. The former can trivially be identified with a stable linear system; the latter can be described by the recursion $\beta_{t+1} = b(\beta_t^q + b^{1/q})^{-q}$, $b_0 = b$, both satisfying the requirements of Assumption II.2.

Equipped with a generic learning system of this form, our aim is to find a data-driven approximation to the stochastic OCP defined by (4), which asymptotically attains the optimal cost while preserving stability and constraint satisfaction during closed-loop operation.

III. DATA-DRIVEN MODEL PREDICTIVE CONTROL

Given a learning system satisfying Assumption II.2, we define the augmented state $z_t = (x_t, s_t, b_t, w_t) \in \mathcal{Z} := \mathbb{R}^{n_x} \times \mathbb{S} \times \mathbb{I} \times \mathcal{W}$, which evolves over time according to the dynamics

$$z_{t+1} = f(z_t, u_t, w_{t+1}) := f(x_t, s_t, w_{t+1}) = L(s_t, w_{t+1}) C(\beta_t)_{w_{t+1}}^{-1},$$

where $w_{t+1} \sim P_{w_t}$, for $t \in \mathbb{N}$. Consequently, our scheme will result in a feedback law $\kappa : \mathcal{Z} \rightarrow \mathbb{R}^{n_u}$. To this end, we will formulate a DR counterpart to the stochastic OCP (4), in which the expectation operator in the cost and the conditional probabilities in the constraint will be replaced by operators that account for ambiguity in the involved distributions.

A. Ambiguity and risk

In order to reformulate the cost function (3), we first introduce an ambiguous conditional expectation operator, leading to a formulation akin to the Markovian risk measures utilized in [7], [19]. Consider a function $\xi : \mathcal{Z} \times \mathcal{W} \rightarrow \mathbb{R}$, defining a stochastic process $(\xi_t)_{t \in \mathbb{N}} = (\xi(z_t, w_{t+1}))_{t \in \mathbb{N}}$ on $(\Omega, \mathcal{F}, \mathcal{P})$, and suppose that the augmented state $z_t = z = (x, s, \beta, w)$ is given. For simplicity, let us assume for the moment that $\beta \in [0, 1]$ is scalar; the following definition can be repeated for each component in the general case. The ambiguous conditional expectation of $\xi(z, v)$, given $z$ is

$$\rho_{s,w}^\beta(\xi(z, v)) := \max_{p \in A_\beta(s, w)} \mathbb{E}_P[p\xi(z, v)|z] = \max_{p \in A_\beta(s, w)} \sum_{v \in \mathcal{W}} P_{w,v}\xi(z, v).$$

Trivially, it holds that if the $w$'th row of the transition matrix lies in the corresponding ambiguity set: $P_{w} \in A_\beta(s, w)$, then

$$\rho_{s,w}^\beta(\xi(z, v)) \geq \mathbb{E}_{P_w}[\xi(z, v)|z] = \sum_{v \in \mathcal{W}} P_{w,v}\xi(z, v).$$

Note that the function $\rho_{s,w}^\beta$ defines a coherent risk measure [20, Sec. 6.3]. We say that $\rho_{s,w}^\beta$ is the risk measure induced by the ambiguity set $A_\beta(s, w)$.

A similar construction can be carried out for the chance constraints (2). In their standard form, chance constraints lead to nonconvex, nonsmooth constraints. For this reason, they are commonly approximated using risk measures [21]. Particularly, the (conditional) average value-at-risk (at level $\hat{\alpha} \in (0, 1]$ and with reference distribution $p \in \Delta_M$) of $\xi$ is the coherent risk measure

$$\text{AVAR}_{\hat{\alpha}}^p(\xi(z, v)|z) = \begin{cases} \min_{t \in \mathbb{R}} t + \frac{1}{\alpha} \mathbb{E}_P[\xi(z, v) - t | z] & , \hat{\alpha} \neq 0 \\ \max_{v \in \mathcal{W}} \mathbb{E}_P[\xi(z, v)] & , \hat{\alpha} = 0. \end{cases}$$

It can be shown (e.g., [20, sec. 6.2.4]) that if $p = P_w$, then the following implication holds tightly

$$\text{AVAR}_{\hat{\alpha}}^p(\xi(z, v)|z) \leq 0 \Rightarrow \mathbb{P}[(\xi(z, v) \leq 0 | z) \geq 1 - \hat{\alpha}].$$

By exploiting the dual risk representation [20, Thm 6.5], the left-hand inequality in (9) can be formulated in terms of only linear constraints [8]. As such, it can be used as a tractable
surrogate for the original chance constraints, given perfect probabilistic information. Accounting also for the ambiguity in the knowledge of \(P_w\) through \(A_{\beta}(s, w)\), we define

\[
\tilde{\rho}^\beta_{s,w} [\xi(z, v)] := \max_{p \in A_{\beta}(s, w)} \text{AVR}_p^\beta [\xi(z, v) \mid z] \leq 0. \quad (10)
\]

The function \(\tilde{\rho}^\beta_{s,w}\) in turn defines a coherent risk measure.

We now present a condition on the choice of \(\alpha\) under which a constraint of the form (10) can be used as a tractable and safe approximation of a chance constraint when there is ambiguity in the probability distribution.

**Proposition III.1.** Let \(\beta, \alpha \in [0,1]\) be given values with \(\beta < \alpha\). Consider the random variable \(s : \Omega \to S\), denoting an (a priori unknown) learner state satisfying **Assumption II.2**, i.e., \(\mathbb{P}[P_w \in A_{\beta}(s, w)] \geq 1 - \beta\). If the parameter \(\alpha\) is chosen to satisfy \(0 \leq \alpha \leq \frac{\alpha - \beta}{\beta} \leq 1\), then, for an arbitrary function \(g : Z \times W \to \mathbb{R}\), the following implication holds:

\[
\tilde{\rho}^\beta_{s,w} [g(z, v)] \leq 0, \ a.s. \Rightarrow \mathbb{P}[g(z, v) \leq 0 \mid x, w] \geq 1 - \alpha. \quad (11)
\]

**Proof.** If \(\tilde{\rho}^\beta_{s,w} [g(z, v)] \leq 0, \ a.s.,\) then by (9)-(10),

\[
\mathbb{P}[g(z, v) \leq 0 \mid x, w, P_w \in A_{\beta}(s, w)] \geq 1 - \alpha, \ a.s.
\]

Therefore,

\[
\mathbb{P}[g(z, v) \leq 0 \mid x, w] \geq \mathbb{P}[g(z, v) \leq 0 \mid x, w, P_w \in A_{\beta}(s, w)] \mathbb{P}[P_w \in A_{\beta}(s, w)] \geq (1 - \alpha)(1 - \beta).
\]

Requiring that \((1 - \alpha)(1 - \beta) \geq (1 - \alpha)\) immediately yields the sought condition. \(\square\)

Notice that the implication (11) in **Proposition III.1** provides an *a priori* guarantee, since the learner state is considered to be random. In other words, the statement is made before the data is revealed. Indeed, for a given learner state \(s\) and mode \(w\), the ambiguity set \(A_{\beta}(s, w)\) is fixed and therefore, the outcome of the event \(E = \{P_w \in A_{\beta}(s, w)\}\) is determined. Whether (11) then holds for these fixed values depends on the outcome of \(E\). This is naturally reflected through the above condition on \(\alpha\) which implies that \(\alpha \leq \alpha\), and thus tightens the chance constraints that are imposed for a *fixed* \(s\). Hence, the possibility that for this particular \(s\), the ambiguity set may not include the conditional distribution, is accounted for. This effect can be mitigated by decreasing \(\beta\) at the cost of a larger ambiguity set. A more detailed study of this trade-off is left for future work.

**B. Risk-averse optimal control**

We are now ready to describe the DR counterpart to the OCP (4), which, when solved in receding horizon fashion, yields the proposed data-driven MPC scheme.

For a given augmented state \(z = (x, s, \beta, w) \in Z\), we use (10) to define the DR set of feasible inputs \(\mathcal{U}(z)\) in correspondence to (2). Without loss of generality, let us assume that the \(i\)th entry \(\beta^i\) in the confidence vector \(\beta\) corresponds to the \(i\)th constraint, so that

\[
\mathcal{U}(z) := \{u \mid \tilde{\rho}^\beta_{s,w} [g_i(x, u, v)] \leq 0, \forall i \in \{1, n_g\}\}. \quad (12)
\]

**Remark III.2.** The parameters \(\alpha_i\) remain to be chosen in relation to the confidence levels \(\beta\) and the original violation rates \(\alpha_i\). In light of **Proposition III.1**, \(\alpha_i = \frac{\alpha - \beta}{\beta}\) yields the least conservative choice. This choice is valid as long as it is ensured that \(\beta^i \leq \alpha_i\).

Let us denote the remaining element of the confidence vector \(\beta\) corresponding to the cost by \(\beta^0\). Using (7), we can then express the DR cost of a policy \(\pi = (\pi_k)_{k=0}^{N-1}\) as

\[
\tilde{V}^\pi_N(z) := \ell(x_0, u_0, w_0) + \rho^0_{s_0,w_0} [\ell(x_1, u_1, w_1) + \rho^0_{s_1,w_1} [\cdots + \rho^0_{s_N,w_N} [\ell(x_{N-1}, u_{N-1}, w_{N-1}) + \rho^0_{s_N,w_N} [V^\pi_N(x_N, s_N, \beta, w_N)] ]]]], \quad (13)
\]

where \(z_0 = z, z_{k+1} = \hat{f}(z_k, u_k, w_{k+1})\) and \(u_k = \pi_k(z_k)\), for all \(k \in \mathbb{N}_{[0,N-1]}\). In **Section IV**, conditions on the terminal cost \(\hat{V}_T : Z \to \mathbb{R}^+ : (x, s, \beta, w) \to V_T(x, w) + \delta^T(x, s, \beta)\) and its domain are provided in order to guarantee recourse feasibility and stability of the MPC scheme defined by the following OCP.

**Definition III.3 (DR-OCP).** Given an augmented state \(z \in Z\), the optimal cost of the distributionally robust optimal control problem (DR-OCP) is

\[
\hat{V}_N(z) = \min_{\pi} \tilde{V}^\pi_N(z) \quad (14a)
\]

subject to

\[
(x_0, s_0, \beta_0, w_0) = z, \quad \pi = (\pi_k)_{k=0}^{N-1},
\]

\[
z_{k+1} = \hat{f}(z_k, \pi_k(z_k), u_{k+1}),
\]

\[
\pi_k(z_k) \in \mathcal{U}(z_k), \forall u \in \{0,1\} \quad (14d)
\]

for all \(k \in \mathbb{N}_{[0,N-1]}\). We denote by \(\hat{V}_N(z)\) the corresponding set of minimizers.

We thus define the data-driven MPC law analogously to the stochastic case as

\[
\hat{u}_N(z) = \hat{u}_N^\alpha(z), \quad (15)
\]

where \((\hat{f}^\alpha_N(z))_{k=0}^{N-1} \in \tilde{V}_N(z)\). At every time \(t\), the data-driven MPC scheme thus consists of (i) computing a control action \(u_t = \hat{u}_N(z_t)\) and applying it to the system (1); (ii) observing the outcome of \(w_{t+1} \in \mathcal{W}\) and the corresponding next state \(x_{t+1} = \hat{f}(x_t, u_t, w_{t+1})\); and (iii) updating the learner state \(s_{t+1} = \mathcal{L}(s_t, u_t, w_{t+1})\) and the confidence levels \(\beta_{t+1} = \mathcal{C}(\beta_t)\), gradually decreasing the size of the ambiguity sets.

**Remark III.4 (Scenario tree representations).** Since \(W\) is a finite set, the possible realizations of \(w_{[0,N]}\), given \(z_0\) can be enumerated such that the corresponding predicted states and controls can be represented on a scenario tree, which is a directed graph with a single root node, corresponding to \(w_0\). Each node is connected to a number of child nodes, representing the possible realizations of the stochastic process at the next time step [22]. It therefore suffices to optimize over a finite number (equal to the number of nodes in the tree) of control actions instead of infinite-dimensional control laws.
When represented in this manner, it is apparent that (14) falls
within the class of risk-averse, risk-constrained optimal control
problems, described in [8]. In particular, the constraints
(14d) at stage k can be represented in the framework of [8]
as nested risk constraints which are compositions of a set
of conditional risk mappings. In this case, the composition
consists of \( k - 1 \) max operators over values on the nodes
in the first stages and a conditional risk mapping based on
(10) at stage k. This is in line with the observations of [23, Sec. 7.1]. Consequently, if the risk measures employed in the
definition of the DR-OCP (14) belong to the broad family of
conic risk measures and the dynamics \( f(\cdot, \cdot, w) \), \( w \in W \)
are linear, then, using the reformulations in [8], (14) can be cast
as a convex conic optimization problem. This is the case
for many commonly used coherent risk measures, including
the risk measure induced by the \( \ell_1 \)-ambiguity set discussed in
Example II.5 (see [24] for a numerical case study). For
nonlinear dynamics, the problem is no longer convex but
Can in practice still be solved effectively with standard NLP
solvers.

IV. THEORETICAL ANALYSIS

A. Dynamic programming

To facilitate theoretical analysis of the proposed MPC
scheme, we represent (14) as a dynamic programming
recursion, similarly to [7]. We define the Bellman operator
\( T(V(z)) := \min_{u \in U(z)} f(z, u, v) + \rho_z w[V(f(z, u, v))] \),
where \( z = (x, s, \beta, w) \in Z \) are fixed quantities and \( v \sim P_v \).
We denote by \( S(V(z)) \) the corresponding set of minimizers.
The optimal cost \( V_N(z) \) of (14) is obtained through the iteration,
\[
\hat{V}_k = T \hat{V}_{k-1}, \quad \hat{V}_0 = \hat{V}_f, \quad k \in [1, N].
\]
Similarly, \( \hat{Z}_k := \text{dom} \hat{V}_k \) is given recursively by
\[
\hat{Z}_k := \left\{ z \left| \exists u \in U(z) : f(z, u, v) \in \hat{Z}_{k-1}, \forall v \in W \right\} \right. \tag{16}
\]

Now consider the stochastic closed-loop system
\[
z_{t+1} = \hat{f}^{\hat{R}_N}(z_t, w_{t+1}) := \hat{f}(z_t, \hat{R}_N(z_t), w_{t+1}), \tag{17}
\]
where \( \hat{R}_N(z_t) \in S(\hat{V}_{N-1}(z)) \) is an optimal control law
obtained by solving the data-driven DR-OCP of horizon \( N \)
in receding horizon.

B. Constraint satisfaction and recursive feasibility

In order to show existence of \( \hat{R}_N \in S(\hat{V}_{N-1}) \) at every time
step, Proposition IV.2 will require that \( \hat{X}_N \) is a robust
controller invariant set. We define robust control invariant for
the augmented control system under consideration as follows.

Definition IV.1 (Robust invariance). A set \( R \subseteq Z \) is a robust
control invariant (RCI) set for the system (6) if for all \( z \in R \),
\( \exists u \in U(z) \) such that \( f(z, u, v) \in R, \forall v \in W \). Similarly, \( R \)
is a robust positive invariant (RPI) set for the closed-loop
system (17) if for all \( z \in R \), \( \hat{f}^{\hat{R}_N}(z, v) \in R, \forall v \in W \).

Since \( U \) consists of conditional risk constraints, Definition
IV.1 provides a DR counterpart to the notion of stochastic
robust invariance in [25]. It is thus less conservative than
the more classical notion of robust invariance for a set \( R_x \),
obtained by imposing that \( x \in R_x \Rightarrow \exists u : g_i(x, u, w, v) \leq 0, \)
for all \( i \in N \). In fact, \( R_x \times S \times I \times W \) is covered by Definition IV.1.

Proposition IV.2 (Recursive feasibility). If \( \hat{X}_N \) is an RCI set
for (6), then (14) is recursively feasible. That is, feasibility of
DR-OCP (14) for some \( z \in Z \), implies feasibility for
\( z^+ = \hat{f}^{\hat{R}_N}(z, v), \) for all \( v \in W, N \in \mathbb{N} > 0 \).

Proof. We first show that if \( \hat{X}_N \) is RCI, then so is \( \hat{Z}_N \). This is
done by induction on the horizon \( N \) of the OCP.

Base case \((N = 0)\). Trivial, since \( \hat{Z}_0 = \hat{X}_N \).

Induction step \((N \Rightarrow N + 1)\). Suppose that for some \( N \in \mathbb{N} \), \( \hat{Z}_N \) is RCI for (6). Then, by definition of \( \hat{Z}_{N+1} \), there
exists for each \( z \in \hat{Z}_{N+1} \), a nonempty set \( U_N(z) \subseteq U(z) \)
such that for every \( u \in U_N(z) \) and for all \( v \in W \), \( z^+ \in \hat{Z}_N \),
where \( z^+ = f(z, u, v) \). Furthermore, the induction
hypothesis \( (\hat{Z}_N) \) is RCI, implies that there also exists a
\( u^+ \in U(z^+) \) such that \( f(z, u^+, v^+) \in \hat{Z}_N(v^+), \forall v^+ \in W \).
Therefore, \( z^+ \) satisfies the conditions defining \( \hat{Z}_{N+1} \).
In other words, \( \hat{Z}_{N+1} \) is RCI.

The claim follows from the fact that for any \( N > 0 \) and \( z \in \hat{Z}_N \), \( u = \hat{R}_N(z) \in S(\hat{V}_{N-1}(z)) \subseteq U_R(z) \), as any
other choice of \( u \) would yield infinite cost in the definition
of the Bellman operator.

□

Corollary IV.3 (Chance constraint satisfaction). If Proposition
IV.2 holds, then by Proposition III.1, the stochastic
process \((z_t)_{t \in \mathbb{N}} = (x_t, s_t, \beta_t, w_t)_{t \in \mathbb{N}} \) satisfying dynamics (17)
satisfies the nominal chance constraints
\[
P[\alpha_i(x_t, \hat{R}_N(z_t), w_{t+1}) > 0 | x_t, w_t] < \alpha_i, \tag{18}
\]
a.s., for all \( i \in N \).

We conclude this section by emphasizing that although the
MPC scheme guarantees closed-loop constraint satisfaction,
it does so while being less conservative than a fully robust
approach, which is recovered by taking \( \mathcal{A}_{\alpha}(s, w) = \Delta_M \)
for all \( s, w, \beta \). It is apparent from (10) and (12), that for all
other choices of the ambiguity set, the set of feasible control
actions will be larger (in the sense of set inclusion).

C. Stability

We will now provide sufficient conditions on the control
setup under which the origin is mean-square stable (MSS) for
(17), i.e., \( \lim \mathbb{E}[\|x_t\|^2] = 0 \) for all \( x_0 \) in some specified
compact set containing the origin.

Our main stability result, stated in Theorem IV.5, hinges
in large on the following lemma, which relates risk-square
stability [7, Lem. 5] of the origin for the autonomous system
(17) to stability in the mean-square sense, based on the
statistical properties of the ambiguity sets.

Lemma IV.4 (DR MSS condition). Suppose that Assumption
II.4 holds and that there exists a nonnegative, proper function
\( V : Z \to \mathbb{R}_+ \), such that (i)
\[
dom V \subseteq \mathcal{X} \times S \times I \times W \text{ is RPI for system (17), where } \mathcal{X} \subset \mathbb{R}_{\mathbb{N}_1}^n \text{ is a compact set containing the origin;} \tag{19}
\]
(ii)
\[ \rho_{\text{MPC}}^\infty \{ \tilde{f}^{\mathcal{N}}(z, v), v \} \rightarrow V(z) \leq -c\|x\|^2, \text{ for some } c > 0, \text{ for all } z \in \text{dom } V; \ (iii) \ V \text{ is uniformly bounded on its domain, i.e., there exists a } \tilde{V} \geq 0, \text{ such that } V(z) \leq \tilde{V} \text{ for all } z \in \text{dom } V. \text{ Then, } \lim_{t \to \infty} \mathbb{E}[\|x_t\|^2] = 0 \text{ for all } z_0 \in \text{dom } V, \text{ where } (z_t)_{t \in \mathbb{N}} = (x_t, s_t, \beta_t, w_t)_{t \in \mathbb{N}} \text{ is the stochastic process governed by dynamics (17).} \]

Proof. See Appendix. \hfill \square

Theorem IV.5 (MPC stability). Suppose that Assumption II.4 is satisfied, and let \( \tilde{Z} := \tilde{X} \times \mathcal{S} \times \tilde{X} \times \mathcal{W} \subseteq \text{dom } \tilde{V} \) be an RPI set for (17), where \( \tilde{X} \subseteq \mathbb{R}^{n_x} \) is a compact set containing the origin. Assume furthermore that the following statements hold: (i) \( \tilde{T} \tilde{V} \leq \tilde{V} \); (ii) \( c\|x\|^2 \leq f(x, w) \) for some \( c > 0 \) for all \( z = (x, w, \beta, s) \in \text{dom } \tilde{V} \) and all \( w \in \tilde{U}(z) \). (iii) \( \tilde{V} \) is locally bounded in \( \tilde{Z} \). Then, the origin is MSS for the MPC-controlled system (17), for all initial states \( z_0 \in \tilde{Z} \).

Proof. The proof is along the lines of that of [7, thm. 6] and shows that \( \tilde{V} \) satisfies the conditions of Lemma IV.4. Details are in the Appendix. \hfill \square

V. CONCLUSIONS

We presented a distributionally robust MPC strategy for Markovian switching systems with unknown transition probabilities subject to general chance constraints, using data-driven, high-confidence ambiguity sets, we derive a DR counterpart to a nominal stochastic MPC scheme. We show that the resulting scheme provides a priori guarantees on closed-loop constraint satisfaction and mean-square stability of the true system, without requiring explicit knowledge of the transition probabilities.

REFERENCES

APPENDIX

Proof of Lemma IV.4.

Let \( (z_t)_{t \in \mathbb{N}} = (x_t, s_t, \beta_t, w_t)_{t \in \mathbb{N}} \) denote the stochastic process satisfying dynamics (17), for some initial state \( z_0 \in \text{dom } V. \) For ease of notation, let us define \( V_t := V(z_t), t \in \mathbb{N}. \) Due to nonnegativity of \( V, \)

\[
\begin{align*}
\mathbb{E} \left[ \sum_{t=0}^{k-1} \|x_t\|^2 \right] & \leq \mathbb{E} \left[ V_k + \sum_{t=0}^{k-1} \|x_t\|^2 \right] \\
& = \mathbb{E} \left[ V_k - V_0 + \sum_{t=0}^{k-1} \|x_t\|^2 \right] + V_0,
\end{align*}
\]

where the second equality follows from the fact that \( V_0 \) is deterministic. By linearity of the expectation, we can in turn write

\[
\begin{align*}
\mathbb{E} \left[ V_k - V_0 + \sum_{t=0}^{k-1} \|x_t\|^2 \right] & = \mathbb{E} \left[ \sum_{t=0}^{k-1} (V_{t+1} - V_t) + \|x_t\|^2 \right] \\
& = \sum_{t=0}^{k-1} \mathbb{E} \left[ V_{t+1} - V_t + \|x_t\|^2 \right].
\end{align*}
\]

Therefore,

\[
\mathbb{E} \left[ \sum_{t=0}^{k-1} \|x_t\|^2 \right] - V_0 \leq \sum_{t=0}^{k-1} \mathbb{E} \left[ V_{t+1} - V_t + c \|x_t\|^2 \right].
\]
Recall that \( \beta^0 \) denotes the coordinate of \( \beta \) corresponding to the risk measures in the cost function (13). Defining the event \( E_t := \{ \omega \in \Omega \mid P_{w_t(\omega)} \in A_{\beta^0}(s_t(\omega), w_t(\omega)) \} \), and its complement \( \neg E_t = \Omega \setminus E_t \), we can use the law of total expectation to write

\[
E[V_{t+1} - V_t] = E[V_{t+1} - V_t \mid E_t] P[E_t] + E[V_{t+1} - V_t \mid \neg E_t] P[\neg E_t].
\]

By condition (i), \( P[\neg E_t] < \beta^0_t \). From condition (i), it follows that \( x_t \in \text{dom} \ V, \forall t \in \mathbb{N} \) and that there exists a \( \hat{V} \geq 0 \) such that \( V(z) \leq \hat{V} \), for all \( z \in \text{dom} \ V \). Therefore, \( E[V_{t+1} - V_t \mid \neg E_t] \leq \hat{V} \). Finally, by condition (ii), \( E[V_{t+1} - V_t \mid E_t] \leq E[-c \| x_t \|^2] \). Thus,

\[
E[V_{t+1} - V_t] \leq E[-c \| x_t \|^2 \mid E_t] P[E_t] + \hat{V} \beta^0_t.
\]

This allows us to simplify expression (18) as

\[
E\left[\sum_{t=0}^{k-1} ||x_t||^2 - V_0 \right] \\
\leq \sum_{t=0}^{k-1} -c E[||x_t||^2 \mid E_t] P[E_t] + \hat{V} \beta^0_t + c E[||x_t||^2] \\
\leq \sum_{t=0}^{k-1} -c E[||x_t||^2 \mid E_t] P[E_t] + \hat{V} \beta^0_t \\
\ \\
= \sum_{t=0}^{k-1} \hat{V} \beta^0_t + c E[||x_t||^2 \mid \neg E_t] P[\neg E_t] \\
\leq \sum_{t=0}^{k-1} \beta^0_t (\hat{V} + c E[||x_t||^2 \mid \neg E_t]) \\
\]

Since \( x_t \in \mathcal{X}, t \in \mathbb{N} \), and \( \mathcal{X} \) is a compact set containing the origin, there exists an \( r \geq 0 \) such that \( \| x_t \|^2 \leq r \). Therefore,

\[
E\left[\sum_{t=0}^{k-1} ||x_t||^2 \right] \leq \frac{\hat{V} + r}{c} \sum_{t=0}^{k-1} \beta^0_t, \\
\]

which remains finite as \( k \to \infty \), since \( (\beta^0_t)_{t \in \mathbb{N}} \) is summable. Thus, necessarily, \( \lim_{k \to \infty} E[||x_t||^2] = 0 \). \( \square \)

**Proof of Theorem IV.5.**

First, note that using the monotonicity of coherent risk measures [20, Sec. 6.3, (R2)], a straightforward inductive argument allows us to show that under Condition (i),

\[
\mathbf{T} \hat{V}_N \leq \hat{V}_N, \quad \forall N \in \mathbb{N}. \tag{19}
\]

Since \( \hat{Z} \subseteq \text{dom} \hat{V}_N \), recall that by definition (16), we have for any \( z \in \hat{Z} \) that

\[
\hat{V}_N(z) = \ell(x, \hat{r}_N(z), w) + \rho^\beta_{w,s} \left[ \hat{V}_{N-1} \left( \tilde{f}^{\hat{r}_N}(z, v) \right) \right] .
\]

Therefore, we may write

\[
\rho^\beta_{w,s} \left[ \hat{V}_N(\tilde{f}^{\hat{r}_N}(z, v)) \right] - \hat{V}_N(z) \\
= \rho^\beta_{w,s} \left[ \hat{V}_N(\tilde{f}^{\hat{r}_N}(z, v)) \right] - \ell(x, \hat{r}_N(z), w) \\
- \rho^\beta_{w,s} \left[ \hat{V}_{N-1} \left( \tilde{f}^{\hat{r}_N}(z, v) \right) \right] \leq -\ell(x, \hat{r}_N(z), w) \leq -c \| x \|^2,
\]

where the first inequality follows by (19) and monotonicity of coherent risk measures. The second inequality follows from Condition (ii). Therefore, \( V : z \to \hat{V}_N(z) + \delta_\hat{Z}(z) \) satisfies the conditions of Lemma IV.4 and the assertion follows. \( \square \)
