Trading off Accuracy for Speedup: Multiplier Bootstraps for Subgraph Counts

Qiaohui Lin, Robert Lunde, Purnamrita Sarkar
Department of Statistics and Data Sciences
The University of Texas at Austin

Abstract

We propose a new class of multiplier bootstraps for count functionals. We consider bootstrap procedures with linear and quadratic weights. These correspond to the first and second-order terms of the Hoeffding decomposition of the bootstrapped statistic arising from the multiplier bootstrap, respectively. We show that the quadratic bootstrap procedure achieves higher-order correctness for appropriately sparse graphs. The linear bootstrap procedure requires fewer estimated network statistics, leading to improved accuracy over its higher-order correct counterpart in sparser regimes. To improve the computational properties of the linear bootstrap further, we consider fast sketching methods to conduct approximate subgraph counting and establish consistency of the resulting bootstrap procedure. We complement our theoretical results with a simulation study and real data analysis and verify that our procedure offers state-of-the-art performance for several functionals.

1 Introduction

From social networks like Twitter and Facebook to biological networks like protein-protein interaction networks and brain networks, network data has become ubiquitous in a broad range of real-world applications.

Count functionals play a pivotal role in the analysis of network data. In biological networks, it is believed that certain subgraphs may represent functional subunits within the larger system (Milo et al., 2002; Chen and Yuan, 2006; Daudin et al., 2008; Kim et al., 2014). In social networks, the frequency of triangles provides information about the likelihood of mutual friendships (Newman, 2001; Myers et al., 2014; Ugander et al., 2011). At a more theoretical level, count functionals may be viewed as network analogs of the moments of a random variable. Thus, a method of moments approach may be used to estimate the underlying model under suitable conditions (Bickel et al., 2011). Furthermore, the convergence of graph sequences (at least dense sequences) may be stated in terms of the convergence of a collection of subgraph frequencies (Borgs et al., 2008).

Given their practical and theoretical importance, quantifying the uncertainty of count functionals is naturally of substantial interest. While real-world networks share
many qualitative features (see for example, Newman (2003)), they often vary substan-
tially in terms of size, given by the number of vertices in the network, and sparsity
level, given by the number of edges relative to the number of vertices. For networks
of small to moderate size, inferential methods that are highly accurate are advanta-
geous; for sparse, massive networks, one needs to simultaneously consider computa-
tional tractability and accuracy.

To meet these diverse needs in real-world applications, we develop a new family
of bootstrap procedures for count functionals of networks, ranging from a very fast
and consistent randomized linear bootstrap to a fast quadratic bootstrap procedure that
offers improved accuracy for moderately sparse networks. Both procedures may be
viewed as approximations to a multiplier bootstrap method in which each potential
subgraph in the network is perturbed by the product of independent multiplier random
variables. This multiplier bootstrap is closely related to a bootstrap method for U-
statistics (see for example, Bose and Chatterjee (2018)). Under the sparse graphon
model (see Section 3.1), subgraph counts may be viewed as U-statistics perturbed by
asymptotically negligible noise, allowing the adaptation of bootstrap methods for U-
statistics to the network setting.

One of the main theoretical contributions of our paper is deriving (uniform) Edge-
worth expansions for the quadratic bootstrap. Edgeworth expansions may be viewed
as a refinement of the Normal approximation that accounts for skewness of the dis-
tribution of interest; an excellent treatment of this topic in the IID setting is given by
Hall (2013). By establishing an Edgeworth expansion for the quadratic bootstrap and
showing that it is very close to the Edgeworth expansion of the sampling distribution,
we show that the bootstrap is higher-order correct under certain sparsity conditions,
meaning that it offers a faster convergence rate in the Kolmogorov distance than the
Berry-Esseen bound. Establishing higher-order correctness is often key to justifying
the (typically) computationally intensive bootstrap over a Normal approximation.

Edgeworth expansions of network moments were first studied by Zhang and Xia
(2020). The authors show that the network noise has a smoothing effect that allows
them to bypass the typical Cramér condition, which is restrictive in the network set-
ing. We also bypass the Cramér’ condition for the bootstrap, but by using a different
approach. We choose a continuous multiplier that matches the first three moments of
the data; it is well-known that continuous random variables satisfy Cramér’s condi-
tion. To derive our Edgeworth expansion for the bootstrap, we also build upon results
from Wang and Jing (2004) for order two U-statistics. It turns out that network noise,
particularly when the graph is sparse, causes certain terms related to our Edgeworth
expansion to blow up. While the details are technical, we show that a valid Edgeworth
expansion is still possible, with the sparsity level directly affecting the convergence
rate.

On the other hand, the linear bootstrap is not higher-order correct in any sparsity
regime as it only aims to approximate the leading term of the Hoeffding decomposition.
However for sparser networks, we observe an interesting phenomenon; in this case, the
linear bootstrap outperforms the higher-order correct variants in terms of accuracy.

1 More precisely, the linear and quadratic bootstraps may be viewed as first and second-order terms of a
Hoeffding decomposition for the multiplier bootstrap, respectively.
In essence, the extra terms in the quadratic bootstrap cannot be estimated accurately enough for sparse graphs and consequently these terms hurt more than they help in sparse regimes. For sparser graphs, we propose speeding up the linear bootstrap further by randomizing the precomputation of count functionals. By randomizing to an extent that is appropriate for the sparsity level of the network, we sacrifice very little statistical performance for vastly reduced computation. Thus, the approximate linear bootstrap is well-suited for scalable inference on large, sparse graphs.

In addition to obtaining Edgeworth expansions for count statistics, we also obtain Edgeworth expansions for smooth functions of U-statistics. We show that, under suitable sparsity assumptions, the cumulative distribution function of smooth functions arising from the quadratic bootstrap match this asymptotic expansion and are therefore higher-order correct. In this setting, obtaining analytical expressions for Edgeworth expansions are cumbersome, whereas the bootstrap is automatic and user-friendly.

We will now provide a roadmap for the rest of the paper. In Section 2 we discuss related work, focusing on the emerging area of resampling methods for network data. The problem setting and our bootstrap proposal is introduced in Section 3. In Section 5, we present our main results, which establish higher-order correctness for our bootstrap procedures. In Section 6, we present a simulation study, which shows that our procedure exhibits strong finite-sample performance in various settings. Finally, in Section 7, we use our bootstrap methods to compare networks representing the voting similarities of U.S. Congress from 1949 to 2012.

### 2 Related Work

The first theoretical result for resampling network data was attained by Bhattacharyya and Bickel (2015). Their subsampling proposals involve expressing the variance of a count functional in terms of other count functionals and estimating the non-negligible terms through subsampling. Lunde and Sarkar (2019) show that it is also possible to conduct inference using quantiles of the subsampling distribution as in Politis and Romano (1994). Green and Shalizi (2017) propose a bootstrap based on the empirical graphon. Lin et al. (2020) establish the validity of the network jackknife for count functionals.

Levin and Levina (2019) study a two-step procedure that is closely related to our linear bootstrap procedure. The above authors propose estimating the latent positions with the adjacency spectral embedding in the first step (see, for example, Athreya et al. (2018)) and resampling the corresponding U-statistic with the estimated positions in the second step. They derive theoretical results under the assumption that the rank is known of the random dot product graph model is known and finite. In contrast, our procedures do not impose assumptions on the spectral properties of the underlying graphon.

Zhang and Xia (2020) establish conditions under which the empirical graphon bootstrap exhibits higher order correctness. They require Crámer’s condition for the leading term of the Hoeffding projection, which is restrictive for network models. The empirical Edgeworth expansion proposal, which has been considered in other settings (see, for example, Putter and Van Zwet (1998) and Maesono (1997)), involves stude-
tizing by a variance estimate and plugging in estimated moments into an Edgeworth expansion. While our rates are less sharp than existing work, we see that multiplier bootstraps can handle functions of subgraph counts more easily than empirical Edgeworth corrections. We show that even for smooth functions, our proposed bootstrap procedures exhibit higher-order correctness. While computationally more demanding, work in other settings suggests that the bootstrap may have some favorable properties over empirical Edgeworth expansions (see, for example, Hall (1990)).

On the mathematical side, the analysis of our multiplier bootstrap involves Edgeworth expansions for weighted sums. Prior work (c.f. Bai and Zhao (1986) and Liu (1988)) suggests that establishing sharp rates of convergence for the independent but non-identically distributed sequences is more difficult, with the above references establishing a $o(n^{-1/2})$ error bound instead of the $O(n^{-1})$ bound for i.i.d. sequences. Edgeworth expansions for multiplier bootstraps of (degree 2) U-statistics are also considered in Wang and Jing (2004).

From the computational standpoint, (Chen and Kato, 2019) presented a randomized algorithm to estimate high dimensional U-statistics from a subsample of subsets from the set of all subsets of a given size. We propose a different sampling method that exploits the structure of U-statistics and draws random permutations instead of subsets. Empirically, we show that this method provides faster computation over subset sampling.

3 Problem Setup and Notation

3.1 The Sparse Graphon Model

Let $\{A^{(n)}\}_{n \in \mathbb{N}}$ denote a sequence of $n \times n$ binary adjacency matrices and let $w : [0,1]^2 \to \mathbb{R}$ be a symmetric measurable function such that $\int_0^1 \int_0^1 w(u,v) \, du \, dv = 1$ and $w(u,v) \leq C$ for some $1 \leq C < \infty$. We assume that $A^{(n)}$ is generated by the following model:

$$A^{(n)}_{ij} = A^{(n)}_{ji} \sim \text{Bernoulli}(\rho_n w(X_i, X_j))$$

where $X_i, X_j \sim \text{Unif}[0,1]$, $\rho_n \to 0$, and $A^{(n)}_{ii} = 0$. While closely related models were considered by Bollobas et al. (2007), Hoff et al. (2002), and Borgs et al. (2019) this particular parameterization was introduced by Bickel and Chen (2009). We will refer to \[[\text{I}]\] as the sparse graphon model. Sparse graphons are a very rich class of models, subsuming many widely used models, including stochastic block models and their variants (Holland et al., 1983; Karrer and Newman, 2011; Airoldi et al., 2008), and (generalized) random dot product graphs (Young and Scheinerman, 2007; Rubin-Delanchy et al., 2018). More generally, sparse graphons are natural models for graphs that exhibit vertex exchangeability; the functional form is motivated by representation theorems for exchangeable arrays established by Aldous (1981) and Hoover (1979). The parameter $\rho_n = P(A_{ij} = 1)$ determines the sparsity level of the sequence $\{A^{(n)}\}_{n \in \mathbb{N}}$. Many real world graphs are thought to be sparse, with $o(n^2)$ edges; $\rho_n \to 0$ is needed for graphs generated by \[[\text{I}]\] to exhibit this behavior.
While boundedness of the graphon is a common assumption in the statistics literature (see, for example, the review article by Gao and Ma (2019)), it should be noted that unbounded graphons are known to be more expressive. As noted by Borgs et al. (2019), unboundedness allows graphs that exhibit power-law degree distributions, a property that bounded graphons fail to capture. For mathematical expedience, in the present article, we focus on the bounded case, but we believe that our analysis may be extended to sufficiently light-tailed unbounded graphons as well.

3.2 Count Functionals

Now we will introduce notation related to our functional of interest. Let \( R \) denote the adjacency matrix of a subgraph of interest, with \( r \) vertices and \( s \) edges. Let \( A^{(n)}_{i_1,\ldots,i_r} \) denote the adjacency matrix formed by the node subset \( \{i_1,\ldots,i_r\} \) and for each such \( r \)-tuple, define the following function:

\[
H(A^{(n)}_{i_1,\ldots,i_r}) := 1(A^{(n)}_{i_1,\ldots,i_r} \cong R)
\]

where we say that \( A^{(n)}_{i_1,\ldots,i_r} \cong R \) if there exists a permutation function \( \pi \) such that \( A^{(n)}_{\pi(i_1),\ldots,\pi(i_r)} = R \). Our count functional, which we denote \( \hat{T}_n(R) \), or \( \hat{T}_n \) when there is no ambiguity, is formed by averaging over all \( r \)-tuples in the graph.

\[
\hat{T}_n := \frac{1}{\binom{n}{r}} \sum_{1 \leq i_1 < i_2 < \ldots < i_r \leq n} H(A^{(n)}_{i_1,\ldots,i_r})
\]  

(2)

Now let \( V(Q) \subset \{1,\ldots,n\} \) denote the vertex set associated with a graph \( Q \) and \( E(Q) \subset V(Q) \times V(Q) \) the corresponding vertex set. Furthermore, let \( \overline{E(Q)} \) denote the complement of \( E(Q) \) given the universal set \( V(Q) \times V(Q) \). Define the following kernel:

\[
h_n(X_{i_1},\ldots,X_{i_r}) := E\{H(A^{(n)}_{i_1,\ldots,i_r}) | X_{i_1},\ldots,X_{i_r}\}
\]

\[
= \sum_{Q-R, V(Q) = \{i_1,\ldots,i_r\}} \prod_{(i,j) \in E(Q)} \rho_n w(X_i,X_j) \prod_{(i,j) \in \overline{E(Q)}} \{1 - \rho_n w(X_i,X_j)\}
\]  

(3)

For readability, we will suppress the \( n \) in \( h_n \) in what follows. Now, define the following (conventional) \( U \)-statistic:

\[
T_n := \frac{1}{\binom{n}{r}} \sum_{1 \leq i_1 < i_2 < \ldots < i_r \leq n} h(X_{i_1},\ldots,X_{i_r})
\]

For notational convenience we will refer to \( h(X_{i_1},\ldots,X_{i_r}) \) by \( h(X_S) \), where \( S \) is the subset \( \{i_1,\ldots,i_r\} \). Denote \( \theta_n := E\{h(X_S)\} \). We see that \( \theta_n/\rho_n \to \mu \). This can be thought of as a normalized subgraph density that we want to infer. The normalization by \( \rho_n^* \) is to ensure that our functional converges to an informative non-zero quantity.
By a central limit theorem for U-statistics (Hoeffding, 1948), it can be shown that \((T_n - \theta_n)/\sigma_n\) is asymptotically Gaussian. Here we have:

\[
\begin{align*}
r_n^2 = & \text{var} \{E \{h(X_S) \mid X_1\} \}, \quad \sigma_n^2 = r_n^2 r_n^2 / n \\
\end{align*}
\]

Furthermore, Bickel et al. (2011) show that, \((\hat{T}_n - T_n)/\sigma_n = o_P(1)\) under mild sparsity conditions for a wide range of subgraphs. Thus, we may view \((T_n - \theta_n)/\sigma_n = (\hat{T}_n - T_n)/\sigma_n + (T_n - \theta_n)/\sigma_n\) as a U-statistic perturbed by asymptotically negligible noise.

### 3.3 Preliminaries of proposed bootstrap procedures

In order to estimate the subgraph density, we will consider the following multiplier bootstrap procedures. In what follows let \(\xi_1, \ldots, \xi_n\) be i.i.d. continuous random variables with mean \(\mu = 1\) and central moments \(\mu_2 = 1\), and \(\mu_3 = 1\). An example of such a random variable is the product \(Z\) of two independent Normal random variables \(X\) and \(Y\), defined below:

\[
X \sim N(1, 1/2) \quad Y \sim N(1, 1/3) \quad Z = XY 
\]

Let \(\xi_{i_1 \ldots i_r}\) denote \(\xi_{i_1} \times \ldots \times \xi_{i_r}\) and define the following multiplicative bootstrap:

\[
\hat{T}_{n,M} = \hat{T}_n + \frac{1}{r} \sum_{1 \leq i_1 < i_2 < \ldots < i_r} \xi_{i_1 \ldots i_r} \cdot \left\{ H(A_{i_1 \ldots i_r}^{(n)}) - \hat{T}_n \right\} 
\]

Our multiplicative bootstrap is motivated by Hoeffding’s decomposition (see Supplementary Section A for details). The first two terms of the decomposition for \(T_n - \theta_n\) are given by:

\[
\begin{align*}
g_1(X_i) &= E \{h(X_i, X_{i_2} \ldots X_{i_r}) \mid X_i\} - \theta_n \\
g_2(X_i, X_j) &= E \{h(X_i, X_j, X_{i_3} \ldots X_{i_r}) \mid X_i, X_j\} - g_1(X_i) - g_1(X_j) - \theta_n, \\
\end{align*}
\]

leading to the representation:

\[
T_n - \theta_n = \frac{r}{n} \sum_{i=1}^{n} g_1(X_i) + \frac{r(r-1)}{n(n-1)} \sum_{i<j} g_2(X_i, X_j) + o_p \left( \frac{\rho_n^2}{n} \right) 
\]

Similarly, conditional on the data, it can be shown that we have the following bootstrap analog. Let:

\[
\begin{align*}
\hat{g}_1(i) &= \frac{1}{r-1} \sum_{1 \leq i_2 < \ldots < i_r \leq n, i_r \neq i} \left\{ H(A_{i,i_2 \ldots i_r}^{(n)}) - \hat{T}_n \right\} \\
\hat{g}_2(i, j) &= \frac{1}{r-2} \sum_{1 \leq i_3 < \ldots < i_r \leq n, i_r \neq i, i_u \neq j} \left\{ H(A_{i,i_2 \ldots i_r}^{(n)}) - \hat{T}_n \right\} \\
\hat{g}_2(i, j) &= \hat{g}_2(i, j) - \hat{g}_1(i) - \hat{g}_1(j) 
\end{align*}
\]
Furthermore, Eq 8 can be used to standardize the bootstrap replicates using the following estimate of $\tau_n$ (Eq 4):

$$\hat{\tau}_n^2 = \sum_i \hat{g}_1(i)^2$$  \hspace{1cm} (11)

We now present the Hoeffding decomposition for our bootstrap statistic. The proof is deferred to the Supplementary Material.

**Lemma 1.** We have the following decomposition:

$$\hat{T}_{n,M}^* - \hat{T}_n = \frac{r}{n} \sum_{i=1}^{n} (\xi_i - 1) \cdot \hat{g}_1(i) + \frac{r(r-1)}{n(n-1)} \sum_{i<j} (\xi_i \xi_j - \xi_i - \xi_j + 1) \cdot \hat{g}_2(i,j)$$

$$+ O_P \left( \rho_n^{-1/2} \delta(n, \rho_n, R) \right),$$  \hspace{1cm} (12)

where $\delta(n, \rho_n, R)$ is defined as follows:

$$\delta(n, \rho_n, R) = \begin{cases} 1 & \text{R is acyclic} \\ \frac{n\rho_n}{1} & \text{R is a simple cycle} \\ \frac{n\rho_n^{3/2}}{1} & \text{R is a simple cycle} \end{cases}$$

Although the quadratic term in the above expansion may seem different from Eq 7, some manipulation yields that $\sum_{i<j} (\xi_i \xi j - 1) \cdot \hat{g}_2(i,j)$ is equivalent to $\sum_{i<j} (\xi_i \xi j - 1) \cdot \hat{g}_2(i,j)$, which is similar to the corresponding term in the Hoeffding decomposition of the U statistic (see Eq 7).

Viewing $\hat{g}_1(i)$ and $\hat{g}_2(i,j)$ as estimates of $g_1(X_i)$ and $g_2(X_i, X_j)$, respectively, it is clear that our weighted bootstrap version encapsulates important information about $T_n - \theta_n$. The above decomposition also suggests that one may approximate the non-negligible terms more directly. Ignoring the remainder term, we arrive at the linear and quadratic bootstrap estimates:

$$\hat{T}_{n,L}^* = \hat{T}_n + \frac{r}{n} \sum_{i=1}^{n} (\xi_i - 1) \cdot \hat{g}_1(i)$$  \hspace{1cm} (13)

$$\hat{T}_{n,Q}^* = \hat{T}_{n,L}^* + \frac{r(r-1)}{n(n-1)} \sum_{i<j} (\xi_i \xi_j - \xi_i - \xi_j + 1) \cdot \hat{g}_2(i,j).$$  \hspace{1cm} (14)

Now that we have introduced the main concepts, we are ready to present the our bootstrap procedures. We first present the results on our fast linear bootstrap method.

### 4 Proposed algorithms

In this section, we present a fast linear bootstrap method using Eq 13. Recall that the multiplicative bootstrap requires to precompute $\hat{T}_n$ and $\hat{g}_1(i)$ for all $i$. This computation is $O(n^r)$ in the worst case. In addition to this, the computation complexity for MB-L is $O(Bn)$. Therefore, in what follows, our goal is to reduce the precomputation time.
4.1 Fast linear bootstrap

We propose a randomized approximation for $\hat{T}_n$ and $\hat{g}_1(i)$. The main idea is that an average over all size $r$ subset can be written as an average over $n!$ permutations (see Hoeffding [1948], Lunde and Sarkar [2019]).

For any $i \in \{1, \ldots, n\}$, denote the set of all subsets of size $r - 1$ taken from $\{1, \ldots, i - 1, i + 1, \ldots n\}$ as $S_{-i}$. Denote $H(A_{i,i+1,\ldots,i_r})$ for $S = \{i_2, \ldots, i_r\} \in S\{\ldots\}$ as $H(A_{S,i})$.

Denote

$$H_1(i) = \frac{1}{(n-1)!} \sum_{S \in S\{\ldots\}} H(A_{S \cup i}).$$

One can also write $H_1(i)$ as follows:

$$H_1(i) = \frac{1}{(n-1)!} \sum_{\pi} H_{\pi}(i).$$

Here $H_{\pi}(i) = \sum_{S \in S_{\pi}} H(A_{S \cup i})$, where $S_{\pi}$ denotes the set of all disjoint subsets $\{\pi(i-1)(r-1)+1, \ldots, \pi(r-1)\}$, $i = 1, \ldots, \frac{n-1}{r-1}$ obtained from permutation $\pi$. Now let $\pi_j$ be a permutation picked with replacement and uniformly at random from the set of all permutations of $\{1, \ldots, n\}\setminus i$.

Our randomized algorithm makes use of this structure and draws $j = 1, \ldots, N$ independent permutations $\pi_j$. We compute

$$\tilde{H}_1(i) = \frac{\sum_j H_{\pi_j}(i)}{N}; \quad \tilde{T}_n = \frac{1}{n} \sum_{i=1}^{n} \tilde{H}_1(i)$$ (15)

To calculate $\tilde{H}_1(i)$, for each $i$, we permute the node set excluding $i$ for $N$ times and for each of these permutations $\pi$ we check the disjoint set $S_{\pi}$ for count functionals. Thus, the complexity for calculating $\tilde{H}_1(i)$ is now $O\left(\frac{N n^r}{r}\right)$. From $\{\tilde{H}_1(i)\}_{i=1}^n$, $\tilde{T}_n$ is calculated from their mean and $\tilde{T}_n$ is defined as

$$\tilde{T}_n = \tilde{T}_n + \frac{r}{n} \sum_{i=1}^{n} (\xi_i - 1)\{\tilde{H}_1(i) - \tilde{T}_n\}.$$ (17)

We denote this algorithm by MB-$L$-apx and explicitly provide the algorithm in Algorithm 1.

4.2 Higher order correct bootstrap procedures

In this section, we present our proposed Quadratic, and Multiplicative algorithms (MB-$Q$, and MB-$M$).
Algorithm 1. Construction of linear or approximated linear bootstrap estimate of CDF

Input: Network $A$, motif $R$, number of resamples $B$, approximate $\in \{True, False\}$, parameter $u$

If approximate = True

Compute $\{H_1(i)\}_{i=1}^n, \bar{T}_n$ (Eq 15) and $\bar{\tau}_n$ (Eq 16)

Else

Compute $\hat{T}_n, (Eq 2), \{\hat{g}_1(i)\}_{i=1}^n$ (Eq 8) and $\hat{\tau}_n$ (Eq 11)

End

for $j \in \{1, \ldots, B\}$ do

Generate $n$ weights $\xi^{(j)} = \{\xi^{(j)}_i, i = 1, \ldots, n\}_{j=1}^B$ using Eq 5

If approximate = True

$T^*_n(j) \leftarrow T^*_{n,L}$ (using Eq 17)

Else

$T^*_n(j) \leftarrow T^*_{n,L}$ (using Eq 13)

End

Return $\frac{1}{B} \sum_j 1 \left( \frac{T^*_n(j) - \bar{T}_n}{\bar{\tau}_n} \leq u \right)$

Algorithm 2. Construction of quadratic or multiplier bootstrap estimate of CDF

Input: Network $A$, motif $R$, number of resamples $B$, choice of bootstrap procedure $a \in \{M, Q\}$, parameter $u$

Compute $\hat{T}_n, (Eq 2), \{\hat{g}_1(i)\}_{i=1}^n$ (Eq 8), $\{\hat{g}_2(i, j)\}_{i=1}^n$ (Eq 10) and $\hat{\tau}_n$ (Eq 11)

for $j \in \{1, \ldots, B\}$ do

Generate $n$ weights $\xi^{(j)} = \{\xi^{(j)}_i, i = 1, \ldots, n\}_{j=1}^B$ using Eq 5

If $a = M$

$T^*_n(j) \leftarrow T^*_{n,M}$ (using Eq 6)

Else

$T^*_n(j) \leftarrow T^*_{n,Q}$ (using Eq 14)

End

Return $\frac{1}{B} \sum_j 1 \left( \frac{T^*_n(j) - \bar{T}_n}{\bar{\tau}_n} \leq u \right)$

For a given network, we first compute $\hat{T}_n$ and $\bar{\tau}_n$ (see Eqs 2, 11). For each algorithm, we generate $B$ samples of $n$ weights $\{\xi^{(j)}_i, i = 1, \ldots, n\}_{j=1}^B$ from the Gaussian Product distribution (see beginning of Section 3.3). For each of these, $MB-M$, $MB-Q$, and $MB-L$ respectively values $T^*_{n,M}, T^*_{n,Q}$ and $T^*_{n,L}$. From the $B$ values one then constructs the CDF of the statistic in question, after shifting and normalizing it appropriately. We present this in Algorithm 2.

While we divide by $\frac{1}{n^{1/2}} \bar{\tau}_n$, note that our statistic is not studentized, which is why our expansion differs from previous work. Conditioned on the data, $\bar{\tau}_n$ is constant for the bootstrap samples.
Note that $\text{MB-M}$ is computationally expensive since it involves computing the expression in Eq 6 for each sample of the bootstrap. The worst-case complexity of evaluating all $C^n$ subsets of nodes is $n^r$. For $B$ bootstrap samples, the worst-case timing of $\text{MB-M}$ will be $Bn^r$. In comparison, for $\text{MB-L}$ and $\text{MB-Q}$, we can precompute the $\hat{g}_1(i)$ and $\hat{g}_2(i,j)$ values in $O(n^r)$ time. After that, the time per bootstrap sample is linear for $\text{MB-L}$ and quadratic for $\text{MB-Q}$. Thus worst-case computational complexity for a dense network for $\text{MB-M}$, $\text{MB-Q}$, and $\text{MB-L}$ is $O(Bn^r)$, $Bn^2$ and $Bn$ respectively, excluding precomputation time (which is $O(n^r)$ in the worst case). In contrast, the approximate linear bootstrap algorithm $\text{MB-L-apx}$ takes $O({Nn/r})$ computation for each $\tilde{H}_1(i)$, $i \leq n$. Note that we can easily parallelize this step. With $C$ cores, that will lead to a computational cost of $Nn^2/rC$.

5 Main Results

5.1 Theoretical guarantees for approximate linear bootstrap

In this section, we show that the linear bootstrap statistic using the approximate moments in Eq 15 is indeed first-order correct under appropriate sparsity conditions as long as $N$ is large enough. For theorem 2, we will use the following assumption:

Assumption 1. We assume the following:
(a) $\tau_n/\rho_n^s \geq c > 0$, for some constant $c$.
(b) $0 < w(u,v) < C$, for some constant $C$.

The first condition is a standard non-degeneracy assumption for U-statistics.

Theorem 2. Suppose Assumption 1 is satisfied, the weights $\xi_1, \ldots, \xi_n$ are generated from a distribution such that $E[\xi_1] = 1$, $E[(\xi_1 - 1)^2] = 1$, $E[(\xi_1 - 1)^3] < \infty$. Further assume that $\rho_n = \omega(1/n)$ when $R$ is acyclic or $\rho_n = \omega(n^{-1/r})$ when $R$ is cyclic. Then,

(a) The standardized bootstrap distribution converges at the Berry-Esseen rate to a standard Normal:

$$\sup_{u \in \mathbb{R}} \left| P^* \left( \frac{\tilde{T}_{n,L}^* - \tilde{T}_n}{\sqrt{\text{var}(\tilde{T}_{n,L}^* \mid A,X)}} \right) \right| - \Phi(u) = O_P \left( n^{-1/2} \right),$$

where $P^*(\cdot)$ denotes the conditional measure conditioned on $A$ and $X$.

(b) The variance of $\tilde{T}_{n,L}^*$ satisfies:

$$\frac{\text{var}(\tilde{T}_{n,L}^* \mid A,X)}{\sigma_n^2} = 1 + O_P \left( \frac{1}{n\rho_n} \right) + O_P \left( \frac{1}{Nn\rho^s} \right).$$

(c) If $\tilde{T}_{n,L}^*$ in Eq 18 is replaced by the $T_{n,L}^*$ computed without approximate moments and $\tilde{T}_n$ is replaced by $\tilde{T}_n$, then Eq 18 holds. We also have:

$$\frac{\text{var}(T_{n,L}^* \mid A,X)}{\sigma_n^2} = 1 + O_P \left( \frac{1}{n\rho_n} \right).$$
Remark 1 (Comparison to existing work on approximating $U$-statistics). In Chen and Kato (2019), the authors draw $\omega(n)$ subsets of size $r$ from all $\binom{n}{r}$ subsets with replacement to estimate an incomplete $U$-statistic. The total number of subsets we examine for approximating a local count statistic is also $\omega(n)$. Comparing our Theorem 2 with their result shows that both methods require similar computation to achieve consistency. However, practically, drawing $Nn/r$ subsamples with replacement seems to be slower than drawing a $N$ permutations and then dividing each into disjoint subsets (see Fig 3).

Remark 2 (Approximation quality). In the above theorem, if $Nn/r = \omega(n^{-s})$, then the ratio of the variance of the linear bootstrap statistic and that of the count statistic in question converges in probability to one. This shows that for sparse networks we need larger number of random permutations to estimate the moments.

Remark 3 (Broader Sparsity Regime). Eq 20 suggests that the linear bootstrap without approximation gives a consistent estimate of variance even when the average degree $n\rho_n$ goes to infinity. This shows a stark contrast to Theorem 4 and Corollary 5 where the average degree has to much larger to achieve higher-order correctness. It should be noted that the arguments in Zhang and Xia (2020) require $\rho_n = \omega(1/\sqrt{n})$ for acyclic graphs and therefore, their convergence rates for empirical Edgeworth expansions do not hold in sparser regimes.

Remark 4 (Conditions on subgraphs). While we state Theorem 2 for acyclic and general cyclic subgraphs, it should be noted that weaker sparsity conditions are possible for simple cycles. In particular, for simple cycles one only needs $n^{s-1} < \rho_n \rightarrow \infty$.

5.2 Results on higher-order correct bootstrap procedures

Below, we establish an Edgeworth expansion normalized by the true standard deviation, which is more appropriate for our purposes. Since estimating the variance leads to a non-negligible perturbation, the polynomials in our expansion differ from those established by Zhang and Xia (2020). All proofs and details are deferred to Supplement Section C and Section D. In what follows, let $F_n(u)$ denote the CDF of $\hat{T}_n$ and $G_n(u)$ denote the Edgeworth expansion of interest, given by:

$$G_n(u) = \Phi(u) - \phi(t) \left( \frac{u^2 - 1}{6n^{1/2} \tau_n} \right) \left[ E\{g_3(X_1)\} + 3(r-1)E\{g_1(X_1)g_1(X_2)g_2(X_1, X_2)\} \right].$$

(21)

Furthermore, recall $\tau_n^2 = \text{var}[E\{h(X_S) | X_1\}]$ denotes the asymptotic variance of the $U$-statistic. Throughout this section, we will impose the following condition:

Assumption 2. For acyclic $R$, $\rho_n = \omega(n^{-1/2})$ and for cyclic $R$, $\rho_n = \omega(n^{-1/r})$.

The above is a nontrivial sparsity assumption that we require for higher-order correctness. We have the following result:
Proposition 3. Let $G_n$ be the Edgeworth expansion defined in Eq \ref{eq:expansion} and let $R$ be a fixed subgraph. Suppose that Assumptions 1 and 2 hold. Further suppose that $\rho_n = O(1/\log n)$ or Cramér’s condition holds, i.e. $\limsup_{t \to \infty} |E\{e^{itg_1(X_1)/\tau_n}\}| < 1$ then we have,
\[
\sup_u |F_n(u) - G_n(u)| = O(M(n, \rho_n, R))
\] (22)
where:
\[
M(n, \rho_n, R) = \begin{cases} n\rho_n & R \text{ is acyclic} \\ \frac{1}{n\rho_n} & R \text{ is cyclic} \end{cases}
\] (23)

Now, we will state our bootstrap approximation results. We will first show that conditioned on the network, and latent variables, the CDF of MB-Q matches the asymptotic expansion in Eq \ref{eq:expansion} where the true moments are replaced by their empirical versions. In what follows, let $\hat{E}_n(\cdot)$ denote the expectation operator with respect to the empirical measure of $A$ and $X$. Define
\[
\hat{G}_n(u) = \Phi(u) - \frac{(u^2 - 1)\phi(u)}{6n^{1/2}\tau_n^3} \left[ \hat{E}_n\{g_1(i)^3\} + 3(r - 1)\hat{E}_n\{g_1(i)g_1(j)g_2(i,j)\} \right],
\] (24)
where we have:
\[
\hat{E}_n\{g_1(i)^3\} = \frac{1}{n} \sum_{i=1}^{n} \hat{g}_1(i)^3,
\]
\[
\hat{E}_n\{g_1(i)g_1(j)g_2(i,j)\} = \frac{1}{(n^2)^{1/2}} \sum_{1 \leq i < j \leq n} \hat{g}_2(i,j)\hat{g}_1(i)\hat{g}_1(j).
\] (25)

Theorem 4. If Assumptions 1 and 2 are satisfied, the weights $\xi_1, \ldots, \xi_n$ are generated from a non-lattice distribution (see Feller (1971) page 539) such that $E[\xi_1] = 1$, $E[(\xi_1 - 1)^2] = 1$, $E[(\xi_1 - 1)^3] = 1$, then
\[
\sup_u \left| P^*\left(\frac{\hat{T}_n - \hat{T}_n}{\hat{\sigma}_n} \leq u\right) - \hat{G}_n(u) \right| = o_P(n^{-1/2}) + O_P\left(\frac{\log n}{n^{2/3}\rho_n}\right),
\]
where $P^*(\cdot)$ denotes the conditional probability of event $(\cdot)$ conditioned on $A$ and $X$.

Remark 5. While the above theorem is for standardized bootstraps, our proof may be adapted to yield an analogous statement for bootstraps studentized by a variance estimator inspired by the Delta Method. In essence, the studentized bootstrap may also be expressed as a weighted U-statistic and a negligible remainder term, allowing the use of similar proof techniques.

Remark 6. While Zhang and Xia (2020) establish higher-order correctness under milder sparsity conditions for subsampling and the empirical graphon, our result here does not require Cramér’s condition for $g_1(X_1)$, which is an important feature for network applications. Our simulation study suggests that our rate here can be improved, but we leave this to future work.
Combining Theorem 4 with the Hoeffding decomposition in Eq 12, we obtain the corollary below for the multiplicative bootstrap. Since the remainder term in the Hoeffding decomposition concentrates slowly for well-connected subgraphs of sparser networks, we impose additional assumptions on the subgraph to maintain the rate from the previous theorem.

**Corollary 5.** Suppose Assumption 1 is satisfied and either $R$ is acyclic and $\rho_n = \omega(1/\sqrt{n})$ or $R$ is a simple cycle and $\rho_n = \omega(n^{-1/r})$. Further suppose that the weights $\xi_1, \ldots, \xi_n$ are generated from a non-lattice distribution with such that $E(\xi_1) = 1$, $E((\xi_1 - 1)^2) = 1$, $E((\xi_1 - 1)^3) = 1$, then,

$$\sup_u \left| P^* \left( \frac{\hat{T}^{\ast}_{n,M} - \hat{T}_{n}}{\hat{\sigma}_n} \leq u \right) - \hat{G}_n(u) \right| = o_P(n^{-1/2}) + O_P \left( \frac{\log n}{n^{2/3}\rho_n} \right),$$

where $P^*(\cdot)$ denotes the conditional probability of event $\cdot$ conditioned on $A$ and $X$ and $\hat{\sigma}_n = \hat{\tau}_n/n^{1/2}$.

The proof of Theorem 4 build upon results from [Wang and Jing 2004], which establish higher-order correctness of the weighted bootstrap for order-2 U-statistics. However, certain terms that appear as constants in their work blow up when perturbed by sparse network noise. To deal with this issue, we control various terms unique to the network setting and use different arguments to control the overall error rate.

As in [Zhang and Xia 2020], it is also possible to consider an empirical Edgeworth expansion in which the expectations of interest are estimated. We state a result for this procedure below:

**Lemma 6.** Under the assumptions in Assumption 7 and 2, we have

$$\sup_u |\hat{G}_n(u) - F_n(u)| = O_P(M(n, \rho_n, R))$$

The lemma above suggests that the empirical Edgeworth expansion achieves a better rate than the bootstrap procedures considered. In the experimental section, we see that the empirical Edgeworth expansion (EW) in fact achieves the smallest error when the network is dense enough. However, for smooth functions of counts, it is cumbersome to derive such expansions and the bootstrap emerges as a strong practical alternative that offers improved accuracy over a Normal approximation in certain regimes.

### 5.3 Smooth functions of count statistics

In network science, the transitivity coefficient, which may be defined as a smooth function of triangles and two-stars, is commonly used to quantify how much nodes in the network cluster together. Given the importance of such functions in applications, accurate inference for these parameters is naturally of substantial interest. Our results in this section establish the quadratic and multiplicative bootstraps as accurate and user-friendly methods for smooth functions of counts that sidestep the cumbersome computation of gradients and moments required by empirical Edgeworth expansions.
Our theorem below is the first result in the literature for Edgeworth expansions of smooth functions of count statistics. In fact, to the best of our knowledge, Edgeworth expansions for smooth functions of U-statistics were not derived previously. It turns out that arguments to derive Edgeworth expansions for smooth functions of IID means such as those in Hall (2013) depend heavily on the properties of cumulants of independent random variables and require multivariate Edgeworth expansions, complicating extensions even to U-statistics. In contrast, we adapt flexible Edgeworth expansion results of Jing and Wang (2010) to approximate non-negligible terms arising from a Taylor approximation of the smooth functional.

To state our result, we need to introduce some additional notation. Let $u$ denote a $d$-dimensional vector of count functionals, let $u^*$ be a vector of corresponding bootstrap statistics generated by either the multiplier bootstrap $\hat{T}^*_n,M$ or the quadratic bootstrap $\hat{T}^*_n,Q$. Furthermore, let $f : \mathbb{R}^d \rightarrow \mathbb{R}$ denote the function of interest. Consider the following smooth function of bootstrapped count frequencies:

$$S^*_n = n^{1/2} \left\{ f(u^*) - f(u) \right\} / \hat{\sigma}_f$$

(26)

where $\hat{\sigma}_f$ is used to standardize the bootstrap version and will be defined shortly. The standard Delta Method involves a first-order Taylor expansion; to attain higher-order correctness, we need to consider a second-order expansion. We use the following notation to denote the derivatives of interest evaluated at the expectation $E(u) = \mu$:

$$a_i = \frac{\partial f(x)}{\partial x(i)} \bigg|_{x=\mu}, \quad a_{ij} = \frac{\partial^2 f(x)}{\partial x(i) \partial x(j)} \bigg|_{x=\mu}, \quad (27)$$

Define corresponding gradients for the bootstrap evaluated at the count functional $u$:

$$\hat{a}_i = \frac{\partial f(x)}{\partial x(i)} \bigg|_{x=u}, \quad \hat{a}_{ij} = \frac{\partial^2 f(x)}{\partial x(i) \partial x(j)} \bigg|_{x=u}. \quad (28)$$

Define the asymptotic variance of the smooth function as:

$$\sigma^2_f = \sum_{i=1}^{d} \sum_{j=1}^{d} a_i a_j E \left( \frac{r_i g_1^{(i)}(l)}{\rho_n^i} \frac{r_j g_1^{(j)}(l)}{\rho_n^j} \right), \quad (29)$$

and define the empirical analogue of the asymptotic variance as:

$$\hat{\sigma}^2_f = \sum_{i=1}^{d} \sum_{j=1}^{d} \hat{a}_i \hat{a}_j \hat{E}_n \left( \frac{r_i \hat{g}_1^{(i)}(l)}{\rho_n^i} \frac{r_j \hat{g}_1^{(j)}(l)}{\rho_n^j} \right). \quad (30)$$

We are now ready to state our Edgeworth expansion for the smooth function of the bootstrapped statistics. For simplicity, we state the Edgeworth expansion for $u^*$ resulting from the quadratic bootstrap procedure MB-Q. A similar result holds for MB-M, albeit under stronger conditions on the subgraph like those imposed in Corollary 5.
Theorem 7. Suppose that $\sigma_f > 0$, the function $f$ has three continuous derivatives in a neighbourhood of $\mu$ and suppose that the weights $\xi_1, \ldots, \xi_n$ are generated from a non-lattice distribution such that $E(\xi_1) = 1$, $E((\xi_1 - 1)^2) = 1$, $E((\xi_1 - 1)^3) = 1$. Further suppose that Assumptions 1 and 2 are satisfied. Then, we have:

$$P^*(S_n^* \leq x) = \Phi(x) + n^{-1/2} \phi(x) \{ \tilde{A}_1 \tilde{\sigma}_f^{-1} + \frac{1}{6} \tilde{A}_2 \tilde{\sigma}_f^{-3} (x^2 - 1) \} + O_P \left( \frac{\log n}{n^{2/3} \rho_n} \right).$$

where:

$$\tilde{A}_1 = \frac{1}{2} \sum_{i=1}^d \sum_{j=1}^d \hat{a}_{ij} \hat{E}_n \left( \frac{r_i \hat{g}_1^{(i)}(l) r_j \hat{g}_1^{(j)}(l)}{\rho_n^{\sigma_n}} \right),$$

$$\tilde{A}_2 = \sum_{i=1}^d \sum_{j=1}^d \sum_{k=1}^d \hat{a}_{ij} \hat{a}_{jk} \hat{E}_n \left( \frac{r_i \hat{g}_1^{(i)}(l) r_j \hat{g}_1^{(j)}(l) r_k \hat{g}_1^{(k)}(l)}{\rho_n^{\sigma_n}} \right) + 3 \sum_{i=1}^d \sum_{j=1}^d \sum_{k=1}^d \sum_{l=1}^d \hat{a}_{ij} \hat{a}_{jk} \hat{E}_n \left( \frac{r_i \hat{g}_1^{(i)}(l) r_k \hat{g}_1^{(k)}(l)}{\rho_n^{\sigma_n}} \right) \hat{E}_n \left( \frac{r_j \hat{g}_1^{(j)}(l) r_l \hat{g}_1^{(l)}(l)}{\rho_n^{\sigma_n}} \right) + 3 \sum_{i=1}^d \sum_{j=1}^d \sum_{k=1}^d \hat{a}_{ij} \hat{a}_{jk} \hat{E}_n \left( \frac{r_i \hat{g}_1^{(i)}(l) r_j \hat{g}_1^{(j)}(l) (m) r_k (r_k - 1) \hat{g}_2^{(k)}(l, m)}{\rho_n^{\sigma_n}} \right).$$

In the Supplementary Material, we derive Edgeworth expansions for smooth functions of U-statistics corresponding to the non-negligible component of the count functional in Proposition[E.1] and show that our bootstrap version of the Edgeworth expansion is close to this expansion in Proposition[E.4]. To derive Edgeworth expansions for the U-statistic, we impose a non-lattice condition; however, it is likely that this assumption can be removed for count functionals if a smoothing argument used in Zhang and Xia (2020) is adapted.

6 Simulation Study

We consider two graphons in our simulation study. The first graphon we consider is a Stochastic Blockmodel (SBM), introduced by [Holland et al. (1983)]. The SBM is a popular model for generating networks with community structure. The SBM may be parameterized by a $K \times K$ probability matrix $B$ and a membership probability vector $\pi$ that takes values in the probability simplex in $\mathbb{R}^K$. Let $Y_1, \ldots, Y_n \in \{1, \ldots, K\}$ be random variables indicating the community membership of the corresponding node, with probability given by the entries of $\pi$. Under this model, we have that $P(A_{ij}^{(n)} = 1 \mid Y_i = u, Y_j = v) = \rho_{B_{uv}}$. In our simulations, we consider a two block SBM (SBM-G) with $B_{ij} = 0.6$ for $i = 1, j = 1$ and 0.2 for the rest. $\pi = (0.65, 0.35)$.

The second model we use is a smooth graphon model from Zhang et al. (2017) (SM-G) with $w(u, v) = (u^2 + v^2)/3 \times \cos(1/(u^2 + v^2)) + 0.15$. This graphon is continuous and high rank in contrast to the first graphon, which is piece-wise constant and low rank.
Define \( \text{err}(F, G) \) as the maximum of \( |F(x) - G(x)| \) over a grid on \([-3, 3]\) with grid size 0.1; this will serve as an approximation to the Kolmogorov distance between \( F \) and \( G \). In order to study this error, we first need an estimate of the true CDF. To this end, we conduct Monte Carlo simulations with \( M \) samples generated from each model. Note that, since our goal is to show that the error is better than the Normal approximation, we need \( M = \omega((n \rho_n)^2) \), which ensures that the error from the Monte Carlo samples is \( o(1/n \rho_n) \). To ease the computational burden, we perform simulations on small networks with \( n = 160 \) nodes. We generate \( M = 10^6 \) Monte Carlo simulations, so that the higher order correctness is not obscured by error from the simulations. In addition to this, we also compare the coverage for different resampling methods in Figure 2, where we use \( n = 500 \), since the true CDF does not have to be estimated. In this setting we estimate the true parameter of inferential interest from a 15000 node network. In the next subsection we show how to obtain higher-order correct confidence intervals.

6.1 Higher-order correct confidence intervals

In this paper, we have studied the properties of bootstrap methods for standardized count functionals of networks. While our Edgeworth expansions establish that the standardized bootstrap is higher-order correct in the Kolmogorov norm, it is well known (see Hall (1988)) that corresponding confidence intervals do not offer refined accuracy over those formed from a Normal approximation. In contrast, studentized bootstraps produce higher-order correct confidence intervals. While our theoretical results can be extended to studentized count functionals (see Remark 5), it is also well-known that for statistics such as correlation coefficients, studentization may not be suitable because the variance estimate can be unstable (Hall, 2013). Alternatively, bias-corrected standardized CIs have also been extensively investigated in other settings; see for example, Efron (1980), Efron (1987), and Hall (1988). In this section, we show how to correct standardized intervals to attain higher-order accuracy for coverage.

The (uncorrected) two-sided confidence interval for the standardized bootstrap two-sided confidence interval with nominal coverage \( \alpha \) is given by: \( I_1 = (\hat{\mu}_{1-\alpha}, \hat{\mu}_{1+\alpha}) \), where we define function \( L(t) = P(\hat{T}_n^* < t \mid A, X) \) for bootstrap samples \( \{\hat{T}_n^*\} \), and \( \hat{\mu}_n = \hat{L}^{-1}(\alpha) \). Let \( z_\alpha \) denote standard normal critical point at \( \alpha \) where \( \Phi(z_\alpha) = \alpha \), then \( \hat{\mu}_n = \hat{L}^{-1}(\alpha) \). Equivalently, define \( \hat{u}_\alpha \) as the critical point at \( \alpha \) for standardized bootstrap sample \( (\hat{T}_n^* - \hat{T}_n)/\hat{\sigma}_n \) distribution and \( \hat{v}_\alpha \) as the critical point at \( \alpha \) for studentized bootstrap sample \( (\hat{T}_n^* - \hat{T}_n)/\hat{\sigma}_n^* \) distribution. The standardized bootstrap CI \( I_1 \) can be written as

\[
I_1 = (\hat{T}_n + n^{-1/2} \hat{\sigma}_n \hat{u}_{1-\alpha}, \hat{T}_n + n^{-1/2} \hat{\sigma}_n \hat{u}_{1+\alpha}).
\]

Since the population version of \( I_1 \) involves the true \( \sigma_n \) instead of \( \hat{\sigma}_n \), it follows that \( \sigma_n - \hat{\sigma}_n \) is too large of a perturbation for higher-order correctness to hold. In order to make them higher order correct, i.e. make them identical to the studentized CI, one can correct the CI as follows (see Hall (2013) for more details):
\[ I_i' = \left( \hat{y}_{1/2} + n^{-1}\sigma_n \left\{ \hat{p}_1(z_{1/2}) + \hat{q}_1(z_{1/2}) \right\} \right) \]

where for any \( x \in \mathbb{R} \), \( \hat{p}_1(x) \) and \( \hat{q}_1(x) \) are estimates for \( p_1(x) \) and \( q_1(x) \). Recall that \( p_1(x) \) and \( q_1(x) \) are polynomial coefficients of the second order term in the Edgeworth Expansions of the standardized and studentized statistic.

When the statistic is a count functional like the triangle or two-star density, then we already know the form of \( p_1(x) \) and \( q_1(x) \). For smooth functions of count statistics like the transitivity, we derive the standardized and studentized Edgeworth expansion for the smooth function of the corresponding U statistics in the supplement Sections E.1 and E.2 respectively. We also show that the Edgeworth expansion of the bootstrapped smooth function converges to this population version in the supplement Section E.4.

### 6.2 Competing methods

We compare our algorithms, namely MB-M and MB-Q, with the network resampling procedures discussed in Section 3. In particular, we consider subsampling with subsample size \( b_n = 0.5n \) (SS), the latent space graphon with resample size \( n \) (EG), the latent space bootstrap (LS), and the empirical Edgeworth expansion (EW). For the latent space bootstrap, we treat the latent dimension as known for SMB-G and estimate the latent dimension for SM-G using Universal Singular Value Thresholding (USVT) procedure of [Chatterjee (2015)]). We provide a brief description of each algorithm below.

**Empirical Graphon (EG).** We draw \( B \) size \( n \) resamples \( S_i^* \) with replacement from 1, \ldots, \( n \). We compute the count functional \( \hat{T}_{n,i}^* \) on \( A^{(n)}(S_i^*, S_i^*) \). We also compute \( \hat{T}_n \) and \( \hat{\sigma}_n^2 \) on the whole graph. Now for triangles and two-stars we compute the CDF of \( \{(\hat{T}_{n,i}^* - \hat{T}_n)/\hat{\sigma}_n\}_{i=1}^{B} \). For functions of count functions, we compute the function for each resampled graph, center using the function computed on the whole network.

**Subsampling (SS).** We draw \( B \) size \( b \) subsamples \( S_i^* \) without replacement from 1, \ldots, \( n \). We compute the count functional \( \hat{T}_{n,i}^* \) on \( A^{(n)}(S_i^*, S_i^*) \). We also compute \( \hat{T}_n \) and \( \hat{\sigma}_n^2 \) on the whole graph. We set \( \hat{\sigma}_b^2 = n/b\hat{\sigma}_n^2 \). Now for triangles and two-stars we compute the CDF of \( \{(\hat{T}_{n,i}^* - \hat{T}_n)/\hat{\sigma}_b\}_{i=1}^{B} \). For functions of count functions, we compute the function for each subsampled graph, center using the function computed on the whole network.

**Latent Space (LS).** We first estimate the latent variables \( \hat{X} := \{\hat{X}_1, \ldots, \hat{X}_n\} \) from the given network. For SMB-G, we use the true number of blocks, whereas for smooth graphon SM-G, we use the USVT algorithm to estimate the number of latent variables. We compute the count functional To be concrete, we compute \( g_1(\hat{X}_i) \) for \( i = 1 \ldots n \), and then compute \( T_n(\hat{X}) = T_n(\hat{X}_1, \ldots, \hat{X}_n) \). Now we simply use the additive variant of bootstrap \( T_n(\hat{X}) + \frac{n}{B} \sum_i (g_1(\hat{X}_i) - T_n(\hat{X})) \) (see [Levin and Levina (2019); Bose and Chatterjee (2018)]). For triangles and two-stars, we normalize by the square root of \( \frac{\tau^2}{n} \sum_i g_1(\hat{X}_i)^2 \). For functions of count functionals, we center using the function computed on \( \hat{X} \).
We compare the performance of the resampling methods for two-stars, triangles and a variant of the transitivity coefficient defined in Example 3 of Bhattcharyya and Bickel (2015), which is essentially an appropriately defined ratio between triangle and two-star.

6.3 Results

![Figure 1](image-url)

**Figure 1:** We plot \( \text{err}(F_n, F_n^*) \) for triangle density for all methods on the Y axis, where \( F_n^*(t) \) corresponds to the appropriate resampling distribution. We vary the sparsity parameter \( \rho_n \) on the X axis. The networks in the left column are simulated from SM−G and those in the right column are simulated from SM−G. The first row is centered at bootstrap mean and normalized by variance estimation from each method \( \hat{\sigma}_n \). The second row is centered by triangles density estimated from the whole graph \( \text{MB−L−apx} \) is centered at approximate triangle density estimated from the whole graph) and normalized by \( \hat{\sigma}_n \).

In Figure 1 we plot the maximum of (absolute) difference of the bootstrap CDF \( F_n^* \) over the \([-3, 3]\) range (\( \text{err}(F_n, F_n^*) \)) for triangle density from the true CDF \( F_n \) for sparsity parameter \( \rho_n \) varying from 0.05 to 1. We show the average of the expected difference over 30 independent runs along with errorbars. In this figure we see an interesting phenomenon. For sparse networks with \( \rho_n < 0.2 \), the linear method outperforms the higher order correct methods. As the networks become denser, the higher order correct methods start performing better. For \( \rho_n \geq 0.2 \), we also see that the empirical edgeworth expansion performs worse than the linear bootstrap method. We also compare the bootstrap samples centered at the bootstrap mean (first row) with bootstrap samples centered at the subgraph density computed on the whole network. We see that the latter space method (LS) and approximate linear bootstrap method (MB−L−apx) behave differently under these two centerings, with LS performing much worse. This suggests that while both suffer from bias, LS suffers from it to a higher degree. For all
Figure 2: We present coverage of 95% Bootstrap Percentile CI with correction for triangles (top) and transitivity coefficient (bottom) of the SBM-G (A) and SM-G (B) models with $\rho_n$ varying from 0.05 to 1. Parameter settings, we used $N = 50 \log n$. It is possible that increasing $N$ for sparser settings may lead to reduced bias of MB-L-apx.

Figure 3: Logarithm of running time for four-cycles in SBM-G against sample size $n$.

In Figure 2 we show the coverage of 95% Bootstrap Percentile CI with correction for triangles (top) and transitivity coefficient (bottom) of the SBM-G and SM-G models in $\rho_n$ from 0.05 to 1. We simulate 200 graphs for each $\rho_n$ from SBM-G and SM-G models, construct CI from bootstrap percentiles and correct the CI using Eq 32 for triangles and transitivity respectively. For smooth functions, computing the bootstrap distribution is straightforward. One simply computes $u^*$ which is now a vector of bootstrapped triangles and two-star densities. Now a standardized bootstrap replicate is given by $\{f(u^*) - f(u)\}/\hat{\sigma}_f$, where $u$ is the vector of triangles and two-star densities computed on the whole graph, and $\hat{\sigma}_f$ is given by Eq 30. For transitivity, $f(x, y) = x/y$. 
6.4 Computation time

In Figure 3 we show logarithm of running time for 4-cycles count against growing $n$ for SBM-G model. (See the Supplement for timing of SM-G.) We compare our approximate linear method $MB-L-apx$ with $MB-L-BTS$, which uses a randomized algorithm for approximating U-statistics proposed by [Chen and Kato (2019)], Section 2.2, for precomputation of the local network statistics. We see that among higher order correct methods, $MB-Q$ offers strong computational performance, outperforming methods such as the $EG$ and $SS$. We see that while $EG$ has comparable performance to $MB-Q$, it requires recomputation of the count statistic for every bootstrap iteration, making it about 500 times slower than $MB-Q$ for $n = 500$ for four-cycle counting. $MB-M$ is the slowest one we do not show here as the weights make symmetric counting shortcuts not as simple to apply. $EW$ is the fastest among higher order correct methods, but it cannot be readily adapted for smooth functions of count statistics and is much slower compared to additive methods $LS, MB-L, MB-L-BTS, MB-L-apx$. The four additive methods, i.e. $LS, MB-L, MB-L-BTS, MB-L-apx$ are the fastest four of all methods, but they are not higher order accurate; among them $MB-L-apx$ is the fastest method in all with our proposed approximate precomputation. The procedure $MB-L-BTS$ draws around $N(n-1)/(r-1)$ size $r-1$ subsets with replacement, whereas we draw $N$ permutations at random and then divide each into consecutive disjoint subsets of size $r-1$. While these two methods have similar computational complexity theoretically, we observe that $MB-L-apx$ appears to be faster empirically.

For space considerations, additional experiments including the sup of (absolute) difference of the bootstrap CDFs for two-star density and timing for four-cycles for the SM-G model are deferred to Supplement Section G. The experiments are run on the Lonestar super computer (1252 Cray XC40 compute nodes, each with two 12-core Intel® Xeon® processing cores for a total of 30,048 compute cores) at the Texas Advance Computing Center.

7 Real Data Application

In this section, we apply our algorithms to compare networks representing the voting similarities of U.S. Congress. We use roll call vote data from the U.S. House of Repre-

![Figure 4: Threshold for forming edges between congress members calculated from histograms of same-party (SP) and cross-party (CP) agreements, illustrated with example of 81st Congress and 109th Congress representatives (Jeffrey B. et al., 2020) from 1949 (commencement of the 81st Congress) to](image_url)
2012 (adjournment of 112\textsuperscript{nd} Congress). Each Congress forms a network of representatives (nodes). An edge between a node pair is formed when the number of agreements, i.e. number of times they both vote \textit{yay} or \textit{nay} exceeds a threshold computed by [Andris et al., 2015] of this congress. The threshold is computed by constructing histograms of same-party pairs’ number of agreements and cross-party pair’s number of agreements and using the intersection point of the two histograms as the threshold. We will denote same-party by \textit{SP} and cross-party by \textit{CP}. For example, the threshold value is 124 for 81\textsuperscript{st} Congress and 766 for 109\textsuperscript{th} Congress as illustrated in Figure 4. For each network, we calculate the normalized cross-party edge density and cross-party triangle density, and perform our bootstrap methods on these quantities. We construct 95\% second-order corrected Confidence Intervals from the MB-Q method and present the CIs over 81\textsuperscript{st} to 112\textsuperscript{nd} Congress. Note that the CIs are adjusted by Bonferroni Correction where $\alpha = 0.05/32$ for 32 experiment congresses.

In Figure 5, we can a significant decrease in cross party edge densities and cross party triangle densities over the years, suggesting a trend of decreasing bipartisan agreement.

8 Conclusion

In this paper, we propose multiplier bootstraps for network count functionals. Our multiplicative proposal involves perturbing a potential subgraph by the product of independent multiplier random variables. We also present the linear and quadratic bootstrap, which can be seen as different orders of approximations of the Hoeffding decomposition of the statistic arising from the multiplier bootstrap. We show that the quadratic bootstrap is higher-order correct for moderately sparse graphs whereas the linear bootstrap is first-order correct but faster. For the first time in the literature, we also derive Edgeworth expansions for smooth functions of counts. Empirically, we observe an interesting phenomenon in which the linear bootstrap, which is not higher-order correct in any regime, performs better than other methods for sparse graphs since the higher-order correct methods directly or indirectly involve estimation of higher-order moments that may not be accurately estimated under sparsity. To truly harness the computational power of the linear bootstrap, we also present and analyze an approximate bootstrap method which uses randomized sketching algorithms for estimating
local network counts that are used by the linear method. Taken together, we establish
the multiplier bootstrap as a user-friendly, automatic procedure that can be tailored to
yield higher-order correctness or scalable and consistent inference.

### A Proof of Lemma 1

**Proof.** In what follows, we will consider a projection of $T_{n,M}^*$ with respect to the random variables $\xi_1, \ldots, \xi_n$, conditional on $A$ and $X$.

Recall that $\xi_i$ follows the Gaussian Product distribution. First, we may express $T_{n,M}^*$ as:

$$T_{n,M}^* = \frac{1}{n^r} \sum_{1 \leq i_1 < i_2 < \ldots < i_r} (\xi_{i_1} \cdots \xi_{i_r} - 1) \cdot \{H(A_{i_1,\ldots,i_r}^{(n)}) - \hat{T}_n\}$$

where $\xi_{i_1,\ldots,i_r}$ denotes the product $\xi_{i_1} \times \cdots \times \xi_{i_r}$. It turns out that applying the Hoeffding decomposition directly to $T_{n,M}^*$ leads to tedious combinatorial calculations; following Bentkus et al. (1997), let $\Omega_r$ denote an $r$-tuple of $\{1, \ldots, n\}$. For each summand, we will consider a Hoeffding representation with respect to $\Omega_r$. Note that using the Hoeffding projection (also see Bentkus et al. (1997) section 2.8),

$$\prod_{1 \leq i \leq r} \xi_i - 1 = \sum_{k=1}^{r} \sum_{1 \leq i_1 < \ldots < i_k \leq r} h_k(\xi_{i_1}, \ldots, \xi_{i_k}),$$
where for \( \Omega_k = \{1, \ldots, k\} \),

\[
h_k(\xi_1, \ldots, \xi_k) = \sum_{B \in \Omega_k} (-1)^{|B|} E \left\{ \prod_{1 \leq i \leq r} \xi_i - 1 \mid B \right\}
\]

Thus the first two terms are given by:

\[
h_1(\xi_1) := (\xi_1 - 1)
\]

\[
h_2(\xi_1, \xi_2) := (\xi_1 \xi_2 - 1) - (\xi_1 - 1) - (\xi_2 - 1) = (\xi_1 - 1)(\xi_2 - 1)
\]

In what follows, we will also denote \( A_{i_1, \ldots, i_r}^{(n)} \) by \( A_S^{(n)} \), where \( S = \{i_1, \ldots, i_r\} \). Let

\[
\hat{H}_2(i, j) = \frac{1}{(n-2)} \sum_{S \mid i, j \in S} H(A_S), \quad \tag{A.33}
\]

\[
\hat{H}_u(i_1, \ldots, i_u) = \frac{1}{(n-u)} \sum_{S \mid i_1, \ldots, i_u \in S} H(A_S).
\]

Thus \( T_{n,M}^* \) can be written as follows:

\[
T_{n,M}^* = \frac{1}{(n)} \sum_{1 \leq i_1 < i_2 < \cdots < i_r} (\xi_{i_1 \cdots i_r} - 1) \cdot \left\{ H(A_{i_1 \cdots i_r}^{(n)}) - \hat{T}_n \right\}
\]

\[
= \frac{1}{(n)} \sum_{1 \leq i_1 < i_2 < \cdots < i_r} \sum_{k=1}^{r} \sum_{1 \leq i_t < \cdots < i_k \leq i_r} h_k(\xi_{i_1}, \ldots, \xi_{i_k}) \cdot \left\{ H(A_{i_1 \cdots i_k}^{(n)}) - \hat{T}_n \right\} 1(i_1, \ldots, i_k \in S)
\]

\[
= \frac{1}{(n)} \sum_{k=1}^{r} \binom{n-k}{r-k} \sum_{1 \leq i_1 < \cdots < i_k \leq n} h_k(\xi_{i_1}, \ldots, \xi_{i_k}) \sum_{S \mid 1 \leq i_1 < \cdots < i_k \leq n} \left\{ H(A_{S}^{(n)}) - \hat{T}_n \right\} 1(i_1, \ldots, i_k \in S)
\]

\[
= \frac{1}{n} \sum_{i} (\xi_i - 1) \hat{g}_1(i) + \frac{r(r-1)}{n(n-1)} \sum_{1 \leq i < j \leq n} (\xi_i - 1)(\xi_j - 1) \left( \frac{\hat{H}_2(i,j) - \hat{T}_n}{\hat{g}_2(i,j)} \right) + R_n
\]

\[
(A.34)
\]

Now, it remains to show that the remainder of \( (T_{n,M}^* - \hat{T}_n)/\hat{\sigma}_n \) is \( O(\delta(n, \rho_n, R)) \), where:

\[
\delta(n, \rho_n, R) = \left\{ \begin{array}{ll}
\frac{1}{n \rho_n} & \text{R is acyclic} \\
\frac{1}{n \rho_n^2} & \text{R is a simple cycle}.
\end{array} \right.
\]

The residual \( R_n \) is a sum of higher order Hoeffding projections, which are all uncorrelated. Therefore, we see that the variance of the \( u^{th} \) order term is

\[
\frac{\sum_{1 \leq i_1 < i_2 < \cdots < i_u} \hat{g}_u(i_1, \ldots, i_u)^2}{\hat{\sigma}_n^2(n_u^2)}.
\]

We will now obtain expressions for \( 3 \leq u \leq r \).
Consider any term \( \tilde{g}_u(1, \ldots, u) \). We will now bound \( E\{ \tilde{g}_u(1, \ldots, u)^2 \} \).

\[
E\{ \tilde{g}_u(1, \ldots, u)^2 \} \leq 2[\text{var}\{ \tilde{H}_u(1, \ldots, u) \} + \text{var}(\tilde{T}_n)] / O(\rho_n^2/n)
\]

The bound on the second term follows from Bickel et al. (2011) and will be smaller than that of the first term. Let \( S_{r,u} \) denote all subsets of size \( r - u \), not containing \( 1, \ldots, u \). For any subset \( S \in S_{r,u} \), also define, \( S_u = S \cup \{1, \ldots, u\} \). For the first part, we have:

\[
\text{var}\{ \tilde{H}_u(1, \ldots, u) \} = \sum_{S,T \in S_{r,u}} \text{cov}\{ H(A_{S_u}), H(A_{T_u}) \} / \binom{n-u}{r-u}^2
\]

Note that the dominating term here will indeed be the one where \( |S\cap T| = 0 \). The number of such terms is \( \binom{n}{2r-u} \). Also the covariance of those terms will be \( \rho_n^{2s-E(A_{1,\ldots,u})} \), where \( E(A_{1,\ldots,u}) \) denotes the intersection of the edgset of \( A_{1,\ldots,u} \) and the subgraph we are counting. This number can be at most \( u - 1 \) for acyclic \( R \) and \( u \) for a simple cycle \( R \). For \( |S\cap T| = k \), the number of terms is \( \binom{n}{2r-2u-k} \) and the exponent on \( \rho_n \) is at most \( 2s-(u+k-1) \). Thus, for an acyclic subgraph, we have,

\[
\text{var}\{ \tilde{H}_u(1, \ldots, u) \} \leq \sum_{k=0}^{r} \binom{n}{2r-2u-k} \rho_n^{2s-(u+k-1)} / \binom{n-u}{r-u}^2
\]

\[
\leq \sum_{k=0}^{r} n^{-k} \rho_n^{2s-(u+k-1)} = \rho_n^{2s-(u-1)} \left( 1 + \sum_{k>0} \frac{1}{(n \rho_n)^k} \right)
\]

The cyclic one is worse by a factor of \( \rho_n \). Thus the contribution of the \( u^{th} \) element of the Hoeffding decomposition is

\[
\frac{n}{\binom{n}{r}^2} \sum_{i_1, \ldots, i_u} \tilde{g}_u(i_1, \ldots, i_u)^2 = \begin{cases} O_P \left( \frac{1}{(n \rho_n)^{u-1}} \right) & R \text{ acyclic} \\ O_P \left( \frac{\rho_n^{u-1}}{(n \rho_n)^{u-1}} \right) & R \text{ a simple cycle} \end{cases}
\]

This shows that the third term contributes the most to \( R_n \) in Eq (3.3) By Markov’s inequality, and the definition of \( O_P(\cdot) \) notation, it is easy to see that \( R_n = O_P(\delta(n, \rho_n, R)) \).

\section*{B Proof of Theorem 2}

\textit{Proof.} For any \( i \in \{1, \ldots, n\} \), denote the set of all subsets of size \( r - 1 \) taken from \( \{1, \ldots, i-1, i+1, \ldots, n\} \) as \( S_{-i} \). Denote \( H(A_{i_2, \ldots, i_r}) \) for \( S = \{i_2, \ldots, i_r\} \subset S_{-i} \) as \( H(A_{S_{-i}}) \). Denote

\[
H_1(i) = \frac{1}{\binom{n-1}{r-1}} \sum_{S \in S_{-i}} H(A_{S_{-i}}).
\]
Now let \( \pi_j \) be a permutation picked with replacement and uniformly at random from the set of all permutations of \( \{1, \ldots, n\} \setminus i \). We have \( j = 1, \ldots, N \) independent permutations \( \pi_j \). Let \( S_\pi \) denote the set of all disjoint subsets \( \{\pi_{(i-1)(r-1)+1}, \ldots, \pi_{i(r-1)}\} \), \( i = 1, \ldots, \frac{n-1}{r-1} \) obtained from permutation \( \pi \). We write

\[
\tilde{T}_{n,L} - \tilde{T}_n = \frac{r}{n} \sum_{i=1}^{n} (\xi_i - 1) \{\tilde{H}_1(i) - \tilde{T}_n\},
\]

where

\[
\tilde{H}_1(i) = \frac{\sum_j H_{\pi_j}(i)}{N}, \quad H_{\pi}(i) = \frac{\sum_{S \in S_\pi} H(A_{S,i})}{\frac{n-1}{r-1}}, \quad \tilde{T}_n = \frac{1}{n} \sum_{i=1}^{n} \tilde{H}_1(i).
\]

Note that

\[
\text{var}(\tilde{T}_{n,L} - \tilde{T}_n|A, X) = \frac{r^2}{n^2} \sum \tilde{\sigma}^2_{n,i}
\]

**Proof of Theorem 2 (a):**

Let \( Y_i \) denote \( (\xi_i - 1) \{\tilde{H}_1(i) - \tilde{T}_n\} \). Conditioned on \( A \) and \( X \), \( \tilde{H}_1(i) - \tilde{T}_n \) are observed constants, \( Y_i \) are independent but not identically distributed with variance \( \tilde{\sigma}^2_{n,i} \).

\[
\tilde{\sigma}^2_{n,i} = \text{var}[(\xi_i - 1) \{\tilde{H}_1(i) - \tilde{T}_n\} | A, X] = E[(\tilde{H}_1(i) - \tilde{T}_n)^2 | A, X]
\]

Applying Berry-Esseen theorem to \( \tilde{T}_{n,L} - \tilde{T}_n \) conditioned on \( A \) and \( X \), we have

\[
\sup_{u \in \mathbb{R}} \left| P^* \left( \frac{\tilde{T}_{n,L} - \tilde{T}_n}{\sqrt{\text{var}(\tilde{T}_{n,L} - \tilde{T}_n|A, X)}} \leq u \right) - \Phi(u) \right| = \sup_{u \in \mathbb{R}} \left| P^* \left( \frac{\sum_i Y_i}{\sqrt{\sum_i \tilde{\sigma}^2_{n,i}}} \leq u \right) - \Phi(u) \right|
\]

\[
\leq \left( \sum_{i=1}^{n} (\tilde{\sigma}^2_{n,i}) \right)^{-3/2} \sum_{i=1}^{n} \gamma_i =: C_1 \psi_N,
\]

From Lemma \[D.5\] we have

\[
P \left( \frac{\sum_i \gamma_i / \rho_{n,i}^{3s}}{n} \leq c \right) \to 1, \quad (A.35)
\]

28
for some positive constant $c$.

Now in order to bound $\psi_N$, we need to bound $E\hat{\sigma}_{n,i}^2$. We decompose $\hat{\sigma}_{n,i}^2$ into

$$\hat{\sigma}_{n,i}^2 = E\left[(\tilde{H}_1(i) - \tilde{T}_n)^2 \mid A, X\right]$$

$$= E\left[(\tilde{H}_1(i) - H_1(i))^2 \mid A, X\right] + E\left[(\tilde{T}_n - \tilde{T}_n)^2 \mid A, X\right] + 2E\left[(\tilde{H}_1(i) - H_1(i))(\tilde{T}_n - \tilde{T}_n) \mid A, X\right] - 2E\left[(H_1(i) - \tilde{T}_n)(\tilde{T}_n - \tilde{T}_n) \mid A, X\right]$$

(Eq A.36)

It is easy to see that the first two cross terms are zero. As for the third, the law of iterated expectation gives:

$$E[(\tilde{H}_1(i) - H_1(i))(\tilde{T}_n - \tilde{T}_n)] \mid A, X \leq \frac{1}{n} \text{var}\{\tilde{H}_1(i) \mid A, X\}.$$ 

Now we calculate the second term in Eq (A.36)

$$E \left\{(\tilde{T}_n - \tilde{T}_n)^2 \mid A, X\right\} = E \left\{\left[\frac{1}{n} \sum_{i=1}^{n} (\tilde{H}_1(i) - H_1(i)) \right] \mid A, X\right\} = \frac{\text{var}\{\tilde{H}_1(i) \mid A, X\}}{n}.$$ 

We also have,

$$E \left\{(\tilde{H}_1(i) - H_1(i))^2 \mid A, X\right\} = \text{var}\{\tilde{H}_1(i) \mid A, X\}.$$ 

Collecting all terms in Eq (A.36) we have

$$\hat{\sigma}_{n,i}^2 = \text{var}\{\tilde{H}_1(i) \mid A, X\} \left(1 - \frac{1}{n}\right) + \hat{\sigma}_1^2.$$ 

(A.37)

Since the second term in Eq (A.39) is always positive, $\sum_i \hat{\sigma}_{n,i}^2 \geq n \hat{\sigma}_n^2$. Combining Eq (A.35) and $\hat{\sigma}_n^2 = \Theta(\rho_n^2) (1 + O_P(1/n\rho_n))$ (Lemma D.3), we have:

$$\psi_N = \frac{\sum_{i=1}^{n} \hat{\sigma}_{n,i}^2}{\left(\sum_{i=1}^{n} \hat{\sigma}_{n,i}^2\right)^{3/2}} = O_P \left(n^{-1/2}\right).$$ 

(A.38)

Conditional on $A$ and $X$, we have:

$$\sup_{u \in R} \left| P\left(\frac{n^{1/2}(\tilde{T}_{n,L} - \tilde{T}_n)}{r \sqrt{\sum_{i=1}^{n} \hat{\sigma}_{n,i}^2}} \leq u \mid A, X\right) - \Phi(u) \right| = O_P \left(n^{-1/2}\right).$$

Thus we have proof of Theorem 2(a).

Proof of Theorem 2(b): Note that

$$\text{var}\left(\tilde{T}_{n,L} - \tilde{T}_n \mid A, X\right) = \frac{r^2}{n^2} \sum_i \hat{\sigma}_{n,i}^2$$

29
Using Lemma B.1 we have the following result for its expectation.

\[ E \left[ \operatorname{var}\{ \tilde{H}_1(i) \mid A, X \} \right] = \Theta \left( \frac{r_\rho^s}{Nn} \right). \]

Now it follows from Eq A.37 that:

\[ \frac{\sum_i \sigma_{n,i}^2}{n} = \hat{\tau}_n^2 + O_P \left( \frac{r_\rho^s n}{Nn} \right). \] (A.39)

Using Lemma D.3 (a), it follows that \( \hat{\tau}_n^2 / \tau^2 = 1 + O_P(1/n\rho_n) \).

**Proof of Theorem 2 (c):** For the un-approximated linear bootstrap, there is no randomness in \( \tilde{H}_1(i) \), since it equals \( \hat{H}_1(i) \). Thus \( \operatorname{var}(\tilde{H}_1(i) \mid A, X) = 0 \). So the result follows from Eq A.37. \( \square \)

**Lemma B.1.**

\[ E \left[ \operatorname{var}\{ \tilde{H}_1(i) \mid A, X \} \right] = \Theta \left( \frac{r_\rho^s}{Nn} \right). \]

**Proof.**

\[
E \left[ \operatorname{var}\{ \tilde{H}_1(i) \mid A, X \} \right] = E \left[ \operatorname{var} \left\{ \frac{\sum_j H_{\pi_j}(i)}{N} \mid A, X \right\} \right] = E \left( \frac{1}{N^2} \sum_j \operatorname{var}\{ H_{\pi_j}(i) \mid A, X \} \right) \\
= E \left( \frac{1}{N^2} \sum_j E\left( (H_{\pi_j}(i) - \theta)^2 \mid A, X \right) \right) \\
= E \left( \frac{1}{N^2} \sum_j \sum_{S \in \pi_j} E\left( (A_{S;ij} - \theta)^2 \mid A, X \right) \right) \\
= \frac{\operatorname{var}\{ H(A_{S;ij}) \}}{N^{n-1}} \\
\]

We further have,

\[ \operatorname{var}\{ H(A_{S;ij}) \} = \operatorname{var}\{ E[H(A_{S;ij}) \mid X] \} + E[\operatorname{var}(H(A_{S;ij}) \mid X)] = \Theta(\rho_n^s). \]

Thus, we arrive at

\[ E \left[ \operatorname{var}\{ \tilde{H}_1(i) \mid A, X \} \right] = \Theta \left( \frac{r_\rho^s}{Nn} \right). \] \( \square \)
C Proof of Proposition 3

Proof. In what follows, we prove Proposition 3 holds for Edgeworth expansion of a standardized count functional. Our argument here is closely related to Zhang and Xia (2020), thus we do not present the complete proof here. They have showed in Theorem 3.1 in the above reference, that under same conditions, Edgeworth Expansion for studentized \( \hat{T}_n \), denote as \( \tilde{G}_n(u) \) here, has the same property as Proposition 3.

We have first derived our Edgeworth Expansion formula in eq 21 for standardized \( \hat{T}_n \) instead of studentized \( \hat{T}_n \), and we state the form of the characteristic function of \( G_n(u) \) below:

Proposition C.1. We have:

\[
\psi_{G_n}(t) := \int e^{itu} dG_n(u) = e^{-\frac{t^2}{2}} \left( 1 - \frac{it^3}{6n^{1/2}r_n} \left[ E\{g_1^3(X_1)\} + 3(r - 1)E\{g_1(X_1)g_1(X_2)\} \right] \right).
\]

Our standardized \( \hat{T}_n \), denote as \( \tilde{T}_n \) can be decomposed into

\[
\tilde{T}_n := \hat{T}_n - \mu_n \sigma_n = \frac{T_n - \mu_n}{\sigma_n} + \frac{\hat{T}_n - T_n}{\sigma_n} = T_{n,1} + T_{n,2} + OP \left( \frac{1}{n} \right) + R_n,
\]

where

\[
T_{n,1} = \frac{1}{n^{1/2}r_n} \sum_{i=1}^{n} g_1(X_i), \quad T_{n,2} = \frac{r - 1}{n^{1/2}(n - 1)r_n} \sum_{i<j} g_2(X_i, X_j), \quad R_n = \frac{\hat{T}_n - T_n}{\sigma_n}.
\]

We will begin by bounding \( R_n \). Similar to the theory for U-statistics, the behavior is largely determined by a linear term.

Let:

\[
R_{n,1} = \text{Linear part of } \frac{\hat{T}_n - T_n}{\sigma_n}.
\]

where the linear part has the form:

\[
R_{n,1} = \frac{1}{\binom{n}{2}} \sum_{i<j} c_{ij} \{ A_{ij} - E(A_{ij} | X_i, X_j) \}
\]

for \( c_{ij} = c_{ij}(X_i, X_j, \rho_n) \approx \rho_n^{-1} n^{-1/2} \) defined in Section 7 of the above reference. Theorem 3.1(b) of the above authors establishes that:

\[
R_n - R_{n,1} = OP(\mathcal{M}(n, \rho_n, R)),
\]

Under the assumed sparsity conditions, given \( X \), the distribution of \( R_{n,1} \) permits the following (uniform) approximation by a Gaussian-distributed variable \( Z_n \):

\[
\sup_u \left| F_{R_{n,1}|X}(u) - F_{Z_n} \right| = OP \left( \frac{1}{\rho_n^{1/2}n} \right),
\]

31
where $Z_n \sim N(0, \frac{\sigma^2_w}{n\rho_n})$ and $\sigma^2_w$ is defined as the variance of Eq C. Note that $\sigma_w \approx 1$ when $n \to \infty$.

Now to prove our theorem, we will show the three equations below.

\[
\sup_u \left| F_{\hat{T}_n}(u) - F_{\hat{T}_{n,1}+\hat{T}_{n,2}+\hat{R}_n}(u) \right| = O\left(\mathcal{M}(n, \rho_n, R)\right), \tag{A.40}
\]

\[
\sup_u \left| F_{\hat{T}_{n,1}+\hat{T}_{n,2}+\hat{R}_n}(u) - F_{\hat{T}_{n,1}+\hat{T}_{n,2}+\hat{Z}_n}(u) \right| = O\left(\frac{1}{\rho_n^{1/2}}\right), \tag{A.41}
\]

\[
\sup_u \left| F_{\hat{T}_{n,1}+\hat{T}_{n,2}+\hat{Z}_n} - G_n(x) \right| = O\left(\frac{1}{n}\right), \tag{A.42}
\]

We prove Eq A.42 using Esseen’s smoothing lemma from Section XVI.3 in Feller (1971),

\[
\sup_u \left| F_{\hat{T}_{n,1}+\hat{T}_{n,2}+\hat{Z}_n}(u) - G_n(x) \right| \leq c_1 \int_{-\gamma}^{\gamma} \frac{1}{t} \left| \psi_{\hat{T}_{n,1}+\hat{T}_{n,2}+\hat{Z}_n}(u) - \psi_n(t) \right| dt + c_2 \sup_u \frac{G_n'(u)}{\gamma}, \tag{A.43}
\]

where $\psi$ is the characteristic function. $\gamma$ is set to $n$. We omit the proof here as it is not hard to check by breaking the integral into $|t| \in (0, n^{\epsilon}), (n^{\epsilon}, n^{1/2})$ and $(n^{1/2}, n)$. Using similar arguments as Lemma 8.3 of Zhang and Xia (2020), we have Eq A.43 and thus Eq A.42 hold for our characteristic function in Proposition C.1. It is also not hard to check that, using similar arguments of the above reference, under Assumption 2, Eq A.40 and Eq A.41 hold given Eq A.42. \hfill \Box

## D Edgeworth Expansion for Weighted Bootstrap - Proofs of Theorem 4 and Corollary 5

Using Eq (10), we express our quadratic bootstrap statistic as:

\[
\hat{T}_{n,Q} = \frac{\sum_i (\xi_i - 1) \hat{g}_1(i)}{n^{1/2} \hat{r}_n} + \frac{(r-1) \sum_{1 \leq i < j \leq n} (\xi_i \xi_j - \xi_i - \xi_j + 1) \hat{g}_2(i,j)}{n^{1/2}(n-1) \hat{r}_n} \tag{A.44}
\]

We will first prove Theorem 4. However in order to prove it we state a slightly different version of Theorem 3.1 in Wang and Jing (2004). The main difference is that one condition in the original lemma is not fulfilled in our case. In particular, Bernoulli noise with $\rho_n \to 0$ blows up some terms that are needed to bound the error associated with the Edgeworth expansion. However, a thorough examination reveals that the argument carries through with some modifications.
Let
\[ K_{2,n} = \frac{1}{n^{3/2} B_n^2} \sum_{1 \leq i < j \leq n} b_n b_{nj} d_{nij} E\{Y_1 Y_2 \psi(Y_1, Y_2)\} \] (A.45a)

\[ L_{1,n}(x) = \frac{1}{n} \sum_{j=1}^{n} \left\{ E\Phi(x - b_n Y_j / B_n) - \Phi(x) \right\} - \frac{1}{2} \Phi''(x) \] (A.45b)

\[ L_{2,n}(x) = -K_{2,n} \Phi'''(x) \] (A.45c)

\[ E_{2n}(x) = \Phi(x) + L_{1,n}(x) + L_{2,n}(x), \] (A.45d)

**Lemma D.1.** Consider the following expression.
\[ V_n = \frac{1}{B_n} \sum_j b_n j Y_j + \frac{1}{n^{3/2}} \sum_{i<j} d_{nij} \psi(Y_i, Y_j), \] (A.46)

where \( B_n^2 = \sum_j b_n^2 \). Let \( \beta := E(|Y_1|^3) \) and \( \lambda = E\{\psi^2(Y_1, Y_2)\} \), and let \( E(Y_1) = 0, E(Y_2^2) = 1 \) and \( \kappa(X_1) > 0 \). Furthermore, let \( E\{\psi(Y_1, Y_2) \mid Y_t\} = 0 \) for all \( 1 \leq t \leq n \). For some constants \( \ell_1, \ell_2, \ell_3 \) the sequence \( b_{n,i} \) satisfies
\[ \frac{1}{n} \sum_{i=1}^{n} b_{n,i}^2 \geq l_1 > 0, \quad \frac{1}{n} \sum_{i=1}^{n} |b_{n,i}|^3 \leq l_2 \leq \infty, \] (A.47)

Furthermore, define \( \alpha_i := \frac{1}{n} \sum_{j \neq i} d_{nij}^2 \). and for sufficiently large \( k \), define:
\[ l_{4,n} = \frac{1}{n} \sum_{i=1}^{n} \alpha_i, \quad s_{n}^2 = \frac{1}{n} \sum_{i=1}^{n} \alpha_i^2 - (l_{4,n})^2, \quad l_{5,n} = l_{4,n} + ks_n \] (A.48)

If \( \beta, \kappa(Y_1) \) and \( \lambda \) are bounded, then,
\[ \sup_x |P(V_n \leq x) - E_{2n}(x)| = O \left( \frac{l_{5,n} \log n}{n^{2/3}} \right), \]

Intuitively, arguments for establishing rates of convergence for the Edgeworth expansions require comparing the characteristic function of the random variable of interest with the Fourier transform of the Edgeworth expansion. To this end, the respective integrals are broken up into several pieces. The bounds required in (A.47) are used to estimate the error of the Edgeworth expansion in some of these steps, but appear as constants and are suppressed in the Big-O notation.

On the other hand, as previously mentioned, it turns out that certain terms that appear as constants in Wang and Jing (2004) blow up when perturbed by sparse network noise and appear in the rate. In particular, the term \( l_{5,n} \) arises from needing to bound \( \frac{1}{m} \sum_{i=1}^{m} \alpha_i \) for all \( m \leq M \) for some \( M \) large enough.

Since the data is fixed, we may view \( \alpha_1, \ldots, \alpha_n \) as constants. We therefore have the liberty of choosing a “good set” in which \( \alpha_i \) are well-behaved. Without loss of generality, we may label these elements \( \{\alpha_1, \ldots, \alpha_M\} \); the corresponding multiplier random variables are still independent. Even when there is no randomness, it turns out
that a large proportion of \( \{\alpha_1, \ldots, \alpha_n\} \) must be within \( k \) sample standard deviations of the sample mean \( l_{4,n} \) for \( k \) large enough. This observation, which we believe is novel in the bootstrap setting, allows us to establish a tight bound for \( \frac{1}{m} \sum_{i=1}^{m} \alpha_i \) for all \( m \leq M \). We state this lemma below.

**Lemma D.2.** Let \( x_1, \ldots, x_n \) be constants in \( \mathbb{R} \) and let \( \bar{x}_n = \frac{1}{n} \sum_{i=1}^{n} x_i \) and \( s_n^2 = \frac{1}{n} \sum_{i=1}^{n} (x_i - \bar{x})^2 \) Define the set:

\[
\Gamma_k = \{ x_i \geq \bar{x}_n + ks_n \}
\]

Then,

\[
|\Gamma_k| \leq \frac{n}{k^2}
\]

**Proof.** Observe that:

\[
s_n^2 \geq \frac{1}{n} \sum_{i \in \Gamma_k} (x_i - \bar{x}_n)^2 \geq \frac{1}{n} \sum_{i \in \Gamma_k} k^2 s_n^2 \implies |\Gamma_k| \leq \frac{n}{k^2}
\]

**Remark D.1.** Our lemma is closely related to concentration of sums sampled without replacement from a finite population. In fact, it implies the without-replacement Chebychev inequality; see, for example, Corollary 1.2 of Serfling (1974).

We will show that \( T_{n,Q}^* \) can be written as Eq A.46 with carefully chosen \( \{b_{ni}\} \) and \( \{d_{nij}\} \)’s. We now present some accompanying Lemmas to show that Eq A.47 is satisfied with probability tending to 1. Proofs of Lemmas D.1, D.5, and D.6 are provided in following subsections.

We present some useful results shown in Zhang and Xia (2020) which we will use later in proofs of our theorems.

**Lemma D.3.** Let \( \hat{\tau}_n^2 = \sum_{i} \hat{g}_1(i)^2/n \). We have,

1. For acyclic graphs, if \( n\rho_n \to \infty \), and for cyclic graphs, if \( n\rho_n^2 \to \infty \), we have:

\[
\frac{\hat{\tau}_n^2}{\tau_n^2} = 1 + O_P \left( \frac{1}{n\rho_n} \right) + O_P \left( \frac{1}{\sqrt{n}} \right) \quad (A.49)
\]

\[
E(|\hat{g}_1(i) - g_1(X_i)|/\rho_n^2) = O(1/n\rho_n) \quad (A.50)
\]

2. Under Assumption \(^2\) we have

\[
\left| \frac{\sum_{j} \hat{g}_1(i)^3}{n} - E\{g_1(X_1)^3\} \right| = O_P \left( \rho_n^{3s-1/2} n^{-1/2} \right),
\]

(A.51)
\[
\left\| \sum_{i<j} \hat{g}_1(i) \hat{g}_1(j) \hat{g}_2(i,j) \right\|_{\frac{3s}{n}}^2 - \mathbb{E}\{g_1(X_1)g_1(X_2)g_2(X_1, X_2)\} = \mathcal{O}_P\left(\rho_n^{3s-0.5}n^{-1/2}\right),
\]
(A.52)

and
\[
|\hat{\tau}_n^3 - \tau_n^3| = \mathcal{O}_P\left(\rho_n^{3s}/n^{1/2}\right).
\]
(A.53)

Lemma D.4. Under the sparsity assumptions in Assumption 2 for large enough \(C\),
\[
P\left(\frac{1}{n^2} \sum_i \sum_{j \neq i} \hat{g}_2(i,j)^2 \geq C \rho_n^{2s-1} \right) \to 1
\]

Lemma D.5. Under the sparsity conditions in Assumption 2 and for some arbitrary \(\epsilon > 0\),
\[
P\left(\sum_i \left|\frac{\hat{g}_1(i)}{\rho_n^{s}}\right|^3 \leq c \right) \to 1
\]
\[
P\left(\sum_i \left|\frac{\hat{g}_1(i)}{\rho_n^{s}}\right|^2 \geq c' \right) \to 1,
\]
for positive constants \(c, c'\) not depending on \(n\).

Lemma D.6. Let \(\xi_1\) be generated from the Gaussian product distribution. We have \(E|\xi_1 - 1|^3 < \infty\).

Now we are ready to provide the proof.

of Theorem 4. It is easy to see from Eq A.44 that \(\hat{T}_{n,Q}^s\) can be expressed as:
\[
\hat{T}_{n,Q}^s = \sum_i b_{n,i}Y_i \frac{1}{B_n} + \frac{1}{n^{1/2}(n-1)} \sum_{1 \leq i < j \leq n} \psi(Y_i, Y_j)d_{n,ij},
\]
where we have:
\[
Y_i = \xi_i - 1,
\]
(A.54a)
\[
b_{n,i} = \frac{\hat{g}_1(i)}{\rho_n^{s}},
\]
(A.54b)
\[
B_n^2 = \sum_{i=1}^n b_{n,i}^2,
\]
(A.54c)
\[
d_{n,ij} = \frac{r - 1}{\hat{\tau}_n^s} \hat{g}_2(i,j) \times \frac{n}{n-1},
\]
(A.54d)
\[
\psi(\xi_i, \xi_j) = \xi_i \xi_j - \xi_i - \xi_j + 1.
\]
(A.54e)
Note that since \( \varepsilon_n^2 = \sum_i \hat{g}_1(i)^2/n \). Thus we use \( B_n^2 = n\varepsilon_n^2/\rho_n^2 \). Furthermore, Lemma D.6 shows that our \( \xi_i - 1 \) random variables have finite \( E(\{||\xi_i - 1||^2\}) \).

Lemma D.5 shows that the conditions in Eq A.47 are satisfied on a high probability set of \( A, X \).

Using Lemma D.5, we see that the first two conditions in Eq A.47 are satisfied with probability tending to one under Assumption 2. Since \( B_n^2/n = \sum_i \hat{b}_{n,i}/n \) converges to a positive constant (see Lemma D.3), the first condition holds. Now, we need to bound \( \ell_4, n \) and \( s_n \) as defined Eq A.48. First, let \( \beta_n,i := \sum_{j \neq i} \hat{g}_2(i,j)^2/n \) and \( \beta_n = \sum_i \beta_{n,i}/n \). Also let \( \gamma_n = \sum_i \beta_{n,i}/n - \beta_n^2 \). Then \( \ell_4, n = C\beta_n,i/\hat{\tau}_n^2 \). Note that using Lemma D.4 we have, with probability tending to one, \( \ell_4, n \leq C\rho_n^{-1} \). From Lemma D.3 we have \( \hat{\tau}_n = \Theta(\rho_n^2) \). Furthermore, let \( \tilde{G}_2(i,j) := \hat{H}_2(i,j) - h_2(X_i, X_j) \).

We have
\[
\tilde{G}_2(i,j)^2 = \tilde{G}_2(i,j)^2 - E\{\tilde{G}_2(i,j)^2 \mid X\} + E\{\tilde{G}_2(i,j)^2 \mid X\}.
\]

We now will establish the \( O(\rho_n^{2s-1}) \) bound stated above for the second term. Let \( S_{r}^{ij} \) denote all subsets of size \( r \) not containing \( i, j \).

\[
E\{\tilde{G}_2(i,j)^2 \mid X\} = \sum_{S,T \in S_{r}^{ij}} E\{H(A_{ij,U,S})H(A_{ij,U,T}) \mid X\}/(n-2)^2
\]

In the above sum the terms with \( |S \cap T| = 0 \) dominate, and for each of them the conditional expectation is bounded a.s. by \( O(\rho_n^{2s-1}) \) because of the boundedness of the graphon. Now note that:
\[
\hat{g}_2(i,j)^2 \leq 3 \left[ (\hat{H}_2(i,j) - h_2(X_i, X_j))^2 + h_2(X_i, X_j) - \theta_n \right]^2 + (\hat{T}_n - \theta_n)^2
\]
\[
\leq 3(\hat{H}_2(i,j) - h_2(X_i, X_j))^2 + O(\rho_n^{2s-1})
\]
\[
\beta_{n,i} \leq \frac{1}{n} \sum_{j \neq i} \delta_{ij} + O(\rho_n^{2s-1})
\]
\[
\gamma_n^2 \leq \frac{1}{n} \sum_i \beta_{n,i}^2 \leq \frac{1}{n} \sum_i \left\{ \frac{1}{n} \sum_{j \neq i} \delta_{ij} + O(\rho_n^{2s-1}) \right\}^2
\]
\[
\leq O(\rho_n^{4s-2}) + \frac{1}{n} \sum_i \frac{1}{n} \sum_{j \neq i} \delta_{ij}^2
\]

Now note that, \( E(\delta_{ij}) = E\{E(\delta_{ij} \mid X)\} = 0 \). Thus, for all \( i, \)
\[
E(A) = \frac{1}{n} \sum_i E \left\{ \frac{1}{n} \sum_{j \neq i} \delta_{ij} \right\}^2 = \frac{1}{n} \sum_i \text{var} \left( \frac{1}{n} \sum_{j \neq i} \delta_{ij} \right) = O(\rho_n^{4s-3}/n)
\]

36
Thus, we have, for a large enough $C$,

$$P \left( \gamma_n^2 \geq C \rho_n^{4s-2} \right) \leq P \left( A \geq C' \rho_n^{4s-2} \right) \leq O \left( \frac{E(A)}{\rho_n^{4s-2}} \right) = O \left( \frac{1}{n \rho_n} \right)$$

Therefore, since $s_n^2 = \frac{r_n-1}{(n-1)^2} \gamma_n^2 / \hat{\tau}_n^2$, we have with probability tending to one, $l_{4,n} + k s_n = O(\rho_n^{-1})$.

Since the first two conditions in eq [A.47] are satisfied with probability tending to one, from Wang and Jing (2004) Theorem 3.1, we have,

$$\sup_u \left| L_{1n}(u) + \frac{E(\xi_i - 1)^3}{6B_n^3} \sum_{i=1}^{n} b_{n,i}^3 \Phi''(u) \right| = o_P(n^{-1/2}),$$

Now we see that, using the definitions of $L_{1n}, L_{2n}$ in Eq A.45a, plugging in definitions of $b_{ni}$ and $d_{nij}$’s from Eq A.54, and using the fact that $E[Y_i Y_j \psi(Y_i, Y_j)] = E[(\xi_i - 1)^2(\xi_j - 1)^2] = 1$,

$$\sup_u |E_{2n}(u) - \hat{G}_n(u)| = o_P(n^{-1/2}).$$

Therefore, putting all the pieces together we see that

$$\sup_u \left| P^* \left( \frac{\hat{T}_{n,Q} - \hat{T}_n}{\hat{\sigma}_n} \leq u \right) - \hat{G}_n(u) \right| = o_P \left( \frac{\log n}{n^{2/3} \rho_n} \right)$$

Now we are ready to finish the proof of Corollary 5.

**of Corollary 5** Here we take care of the error term in the Hoeffding projection in Eq 12. Set $X = \frac{\hat{T}_{n,M} - \hat{T}_n}{\hat{\sigma}_n}$, $Y = \hat{T}_{n,Q}$. From Eq 12, we see that $X = Y + R_n$, where $R_n = o_P(\delta(n, \rho_n, R))$. Using Eq [A.55] we see that on a high probability set,

$$F_Y(u + a) - F_Y(u) \leq |F_Y(u + a) - \hat{G}_n(u + a)| + |\hat{G}_n(u + a) - \hat{G}_n(u)| + |\hat{G}_n(u) - F_Y(u)|$$

$$\leq C a + O \left( \frac{\log n}{n^{2/3} \rho_n} \right)$$

Therefore, using Lemma 8.2 in Zhang and Xia (2020),

$$\sup_u \left| P^* \left( \frac{\hat{T}_{n,M} - \hat{T}_n}{\hat{\sigma}_n} \leq u \right) - \hat{G}_n(u) \right| = o_P(n^{-1/2}) + O_P \left( \frac{\log n}{n^{2/3} \rho_n} \right).$$

□
If we can establish Eq A.52 and Eq A.53 from Lemma D.3 for our empirical moments, we will get the desired result. Note that our empirical moments involve the first term as well as a slight variation of the second term, which is given below.

\[ \hat{E}_n\{g_1(i)g_1(j)g_2(i, j)\} = \frac{\sum_{i<j} \hat{g}_1(i)\hat{g}_1(j)\hat{g}_2(i, j)}{\binom{n}{2}} \]

We will show that this follows from Eq A.52

\[
\begin{align*}
\sum_{i<j} \hat{g}_1(i)\hat{g}_1(j)\hat{g}_2(i, j) &= \sum_{i<j} \hat{g}_1(i)\hat{g}_1(j)(\hat{g}_2(i, j) - \hat{g}_1(i) - \hat{g}_1(j)) \\
&= \sum_{i<j} \hat{g}_1(i)\hat{g}_1(j)\hat{g}_2(i, j) - \sum_{i\neq j} \hat{g}_1(i)\hat{g}_1(j)(\hat{g}_1(i) + \hat{g}_1(j)) \\
&= \sum_{i<j} \hat{g}_1(i)\hat{g}_1(j)\hat{g}_2(i, j) - \sum_{i\neq j} \hat{g}_1(i)^2\hat{g}_1(j) \\
&= \sum_{i<j} \hat{g}_1(i)\hat{g}_1(j)\hat{g}_2(i, j) - \frac{(\sum_i \hat{g}_1(i))^2}{\binom{n}{2}} \sum_i \hat{g}_1(i) - \sum_i \hat{g}_1(i)^3 \\
&= \frac{(i) \sum_{i<j} \hat{g}_1(i)\hat{g}_1(j)\hat{g}_2(i, j)}{\binom{n}{2}} + \frac{\sum_i \hat{g}_1(i)^3}{\binom{n}{2}} + O_P\left( \frac{\rho_n^3}{n} \right)
\end{align*}
\]

(i) uses the fact that \( \sum_i \hat{g}_1(i) = 0 \). (ii) uses the fact that \( E\{g_1(X_1)^3\} = O(\rho_n^3) \) along with Eq A.51. Hence from Eq A.52 we have:

\[
\left| \frac{\sum_{i<j} \hat{g}_1(i)\hat{g}_1(j)\hat{g}_2(i, j)}{\binom{n}{2}} - E\{g_1(X_1)g_1(X_2)g_2(X_1, X_2)\} \right| = \max \left\{ O_P \left( \frac{\rho_n^3}{n} \right) , O_P \left( \rho^{3s-\frac{3}{2}} n^{-1/2} \right) \right\} = O_P \left( \rho^{3s-\frac{3}{2}} n^{-1/2} \right).
\]

This, along with Eqs A.51 and A.53 yields the result.

**D.1 Proof of Lemma D.4**

*Proof.* Recall the definition of \( \hat{H}_2(i, j) \) from Eq A.33

\[
\hat{g}_2(i, j) = \hat{H}_2(i, j) - \hat{T}_n = \{\hat{H}_2(i, j) - h_2(X_i, X_j)\} + \{h_2(X_i, X_j) - \theta_n\} - (\hat{T}_n - \theta_n)
\]

\[
\hat{g}_2(i, j)^2 \leq 3 \left[ \{\hat{H}_2(i, j) - h_2(X_i, X_j)\}^2 + \{h_2(X_i, X_j) - \theta_n\}^2 + (\hat{T}_n - \theta_n)^2 \right].
\]
Since \( \text{var}(\hat{T}_n) = O(\rho_n^2/n) \) and the second term is bounded a.s. due to our boundedness assumption. We will just prove that \( \sum_{i,j} \{ \hat{H}_2(i,j) - h_2(X_i, X_j) \}^2 / (n - 1) \rho_n^2 \) is bounded with high probability. It is not hard to check that

\[
E\left\{ \left( \hat{H}_2(i,j) - h_2(X_i, X_j) \right)^2 / \rho_n^2 \right\} = O(1 / \rho_n)
\]

Therefore,

\[
\sum_{j \neq i} E\left\{ \hat{g}_2(i,j)^2 / (n \rho_n^2) \right\} = O(1 / \rho_n)
\]

Furthermore, let \( \hat{G}_2(i, j) := \hat{H}_2(i, j) - h_2(X_i, X_j) \). We have

\[
\hat{G}_2(i, j)^2 = \hat{G}_2(i, j)^2 - E\left\{ \hat{G}_2(i, j)^2 | X \right\} + E\left\{ \hat{G}_2(i, j)^2 | X \right\}
\]

We now will establish the \( O(\rho_n^{2s-1}) \) bound stated above for the second term. Let \( S_{ij}^r \) denote all subsets of size \( r \) not containing \( i, j \).

\[
E\left\{ \hat{G}_2(i,j)^2 | X \right\} = \sum_{S, T \in S_{ij}^r} E\left\{ H(A_{ij} \cup S) H(A_{ij} \cup T) | X \right\} \left( \frac{n}{n - 2r - 2} \right)^2
\]

In the above sum the terms with \( |S \cap T| = 0 \) dominate, and for each of them the conditional expectation is bounded a.s. by \( O(\rho_n^{2s-1}) \) because of the boundedness of the graphon.

We will analyze \( \sum_i \sum_{j \neq i} \delta_{ij} \). Note that \( E(\delta_{ij} | X) = 0 \).

\[
\text{var}\left( \frac{1}{n^2} \sum_i \sum_{j \neq i} \delta_{ij} | X \right) = \sum_i \sum_j \text{var}(\delta_{ij} | X) + \sum_{i, k, k \neq i} \sum_{j, l, j \neq l} \text{cov}(\delta_{ik}, \delta_{jl} | X) \cdot \left( \frac{n}{n - 2r - 2} \right)^4
\]

(A.56)

\[
\delta_{ij} = \frac{1}{\left( \frac{n}{n - 2r - 2} \right)^2} \sum_{S, T \in S_{ij}^r} H(A_{ij} \cup S) H(A_{ij} \cup T) - E\left\{ H(A_{ij} \cup S) H(A_{ij} \cup T) | X \right\}
\]

For variance, we have:

\[
\text{var}(\delta_{ij}) = E\left\{ \text{var}(\delta_{ij} | X) \right\} = \sum_{S_1 \neq T_1, S_2 \neq T_2 \in S_{ij}^r} E\left\{ \text{cov}(H_{ij}^r(S_1, T_1), H_{ij}^r(S_2, T_2) | X \right\} \cdot \left( \frac{n}{n - 2r - 2} \right)^4
\]

The dominant term in the above sum is the one with \( S_1, S_2, T_1, T_2 \) all disjoint. Consider any other term in the above sum where any pair of the subsets have \( p \) nodes,
$d$ edges in common and the rest are disjoint. In this case there are $2(r-2-p) + 2(r-2) + p = 4(r-2) - p$ choices of nodes and the number of edges are lower bounded by $4(s-1) + 1 - d = 4s - 3 - d$ (since all pairs have $\{i,j\}$ in common). When $p \geq 1$, for acyclic graphs, $d \leq p - 1$ and for general subgraphs with a cycle, $d \leq \binom{p}{2}$. Thus, for $p \geq 0$, we have:

$$O \left( \frac{n^{4(r-2)-p} \rho_n^{4s-3-d}}{(r-2)^4} \right) = O(\rho_n^4) \times O \left( \frac{1}{n^p \rho_n^d} \right)$$

Note that for acyclic graphs, it is easy to see that under our sparsity conditions the above is dominated by $p = 0$. For general cyclic graphs, since $\rho_n = \omega(n^{-1/r})$, note that, since $p \leq r$,

$$n^p \rho_n^d \geq n^p \rho_n^{p(p-1)/2} \geq n^p \frac{1}{n^p \rho_n^{d-1}} \rightarrow \infty$$

So, $\text{var}(\delta_{ij}) = O(\rho_n^{4s-3})$.

For covariance, for $i \neq j \neq k \neq \ell$, we have:

$$\text{cov}(\delta_{ij}, \delta_{k\ell}) = E \{ \text{cov}(\delta_{ij}, \delta_{k\ell} | X) \} = \frac{\sum_{S_1 \neq T_1 \in \mathcal{S}_i^d, S_2 \neq T_2 \in \mathcal{S}_j^d} E \{ \text{cov}(H_{ij}^*(S_1, T_1), H_{ik}^*(S_2, T_2) | X) \}}{(n-2)^4}$$

Consider any two pairs of subsets with $p$ nodes and $d$ edges in common. First note that $p \geq 2$ in order to have a nonzero covariance. In this case there will be $4(r-2) - p$ choices for nodes, and $(2s - A_{ik}) + (2s - A_{j\ell}) - d \geq 4s - 3 - d$ edges.

$$= \frac{O \left( \frac{n^{4(r-2)-p} \rho_n^{4s-3-d}}{(r-2)^4} \right)}{O \left( \frac{1}{n^p \rho_n^d} \right)} = \frac{O(\rho_n^{4s-3})}{n^2} \times O \left( \frac{1}{n^p} \right).$$

Note that, for acyclic graphs $d \leq p - 1$ and hence the above is maximized at $p = 2$, $d = 1$ as long as $n \rho_n \rightarrow \infty$.

For general cyclic subgraphs, $d \leq \binom{p}{2}$. Furthermore, since $p + 2 \leq r$, and $\rho_n = \omega(n^{-1/r})$, we have, for $p > 2$:

$$n^p \rho_n^{d-1} = n^{p-2 - \frac{1}{2} \left( \frac{p(p-1)}{2} \right) - 1} = n^{p-2} \frac{(p-2)(p-1)}{2} \geq n^{p-2} \frac{p+1}{2} \rightarrow \infty$$

Thus under the conditions of Assumption 2 we have:

$$\text{cov}(\delta_{ik}, \delta_{j\ell}) = O(\rho_n^{4s-3} / n^2)$$

Step (i) is true, because conditioned on $X$, there needs to be at least two nodes $u_1, u_2$ in common between $\{i, k \cup S_1 \cup T_1\}$ and $\{j, \ell \cup S_2 \cup T_2\}$ to have a nonzero covariance.
This leads to only $4(r - 2) - 2$ choices, which dominates the sum. This along with Eq [A.56] gives us:

$$\text{var} \left( \frac{1}{n^2} \sum_{i,j \neq i} \delta_{ij} \right) = E \left\{ \text{var} \left( \sum_{i,j \neq i} \delta_{ij} / n^2 \mid X \right) \right\} = O(\rho_n^{4s-3} / n^2).$$

Thus we have for large enough $C$, we have

$$P \left( \frac{1}{n^2} \sum_{i,j \neq i} \tilde{g}_2(i,j)^2 \geq C \rho_n^{2s-1} \right) \leq P \left( \left| \sum_i \sum_{j \neq i} \delta_{ij} / n^2 + O(\rho_n^{2s-1}) \right| \geq C \rho_n^{2s-1} \right)$$

$$\leq P \left( \sum_i \left| \sum_{j \neq i} \delta_{ij} / n^2 \right| \geq C' \rho_n^{2s-1} \right)$$

$$\leq C' \rho_n^{4s-3} / n^2 = O \left( \frac{1}{n^2 \rho_n} \right).$$

\[\square\]

### D.2 Proof of Lemma [D.5]

**Proof.** Let $\Delta_i := |\hat{g}_1(i) - g_1(X_i)| / \rho_n^s$. We have:

$$\sum_i |\hat{g}_1(i) / \rho_n^s|^3 \leq \sum_i \Delta_i^3 + 3 \sum_i |g_1(X_i) / \rho_n^s|^3 \Delta_i^2 + 3 \sum_i |g_1(X_i) / \rho_n^s|^2 \Delta_i + \sum_i |g_1(X_i) / \rho_n^s|^3$$

$$= B_1 + B_2 + B_3 + B_4 \quad \text{(A.57)}$$

First note that using the boundedness condition on the graphon, $|g_1(X_i) / \rho_n^s|$ is bounded. Hence $B_4 \leq c \text{ a.s.}$ Using Lemma [D.3], we know that $E(\Delta_i)^2 = O(1/n \rho_n)$. Since $\sum_i \Delta_i \leq n^{1/2} \sum_j \Delta_j^2$, for the second term we have, for some $C > 0$:

$$P(B_2 \geq \epsilon) \leq \frac{n^{1/2} E \sum_i \Delta_i^2}{n \epsilon^2} \leq \frac{C}{n^{1/2} \rho_n \epsilon^2} \quad \text{(A.58)}$$

Furthermore,

$$P(B_3 \geq \epsilon) \leq \frac{E \sum_i \Delta_i^2}{n \epsilon^2} \leq \frac{C}{n \rho_n \epsilon^2} \quad \text{(A.59)}$$

By repeated application of Cauchy Schwarz inequality, we have $(\sum_i x_i^3)^2 \leq \sum_i x_i^2 \sum_i x_i^4 \leq (\sum_i x_i^2)^3$, we also have:

$$P(B_1 \geq \epsilon) \leq \frac{E \sum_i \Delta_i^3}{n \epsilon^2} \leq \frac{(\sum_i E \Delta_i^2)^{3/2}}{n \epsilon^2} \leq \frac{C}{n \rho_n^{3/2} \epsilon^2}$$
Therefore, using the sparsity conditions in Assumption 2, we see that the first equation in the lemma statement is proved. For the second, we use:

$$\sum_{i} \frac{|\hat{g}_1(i)|}{\rho_n}^2 \geq \sum_{i} \frac{|g_1(X_i)|}{\rho_n}^2 + \sum_{i} \Delta_i^2 - 2 \sum_{i} \frac{|g_1(X_i)|}{\rho_n} \Delta_i$$

where $C_1 + \alpha B_2 - \beta B_3$,

where $\alpha, \beta$ are positive constants, and $B_2, B_3$ were defined in Eq A.57. Using Assumption 2 part 1, we see $C_1 > 0$, a.s. Also, now for a small enough constant $\epsilon$, using Eqs A.58 and A.59, we see that the second equation in the lemma statement is proven.

D.3 Proof of Lemma [D.1]

Proof. Define the following quantities.

$$\gamma_j(t) = E\{\exp(itb_{nj}Y_j/B_n)\}$$

Also define $\phi_{1,n}$ and $\phi_{2,n}$ as:

$$\phi_{1,n}(t) = e^{-t^2/2} \left[ 1 + \sum_j \{\gamma_j(t) - 1\} + \frac{t^2}{2} \right]$$

$$\phi_{2,n}(t) = -it^2 K_{2,n} e^{-t^2/2}.$$ 

Finally define,

$$S_n = \frac{1}{B_n} \sum_j b_{nj}Y_j, \quad \Delta_{n,m} = \frac{1}{n^{3/2}} \sum_{i=1}^{m-1} \sum_{j=i+1}^{n} d_{ni,j} \psi(Y_i, Y_j)$$

As in the original proof, we define:

$$\int_{-\infty}^{\infty} e^{itx} d\{\Phi(x) + L_{1,n}\} dx = \phi_{1,n}(t)$$

$$\int_{-\infty}^{\infty} e^{itx} dL_{2,n} dx = it\phi_{2,n}(t)$$

$$\int_{-\infty}^{\infty} e^{itx} E_{2n}(x) dx = \phi_{1,n}(t) + it\phi_{2,n}(t)$$

Now, for some $c > 0$ to be chosen later, from Esseen’s smoothing lemma [Petrov]
and Eq A.60 we have:

\[
\sup_x |P(V_n \leq x) - E_{2n}(x)| \\
\leq \int_{|t| \leq n^{1-c}} |t|^{-1} |E(e^{itV_n}) - \phi_{1,n}(t) - it\phi_{2,n}(t)|dt + C_n c^{-1} \sup_x \left| \frac{dE_{2,n}(x)}{dx} \right| \\
\leq \int_{|t| \leq n^{1-c}} |t|^{-1} |E(e^{itV_n}) - \phi_{1,n}(t) - it\phi_{2,n}(t)|dt + \frac{C_1(|K_{2,n} + \beta|)}{n^{1-c}} \tag{A.61}
\]

The last line is true due to the following argument. Note that, for some \(v_j\) in the \(|b_{nj} Y_j / B_n|\) ball in the neighborhood of \(x\), for \(j \in \{1, \ldots, n\}\),

\[
\frac{dL_{1,n}(x)}{dx} = \sum_{j=1}^{n} \left[ E\{\phi(x - b_{nj} Y_j / B_n)\} - \phi(x) \right] - \frac{1}{2} \Phi'''(x)
\]

\[
= \sum_{j=1}^{n} E\{ -b_{nj} Y_j / B_n \phi'(x) + b_{nj}^2 Y_j^2 / 2 B_n^2 \phi''(x) - b_{nj}^3 Y_j^3 / 6 B_n^3 \phi'''(v_j) \} - \frac{1}{2} \Phi'''(x).
\]

Thus, we have:

\[
\sup_x \left| \frac{dL_{1,n}(x)}{dx} \right| \leq \sum_{j=1}^{n} \left[ c_1 |b_{nj}^2 / B_n^2| \phi''(x) | + c_2 |b_{nj}^3 / B_n^3| E(|Y_j^3|)|\phi'''(v_j)| \right] + \frac{1}{2} |\Phi'''(x)|
\]

\[
\leq C + E(|X_1|^3) \left( \sum_{j} |b_{nj}^3 / B_n^3| \right) + C'
\]

\[
\leq C + \beta / n^{1/2} \leq C \beta \quad \text{Since } \beta \geq 1
\]

Also note that, for any \(\epsilon > 0\), for \(n\) large enough,

\[
\int_{|t| > n^{1-c}} |\phi_{1,n}(t)|/t|dt = O(1/n^{1-c})
\]

\[
\int_{|t| > n^{1-c}} |\phi_{2,n}(t)|/t|dt = O(|K_{2,n}|/n^{1-c})
\]

Thus the main idea is that \(E(e^{itV_n})\) behaves like \(E(itS_n) + it E(itS_n \Delta_{n,n})\).

\[
\int_{|t| \leq n^{1-c}} |t|^{-1} |E(e^{itV_n}) - \phi_{1,n}(t) - \phi_{2,n}(t)|dt \leq 4 \sum_{j=1}^{n} I_{j,n}
\]

Going back to Eq A.61, we break up the first part of the RHS into four parts, and the remainder gets absorbed into \(O(|K_{2,n} + \beta|/n^{1-c})\) term in Eq A.61.
\begin{align*}
|I_{1,n}| &= \int_{|t|<n^c} |t|^{-1} \left| E(e^{itV_n}) - E(itS_n) - itE(itS_n \Delta_{n,n}) \right| dt \\
|I_{2,n}| &= \int_{|t|<n^c} |t|^{-1} \left| E(e^{itS_n}) - \phi_{1,n}(t) \right| dt \\
|I_{3,n}| &= \int_{|t|<n^c} \left| E(\Delta_{n,n} e^{itS_n}) - \phi_{2,n}(t) \right| dt \\
|I_{4,n}| &= \int_{n^c \leq |t|<n^{1-c}} |t|^{-1} \left| E(e^{itV_n}) \right| dt
\end{align*}

First we will bound some terms which will be used frequently. Since \(ab \leq (a^2 + b^2)/2\),

\[
|K_{2,n}| \leq \frac{C}{n^{3/2}B_n^2} \sum_{1 \leq i < j \leq n} \left( b_{ni}^2 b_{nj}^2 + d_{nij}^2 \right) (1 + \lambda)
\]

\[
\leq \frac{C(1 + \lambda)}{n^{3/2}B_n^2} \left( \sum_j b_{nj}^2 \right)^2 \sum_{i<j} d_{nij}^2
\]

\[
\leq \frac{C(1 + \lambda) l_{4,n}}{n^{3/2}}
\]

(A.62)

As for \(\Delta_{n,n}\), we have:

\[
E \Delta_{n,n}^2 = \frac{\lambda}{n^2} \sum_{i=1}^{n-1} \sum_{j=i+1}^{n} d_{nij}^2 = \frac{\lambda_{4,n}}{n}
\]

Furthermore we will use:

\[
R(z) := e^{iz} - 1 - iz \quad |R(z)| \leq |z|^\alpha \text{ for all } \alpha \in [1, 2]
\]

(A.63)

We will first bound \(I_{1,n}\). Using Taylor expansion, for some \(|\eta| \leq 1\),

\[
|I_{1,n}| \leq \int_{|t|<n^c} |t|^{-1} t^2/2 |E(\Delta_{n,n}^2 e^{itS_n} e^{it\Delta_{n,n} \eta})| dt
\]

\[
\leq 1/2 \int_{|t|<n^c} |t| E(\Delta_{n,n}^2) dt \leq C(1 + \lambda) l_{4,n} / n^{1-2c}
\]

Next we bound \(I_{2,n}\). Using a similar argument in the proof of the original version.
of this theorem, we have:

\[
|I_{2,n}| \leq \frac{C_1}{B_n^3} \sum_j b_{n,j}^4 + C_2 \left( \frac{1}{B_n^3} \sum_j |b_{n,j}|^3 E(|X_1|^3) \right)^2 \\
\leq C_1 n^{-2/3} + C_2 \lambda^2 / n
\]

Now we do \(I_{3,n}\). Denote \(Z_j = b_{n,j} Y_j / B_n\) and \(\psi_{ij} = d_{n,j} \psi(Y_i, Y_j)\). First note that

\[
E\{\psi_{ij} e^{it (Z_i + Z_j)}\} = -t^2 \ell_{ij} + \theta_{1,ij}(t) \\
(A.64)
\]

where we have:

\[
\ell_{ij} = E(|\psi_{ij} Z_i Z_j|) \leq |b_{n,j} b_{n,j} d_{n,j}| / B_n^2 |E\{Y_i Y_j \psi(Y_i, Y_j)\}| \leq \lambda^{1/2} (b_{n,j}^2 b_{n,j}^2 + d_{n,j}^2) / B_n^2 \\
(A.65)
\]

Using Eq (A.63) and the fact that \(E\{\psi(Y_i, Y_j)\} = 0\) and \(E\{\psi(Y_i, Y_j) | Y_i\} = 0\),

\[
\theta_{1,ij} = E(\psi_{ij} | t \{Z_i R(t Z_i) + Z_j R(t Z_j)\} + R(t Z_i) R(t Z_j)\}) \\
\leq C |t|^2 E(\psi_{ij} Z_i Z_j^{1.5} + |\psi_{ij} Z_j Z_i^{1.5}|) \\
\leq C |t|^2 E(\{Y_i Y_j Z_i^{1.5} \psi(Y_i, Y_j)\}) \left(|d_{n,j} b_{n,j} b_{n,j} / B_n^{2.5}| + |d_{n,j} b_{n,j} b_{n,j} / B_n^{2.5}| \right) \\
\leq C |t|^3 \lambda \beta / n^{3/2} (d_{n,j}^2 + b_{n,j}^2 |b_{n,j}|^3 + |b_{n,j}|^2 d_{n,j}^2) n^{-5/4}
\]

Using Eq (A.64) and setting \(\prod_{k \neq i,j} \gamma_k(t) = e^{-t^2/2} + \theta_{2,i,j}\) we see:

\[
E(\Delta_{n,ne^{itS_n}}) = n^{-3/2} \sum_{i < j} E(\psi_{ij} e^{itS_n}) = n^{-3/2} \sum_{i < j} E(\psi_{ij} e^{it(Z_i + Z_j)}) \prod_{k \neq i, j} \gamma_k(t) \\
= n^{-3/2} \sum_{i < j} \{-t^2 \ell_{ij} + \theta_{1,ij}(t)\} \left(e^{-t^2/2} + \theta_{2,ij}\right) \\
= n^{-3/2} \sum_{i < j} \{-t^2 \ell_{ij} e^{-t^2/2} + \theta_{3,ij}(t)\} \\
= -K_{2} n t^2 e^{-t^2/2} + n^{-3/2} \sum_{k < i,j} \theta_{3,ij},
\]

where using Lemma A.4 in [Wang and Jing (2004)], for \(|t| < n^{1/6} \)

\[
|\theta_{2,ij}| \leq C \frac{n^{1/2}}{n^{1/2}} \left(\beta + \frac{b_{n,j}^2 + b_{n,i}^2}{n^{1/2}}\right) (t^2 + t^4) e^{-t^2/8}
\]

Furthermore, using Lemma A.4 and \(\sum_i |b_{n,i}|^3 \leq \ell_2 n\)

\[
|\theta_{3,ij}| \leq t^2 |\ell_{ij} \theta_{2,ij}| + |\theta_{1,ij}| \prod_{k \neq i,j} \gamma_k(t) \leq t^2 |\ell_{ij} \theta_{2,ij}| + 4 |\theta_{1,ij}| e^{-t^2/8}
\]

\[
|\ell_{ij} \theta_{2,ij}| \leq C \frac{n^{1/2}}{n^{1/2}} |\ell_{ij}| \left(\beta + \frac{b_{n,j}^2 + b_{n,i}^2}{n^{1/2}}\right) (t^2 + t^4) e^{-t^2/8}
\]
Summing the above expression over \( i < j \), we also have,

\[
\sum_{i<j} |\ell_{i,j} \theta_{2,i,j}| \leq C' \lambda^{1/2} \left( \beta \frac{B_n^4 + l_{4,n} n^2}{n^{3/2}} + \sum_{i<j} |d_{nij}| \left( |d_{nij}^1| + |d_{nij}^2| \right) \right) (t^2 + t^4) e^{-t^2/8}
\]

\[
\leq C' \lambda^{1/2} \left[ \beta \frac{B_n^4 + l_{4,n} n^2}{n^{3/2}} + \frac{c}{n^2} \left\{ \left( \sum_{i<j} d_{nij}^2 \right) \left( \sum_{i<j} b_{ni}^2 b_{nj}^2 \right) \right\} \right]^{1/2} (t^2 + t^4) e^{-t^2/8}
\]

(A.66)

To bound (A) we see:

\[
(A) \leq \left\{ \left( n^2 l_{4,n} (n \ell_2) \sum_{i<j} b_{ni}^2 b_{nj}^2 \right) \right\}^{1/2} \leq n^{3/2} (l_{2} l_{4,n})^{1/2} \left\{ \left( \sum_i b_{ni}^3 \right) \left( \sum_j b_{nj}^2 \right) \right\}^{1/2}
\]

\[
\leq c' n^{5/2} l_{4,n}^{1/2} \ell_2
\]

Plugging this back in Eq[A.66] and assuming WLOG \( l_{4,n} \geq 1 \),

\[
\sum_{i<j} |\ell_{i,j} \theta_{2,i,j}| \leq C' \lambda^{1/2} \left( \beta \frac{B_n^4 + l_{4,n} n^2}{n^{3/2}} + \frac{1}{n^2} n^{5/2} \ell_2 l_{4,n}^{1/2} \right) (t^2 + t^4) e^{-t^2/8}
\]

\[
\leq C' l_{4,n} \lambda^{1/2} \beta n^{1/2} (t^2 + t^4) e^{-t^2/8}
\]

Finally, we also have:

\[
\sum_{i<j} |\theta_{1,i,j}| \leq C |t|^{2.5} (\lambda \beta)^{1/2} (l_{4,n} n^2 + 2 \ell_2 n B_n^2) n^{-5/4} \leq C |t|^{2.5} (\lambda \beta)^{1/2} l_{4,n} n^{1/4}
\]

Finally we have, since \( t^4 \leq |t| + |t|^6 \), and \( |t|^{2.5} \leq |t| + |t|^6 \),

\[
R_{n,4} \leq n^{-3/2} \sum_{i<j} |\theta_{3,i,j}| \leq n^{-3/2} \left( \sum_{i<j} t^2 |\ell_{i,j} \theta_{2,i,j}| + 4 \sum_{i<j} |\theta_{1,i,j}| e^{-t^2/8} e^{-t^2/8} \right)
\]

\[
\leq \left( t^2 l_{4,n} \lambda^{1/2} (t^2 + t^4) e^{-t^2/8} n^{-1} + |t|^{2.5} (\lambda \beta)^{1/2} l_{4,n} n^{-3/4} e^{-t^2/8} \right)
\]

\[
\leq l_{4,n} \left( \lambda^{1/2} \beta n^{-1} + (\lambda \beta)^{1/2} n^{-3/4} \right) (|t| + |t|^6) e^{-t^2/8}
\]

\[
\leq C' l_{4,n} \left( \beta^2 n^{-1} + (\lambda + \beta) n^{-3/4} \right) (|t| + |t|^6) e^{-t^2/8}
\]
Finally, for $I_{3,n}$, we have:

$$|I_{3,n}| \leq \int_{|t| \leq n^*} |t|^{-1} R_{n,4} \, dt$$

$$\leq C|l_{4,n}| \left( \beta^2 n^{-1} + (\lambda + \beta)n^{-3/4} \right) \int_{|t| \leq n^*} (1 + |t|^5) e^{-t^2/8} \, dt$$

$$\leq C'|l_{4,n}| \left( \beta^2 n^{-1} + (\lambda + \beta)n^{-3/4} \right)$$

Now we will bound $I_{4,n}$.

Define $\Omega := \{ k : \min(1/2, \ell_2 / \ell_1^{3/2}) \leq n^{1/2} b_{n,k} / B_n \leq 2 \ell_2 / \ell_1^{3/2} \}$. Using Lemma A.5 in [Wang and Jing (2004)], we see that $|\Omega| \geq c_0 n$, for some $c_0 \in (0,1)$.

Now, let $\Gamma := \{ i | \alpha_i \geq \Delta + k s_n \}$. Applying Lemma D.2 and setting $k = \sqrt{2/c_0}$, we see that $|\Gamma^c| \geq n(1 - c_0/2)$. Therefore, $|\Gamma^c \cap \Omega| \geq nc_0/2$. Let $k_0 = [c_0/2]$.

WLOG assume $b_{n,1} \ldots b_{n,k_0} \in \Omega \cap \Gamma^c$ and $\ell_2 / \ell_1^{3/2} \geq 1/2$. Now for $m \in [2, k_0 n]$, we have:

$$S_m = \frac{1}{B_n} \sum_{k=1}^{m} b_{nk} Y_k = \frac{1}{B_n} \sum_{k \neq i,j} b_{nk} X_k$$

For $1, \ldots, m \leq k_0 n$, we have:

$$\frac{1}{mn} \sum_{i=1}^{m} \sum_{j=1, j \neq i} d_{nij}^2 = \frac{1}{m} \sum_{i=1}^{m} \alpha_i \leq l_{4,n} + k s_n =: \ell_{5,n}$$

As for $\Delta_{n,m}$, we have:

$$E(\Delta_{n,m}^2) = \frac{\lambda}{n^3} \sum_{i=1}^{m-1} \sum_{j=i+1}^{n} d_{nij}^2 \leq \lambda_{5,n} \frac{m}{n^2} \quad (A.67)$$

Now we use the decomposition in [Bickel et al. (1986)] (17)-(22).

$$E(e^{it V_n}) = E\{e^{it (V_n - \Delta_{n,m})} e^{it \Delta_{n,m}} \}
= E\{e^{it (V_n - \Delta_{n,m})} (1 + it \Delta_{n,m}) \} + R_{n,5}
= E\{e^{it (V_n - \Delta_{n,m})} (1 + it \Delta_{n,m}) \} + Ct^2 \lambda_{5,n} m / n^2$$

$$\leq E\{e^{it (V_n - \Delta_{n,m})} \} + \frac{it}{n^{3/2}} \sum_{i=1}^{m} \sum_{j=i+1}^{n} E\left\{e^{it (V_n - \Delta_{n,m})} \psi_{ij} \right\}_{D_{ij}} + Ct^2 \lambda_{5,n} \frac{m}{n^2}$$

where the last line is obtained using Eqs [A.63] and [A.67] as follows:

$$R_{n,5} \leq |E\{e^{it (V_n - \Delta_{n,m})} \Delta_{n,m}^2 \}| \leq Ct^2 \lambda_{5,n} m / n^2$$
Note that $V_n - \Delta_{n,m}$ can be written as $S_{m-1} + Y_{m,n}$, where $Y_{m,n}$ does not depend on $Y_1, \ldots, Y_{m-1}$. So we will write:

$$
\left| \sum_{i=1}^{m-1} \sum_{j=i+1}^{n} (D_{ij}) \right| = \left| \sum_{i=1}^{m-1} \sum_{j=i+1}^{n} E\{e^{i(S_{m-1}^{ij} + \psi_{ij} + Y_{m,n})} \psi_{ij}\} \right|
= \left| \sum_{i=1}^{m-1} \sum_{j=i+1}^{n} E\{e^{itS_{m-1}^{ij}}\} E\{e^{(\psi_{ij} + Y_{m,n})} \psi_{ij}\} \right|
\leq \sup_{i<j} |E(e^{itS_{m-1}^{ij}})| \sum_{i=1}^{m-1} \sum_{j=i+1}^{n} E(|\psi_{ij}|)
\leq \sup_{i<j} |E(e^{itS_{m-1}^{ij}})| \sum_{i=1}^{m-1} \sum_{j=i+1}^{n} |d_{nij}| E(|\psi(Y_i, Y_j)|)
\leq \lambda^{1/2} \sup_{i<j} |E(e^{itS_{m-1}^{ij}})| \sqrt{mn} \sum_{i=1}^{m-1} \sum_{j=i+1}^{n} d_{nij}^2
\leq \sqrt{\lambda_{5,5,n}} \sup_{i<j} |E(e^{itS_{m-1}^{ij}})| mn
$$

Plugging it back, we have:

$$
|E(e^{itV_n})| \leq |E(e^{itS_{m-1}^{ij}})| + \frac{|t|}{n^{1/2}} \sqrt{\lambda_{5,5,n}} \sup_{i<j} |E(e^{itS_{m-1}^{ij}})| mn + Ct^2 \lambda_{5,5,n} \frac{m}{n^2}
$$

(A.68)

Now, we have for $|t| \leq 1/4n^{1/2}/E(|Y_1|^3)$

$$
|E(e^{itS_m})| \leq e^{-c_0 m t^2 / n} \quad \text{and} \quad |E(e^{itS_{ij}^{ij}})| \leq e^{-c_0 (m-2) t^2 / n}
$$

Taking $m = \lceil 6n \log n / c_0 t^2 \rceil + 1$ (for a large enough $\epsilon$, this is still smaller than $k_0 n$), from Eq\[(A.68)\] we have:

$$
\int_{n^* \leq |t| < 1/4n^{1/2}/E(|Y_1|^3)} |t|^{-1} |E(e^{itV_n})| \ dt
\leq \int_{n^* \leq |t| < 1/4n^{1/2}/E(|Y_1|^3)} \left( \frac{e^{-c_0 m t^2 / n}}{|t|} + \frac{m}{n^{1/2}} \sqrt{\lambda_{5,5,n}} e^{-c_0 (m-2) t^2 / n} + C |t| \lambda_{5,5,n} \frac{m}{n^2} \right) \ dt
\leq C' \lambda_{5,5,n} \frac{\log^2 n}{n}
$$

Now we will deal with the range $1/4n^{1/2}/E(|Y_1|^3) \leq |t| \leq n^{1-c}$. Since $\kappa(Y_1) > 0$, the case $\kappa(Y_1) < 0$
and hence for large enough $n$,

\[ |\gamma_k(t)| \leq 1 - \kappa(Y_1) \]
\[ |E(e^{itS_m})| \leq e^{-mn(\kappa(Y_1))} \]
\[ E(e^{itS_m}) \leq e^{-(m-2)\kappa(Y_1)} \]

Using this in conjunction with Eq A.68 and setting $m = [4 \log n/\kappa(Y_1)] + 2$,

\[
\int_{1/4n^{1/2}/E(|Y_1|^3)}^{1/4n^{1/2}/E(|Y_1|^3)} |t|^{-1} |E(e^{itV_n})| \, dt
\]
\[
\int_{1/4n^{1/2}/E(|Y_1|^3)}^{1/4n^{1/2}/E(|Y_1|^3)} \left( \frac{e^{-\kappa(Y_1)m}}{|t|} + \frac{m}{n^{1/2}} \sqrt{\lambda l_5 n e^{-\kappa(Y_1)(m-2)}} + C|t|\lambda l_5 n \frac{m}{n^2} \right)
\]
\[
\leq C \beta n l_5 n \log n \frac{n^{2(1-c)}}{\kappa(Y_1)} = C \beta n l_5 n \log n \frac{n^{2c}}{n^{2c}}
\]

Thus, using the bounds on $I_{1,n}, I_{2,n}, I_{3,n}$ and $I_{4,n}$ along with Eq A.61, Eq A.62 we get:

\[
\sup_x |P(V_n \leq x) - E_{2n}(x)| \leq \sum_{i=1}^4 I_{n,i} + C_\beta + (1 + \lambda)l_{4,n}/n^{1/2}
\]
\[
\leq C \left( \frac{(1 + \lambda)l_{4,n}}{n^{1-c}} + n^{-2/3} + l_{4,n}(\lambda + \beta + \beta^2)n^{-3/4} + \frac{\lambda l_5 n \log n}{\kappa(Y_1) n^{2c}} \right) + C' \frac{\beta + (1 + \lambda)l_{4,n}/n^{1/2}}{n^{1-c}}
\]
\[
\leq (l_{4,n} + ks_n) \frac{\log n}{n^{2/3}}
\]

The last line assumes $\beta$, $\lambda$ and $\kappa(Y_1)$ are all bounded. \hfill \Box

**D.4 Proof of Lemma D.6**

*Proof.* Let $X \sim N(1, c_1^2)$ and $Y \sim N(1, c_2^2)$ be two independent random variables. We have $\xi_1 = XY$.

\[
E(|XY - 1|^3) \leq E(|XY|^3) + 1 + 3E(X^2|Y|) + 3E(|X|Y^2)
\]
\[
= E(|X|^3)E(|Y|^3) + 3E(X^2)E(|Y|) + 3E(|X|)E(Y^2)
\]
\[
< \infty
\]

The last step is true because both $E(|X|^3)$ and $E(|Y|^3)$ are bounded for bounded $c_1, c_2$. \hfill \Box
In this section, we establish Edgeworth expansions for smooth functions of counts for the bootstrap and show that they are close to Edgeworth expansions of the conditional expectation of the count statistic, which is a U-statistic. To our knowledge, Edgeworth expansions for smooth functions are not explicitly stated in the literature even for U-statistics. It turns out that the non-negligible terms arising from a Taylor approximation of the smooth functional are of a form where a flexible Edgeworth expansion result of Jing and Wang (2010) may be invoked. Edgeworth expansions for smooth functionals are also considered in Hall (2013), but the argument provided there requires multivariate Edgeworth expansions and depends heavily on the properties of cumulants of independent random variables, complicating extensions even to U-statistics.

Since the Edgeworth expansion of the conditional expectation requires a non-lattice condition, it is assumed below. However, it is likely that this condition can be removed if one derives an Edgeworth expansion for the count functional directly and uses a proof strategy similar to Zhang and Xia (2020) that exploits the smoothing nature of Bernoulli noise.

### E.1 Edgeworth Expansion for Smooth Functions of Counts

In what follows, let \( f : \mathbb{R}^d \to \mathbb{R} \) denote the smooth function of interest, \( u \) denote a \( d \)-dimensional vector of conditional expectations corresponding to scaled count functionals \( \{ \hat{T}_n^{(1)}(\rho_s^1), \ldots, \hat{T}_n^{(d)}(\rho_s^d) \} \) given \( X \), and \( \mu = E(u) \). In this section, we consider Edgeworth expansions for the statistic:

\[
S_n = n^{1/2} \left( f(u) - f(\mu) \right) / \sigma_f,
\]

where \( \sigma_f^2 \) is the asymptotic variance of \( S_n \). The standard Delta Method involves a first-order Taylor expansion, resulting in a Normal approximation with rate \( O(1/\sqrt{n}) \) when the gradient is not equal to 0 at \( \mu \). To attain higher-order correctness, we need to consider a second-order expansion. Recall the derivatives of interest \( a_i, 1 \leq i \leq d \) and \( a_{ij}, 1 \leq i, j \leq d \) defined in Eq \[27\]. Furthermore, define the following analog the moments of the linear component of the U-statistic:

\[
\lambda_{i_1, \ldots, i_d} = E \left\{ \left( \frac{r_{i_1}g_1^{(i_1)}(X_{i_1})}{\rho_n} \right) \ldots \left( \frac{r_{i_d}g_1^{(i_d)}(X_{i_d})}{\rho_n} \right) \right\}.
\]

In the proposition below, we state the form of the Edgeworth for an appropriately smooth function \( f \).

**Proposition E.1.** Suppose that \( \sigma_f > 0 \), the function \( f \) has three continuous derivatives in a neighbourhood of \( \mu \), and \( \sum_{i=1}^d a_i g_1^{(i)}(X_i) \) is non-lattice. Then,

\[
P(S_n \leq x) = \Phi(x) + n^{-1/2} p_1(x) \phi(x) + o \left( \frac{1}{n^{1/2}} \right),
\]
\[ p_1(x) = -\{A_1 \sigma_f^{-1} + \frac{1}{6} A_2 \sigma_f^{-3} (x^2 - 1)\}, \]

where \( \sigma_f, A_1 \) and \( A_2 \) are given by:

\[ \sigma_f^2 = \sum_{i=1}^{d} \sum_{j=1}^{d} a_i a_j \lambda_{ij}, \]

\[ A_1 = \frac{1}{2} \sum_{i=1}^{d} \sum_{j=1}^{d} a_i a_j \lambda_{ij}, \]

\[ A_2 = \sum_{i=1}^{d} \sum_{j=1}^{d} \sum_{k=1}^{d} a_i a_j a_k \lambda_{ijk} + 3 \sum_{i=1}^{d} \sum_{j=1}^{d} \sum_{k=1}^{d} \sum_{t=1}^{d} a_i a_j a_k \lambda_{ik} \lambda_{jt} + 3 \sum_{i=1}^{d} \sum_{j=1}^{d} \sum_{k=1}^{d} \sum_{t=1}^{d} a_i a_j a_k \lambda_{ij} \lambda_{kt} \]

\[ \rho^{ij} = \frac{r_i g_1^{(i)} (X_i, X_i) r_j g_1^{(j)} (X_j, X_j) r_k (r_k - 1) g_2^{(k)} (X_i, X_i, X_i)}{\rho^{ik} \rho^{jk}}. \]

Before stating the proof in detail we add an auxiliary lemma, which is needed to bound the contribution of a remainder term.

**Lemma E.2.** Let \( S_n = V_n + c/\sqrt{n} \). Let \( P(V_n \leq x) = \Phi(x) + p_1(x) \phi(x)/\sqrt{n} + o(1/\sqrt{n}) \). Then we have:

\[ P(S_n \leq x) = \Phi(x) + (p_1(x) + c) \phi(x)/\sqrt{n} + o(1/\sqrt{n}) \quad (A.69) \]

**Proof.** We have:

\[ P(S_n \leq x) = P(V_n \leq x - c/\sqrt{n}) = \Phi(x - c/\sqrt{n}) + \frac{p_1(x - c/\sqrt{n})}{\sqrt{n}} \phi(x - c/\sqrt{n}) + o(1/\sqrt{n}) \]

Note that \( \text{sup}_x |\phi(x)| \leq C \) for some universal constant \( C \). So we have:

\[ \Phi(x - c/\sqrt{n}) = \Phi(x) - c/\sqrt{n} \phi(x) + O(1/n), \]

and

\[ |\phi(x - c/\sqrt{n}) - \phi(x)| = O(1/n). \]

Using the above two equations with Eq \( \text{[A.69]} \), we attain the stated result. \( \square \)

Now we present the result in Proposition E.1.

**Proof.** A second-order Taylor expansion yields:

\[ n^{1/2} (f(u) - f(\mu)) = n^{1/2} < u - \mu, \nabla f(\mu) > + \frac{1}{2} n^{1/2} (u - \mu)^T H(\mu)(u - \mu) + O_P \left( \frac{1}{n} \right). \quad (A.70) \]
Furthermore, by a multivariate Hoeffding Decomposition for \( u - \mu \):

\[
\begin{align*}
  u - \mu &= \frac{1}{n} \left\{ \frac{r_1}{\rho_n} \sum_{i=1}^{n} g_1^{(1)}(X_i) + \frac{1}{n^2} \left\{ \frac{r_1(\rho_1-1)}{\rho_n^2} \sum_{i<j} g_2^{(1)}(X_i, X_j) \right\} + O_P \left( \frac{1}{n^{3/2}} \right) \right\} \\
  &= \frac{1}{n} u_L + \frac{1}{n^2} u_Q + O_P \left( \frac{1}{n^{3/2}} \right), \quad (A.71)
\end{align*}
\]

where

\[
  n^{-1/2} ||u_L|| = O_P(1), \quad \frac{1}{n^{3/2}} ||u_Q|| = O_P \left( n^{-1/2} \right).
\]

Now for the first term in Eq \((A.70)\) we have

\[
  n^{1/2} < u - \mu, \nabla f(\mu) >= n^{-1/2} < u_L, \nabla f(\mu) > + \frac{1}{n^{3/2}} < u_Q, \nabla f(\mu) > + O_P \left( \frac{1}{n} \right).
\]

The second term in Eq \((A.70)\) is

\[
  n^{1/2}(u - \mu)H(\mu)(u - \mu)
\]

\[
  = n^{1/2} \left\{ \frac{1}{n} u_L + \frac{1}{n^2} u_Q + O_P \left( \frac{1}{n^{3/2}} \right) \right\}^T H(\mu) \left\{ \frac{1}{n} u_L + \frac{1}{n^2} u_Q + O_P \left( \frac{1}{n^{3/2}} \right) \right\}
\]

\[
  = n^{1/2} \left\{ \frac{1}{n^2} u_L^T H(\mu) u_L + \frac{2}{n^3} u_L^T H(\mu) u_Q + O_P \left( \frac{1}{n^{3/2}} \right) \right\}
\]

\[
  = \frac{1}{n^{3/2}} u_L^T H(\mu) u_L + O_P \left( \frac{1}{n} \right)
\]

Now Eq \((A.70)\) may be expressed as:

\[
  n^{1/2}(f(u) - f(\mu)) = n^{-1/2} < u_L, \nabla f(\mu) > + \frac{1}{n^{3/2}} \left\{ < u_Q, \nabla f(\mu) > + \frac{1}{2} u_L^T H(\mu) u_L \right\} + O_P \left( \frac{1}{n} \right).
\]

We have,

\[
  S_n = \frac{A_1}{\sqrt{n\sigma_f}} + n^{-1/2} \alpha(X_l) + n^{-3/2} \sum_{l<m} \beta(X_l, X_m) + O_P \left( \frac{1}{n} \right), \quad (A.72)
\]

where

\[
  \alpha(X_l) = \frac{1}{\sigma_f} \sum_{i=1}^{d} a_i g_1^{(i)}(X_l) \frac{r_l}{\rho_n},
\]

\[
  \beta(X_l, X_m) = \frac{1}{\sigma_f} \left\{ \sum_{i=1}^{d} a_i \frac{r_i(r_i - 1)}{\rho_n} g_2^{(i)}(X_l, X_m) + \sum_{i,j} a_{ij} \frac{r_i r_j}{\rho_n} g_1^{(i)}(X_l) g_1^{(j)}(X_m) \right\}
\]

52
Applying Theorem 2.1 of Jing and Wang (2010), under the conditions of proposition [E.1] we have

\[
\sup_x \left| P \left( S_n - \frac{A_1}{\sqrt{n} \sigma_f} \leq x \right) - E_n(x) \right| = o(n^{-1/2}),
\]

where

\[
E_n(x) = \Phi(x) - \frac{(x^2 - 1)\phi(x)}{6\sqrt{n}} \{ E\alpha(X_1)^3 + 3E\alpha(X_1)\alpha(X_m)\beta(X_1, X_m) \}.
\]

Using Lemma [E.2] and definition of \( A_2 \), we can simply \( E_n(x) \), yielding:

\[
P(S_n \leq x) = \Phi(x) + \frac{1}{2} \frac{1}{\sqrt{n}} n^{1/2} \phi(x) p_1(x) + o(n^{-1/2}),
\]

\[
p_1(x) = - \left\{ A_1 \sigma_f^{-1} + \frac{1}{6} A_2 \sigma_f^{-3} (x^2 - 1) \right\}.
\]

\[
\square
\]

### E.2 Proposed Bootstrap for Smooth Functions of Counts

In this section, we consider Edgeworth expansions of smooth functions for the bootstrap. Recall from Section 5.3 that \( u^* \) denotes a d-dimensional vector of bootstrapped counted functionals generated by either the multiplier bootstrap \( \hat{T}_{n,M}^* \) or the quadratic bootstrap \( \hat{T}_{n,Q}^* \); in the latter case, one may ignore an additional \( O_P(n^{-3/2}) \) term that arises from approximating a U-statistic by the first two terms of the Hoeffding decomposition. Now recall the bootstrap analogue \( S_n^* \) from Eq 26, the gradients of the smooth function evaluated at the empirical counts from Eq [28].

Let \( P^* \) denote the bootstrap measure conditioned on \( A \) and \( X \), with randomness arising from the multiplier weights \( \xi \). Furthermore, let \( \hat{P}_n \) denote the empirical measure \( \hat{P}_n = \frac{1}{n} \sum_{i=1}^{n} \delta_{X_i} \). It will turn out these two measures are closely related. With a slight abuse of notation, the expectation operator corresponding to \( \hat{P}_n \) will be denoted by \( \hat{E}_n f(X) = \frac{1}{n} \sum_{i=1}^{n} f(X_i) \).

We define the following empirical analogues of the moments of interest:

\[
\hat{\lambda}_{i_1, \ldots, i_d} = E^* \left\{ \left( r_{i_1} \frac{g_{i_1}(l)V_i}{\rho_n^{i_1}} \right) \ldots \left( r_{i_d} \frac{g_{i_d}(l)V_i}{\rho_n^{i_d}} \right) \right\} = \frac{1}{n} \sum_{l=1}^{n} \left( r_{i_1} \frac{g_{i_1}(l)}{\rho_n^{i_1}} \right) \ldots \left( r_{i_d} \frac{g_{i_d}(l)}{\rho_n^{i_d}} \right)
\]

\[
= \hat{E}_n \left\{ \left( r_{i_1} \frac{g_{i_1}(l)}{\rho_n^{i_1}} \right) \ldots \left( r_{i_d} \frac{g_{i_d}(l)}{\rho_n^{i_d}} \right) \right\}.
\]

Now recall that the empirical analogue of the asymptotic variance from Eq [30]. We now prove Theorem [7] which establishes an Edgeworth expansion for \( P^*(S_n^* \leq x) \).
E.3 Proof of Theorem[7]

Proof. We will start by establishing Eq[31] Let $V_l$ be $\xi_l - 1$ and let $V$ denote the vector:
$$V = (\xi_1 - 1, \ldots, \xi_n - 1)^T.$$  

Given $A$ and $X$, we have

$$u^* - \hat{u} = \frac{1}{n} \left\{ \begin{array}{c} \frac{r_d}{\rho_d} \sum_{l=1}^{n} \hat{g}_1^{(1)} (l) V_l \\ \vdots \\ \frac{r_d}{\rho_d} \sum_{l=1}^{n} \hat{g}_1^{(d)} (l) V_l \end{array} \right\} + \frac{1}{n^2} \left\{ \begin{array}{c} \frac{r_d (r_d - 1)}{\rho_d} \sum_{l \leq m} \hat{g}_2^{(1)} (l, m) V_l V_m \\ \vdots \\ \frac{r_d (r_d - 1)}{\rho_d} \sum_{l \leq m} \hat{g}_2^{(d)} (l, m) V_l V_m \end{array} \right\} + O_P \left( \frac{1}{n^{3/2}} \right).$$

Using a second-order Taylor expansion analogous to Eq[70], we have:

$$n^{1/2} (f(u^*) - f(\hat{u})) = \frac{1}{n^{1/2}} \left\{ < u_L^*, \nabla f(\hat{u}) > + \frac{1}{n^{3/2}} \left\{ < u_Q^*, \nabla f(\hat{u}) > + \frac{1}{2} u_Q^T H(\hat{u}) u_Q \right\} + O_P \left( \frac{1}{n} \right) \right. \right.$$  

We also have, by definition,

$$E^* \{ \hat{g}_1^{(i)} (l) \hat{g}_1^{(j)} (m) \hat{g}_2^{(k)} (l, m) V_l V_m \} = \tilde{E}_1 \{ \hat{g}_1^{(i)} (l) \hat{g}_1^{(j)} (m) \hat{g}_2^{(k)} (l, m) \}.$$  

Then, by Eq[A.73] and definition of $\tilde{\sigma}_f$ and $\tilde{A}_1$, we have,

$$S_n^* = \frac{n^{1/2} (f(u^*) - f(\hat{u}))}{\tilde{\sigma}_f} = \tilde{A}_1 \sqrt{n \tilde{\sigma}_f} + \frac{1}{B_n^2} \sum_{l=1}^{n} b_{n,l} V_l + \frac{1}{n^{3/2}} \sum_{l < m} d_{n,lm} \psi(V_l, V_m) + O_P \left( \frac{1}{n} \right),$$

where

$$b_{n,l} = \frac{1}{\sigma_f} \sum_{i=1}^{d} \hat{a}_{i,l} \hat{g}_1^{(i)} (l) \frac{r_i}{\rho_n} ,$$  

$$B_n^2 = \sum_{l=1}^{n} b_{n,l}^2 = n ,$$  

$$d_{n,lm} = \frac{1}{\sigma_f} \left\{ \sum_{i=1}^{d} \hat{a}_{i,l} \frac{r_i (r_i - 1)}{\rho_n} \hat{g}_2^{(i)} (l, m) + \sum_{i,j} \hat{a}_{i,l} \frac{r_i r_j}{\rho_n^{s_i + s_j}} \hat{g}_1^{(i)} (l) \hat{g}_1^{(j)} (m) \right\} ,$$  

$$\psi(V_l, V_m) = V_l V_m .$$

Using Lemma[D.1] and similar arguments therein if

$$\frac{1}{n} \sum_{l=1}^{n} b_{n,l}^2 \geq t_1 > 0, \quad \frac{1}{n} \sum_{l=1}^{n} \left| b_{n,l} \right|^2 \leq t_2 \leq \infty ,$$

(A.75)
then
\[
\sup_x |P^* \left( S_n^* - \frac{\hat{\mathbf{A}}_1}{\sqrt{n\sigma_f}} \leq x \right) - \hat{G}(x)| = O \left( \frac{l_{5,n} \log n}{n^{2/3}} \right),
\]  
(A.76)

where and \( \alpha_l := \frac{1}{n} \sum_{m \neq l} d_{n,l,m}^2 \) and for sufficiently large \( k \):
\[
l_{4,n} = \frac{1}{n} \sum_{l=1}^{n} \alpha_l, \quad s_{n}^2 = \frac{1}{n} \sum_{l} \alpha_l^2 - (l_{4,n})^2, \quad l_{5,n} = l_{4,n} + ks_n
\]

and
\[
\hat{G}_n(x) = \Phi(x) + \hat{L}_{1,n}(x) + \hat{L}_{2,n}(x),
\]
\[
\hat{L}_{1,n} = \frac{E(V_1^3)}{6B_n^3} \sum_{l=1}^{n} b_{n,l}(x^2 - 1)\phi(x),
\]
\[
\hat{L}_{2,n} = \frac{1}{n^{3/2}B_n^2} \sum_{l<m} b_{n,l}b_{n,m}d_{n,l,m} E(V_lV_m\psi(V_l,V_m))(x^2 - 1)\phi(x).
\]

Since \(|\cdot|^3\) is convex,
\[
\frac{1}{n} \sum_i |b_{n,i}|^3 \leq \frac{d^2}{\sigma_f^2} \sum_{j=1}^{d} \frac{1}{n} \sum_i |\hat{a}_i \hat{g}_1(i)|^3
\]

Since the function \( f \) has three gradients in the neighborhood of \( \mu \), Lemma D.5 shows that the above is bounded, thereby satisfying the second condition in Eq A.75.

Simplifying \( \hat{L}_{1,n} \) and \( \hat{L}_{2,n} \) using Eq A.74 we have
\[
\hat{G}_n(x) = \Phi(x) + n^{-1/2}\phi(x) \frac{1}{6} \hat{A}_2 \sigma_f^{-3}(x^2 - 1).
\]

Now we bound the remainder term by bounding \( l_{5,n} \). We write \( \alpha_l \) as
\[
\alpha_l = \frac{1}{n\sigma_f^2} \sum_{m \neq l} \left\{ \sum_{i=1}^{d} \hat{a}_i \frac{r_{i,j} - 1}{\rho_{n}^{i,j}} \hat{g}_2^{(i)}(l,m) + \sum_{i,j} \hat{a}_{ij} \frac{r_{i,j}}{\rho_{n}^{i,j} + \sigma_j} \hat{g}_1^{(i)}(l) \hat{g}_1^{(j)}(m) \right\}^2.
\]  
(A.77)

Expanding \((Y_{1,l,m} + Y_{2,l,m})^2\) in Eq A.77 it is straightforward that, by Lemma D.4 \( l_{4,n} \) is \( O_P(\rho_{n}^{-1}) \).
Now we bound $s_n$. Since $\alpha_l \geq 0$ and $(Y_{1,lm} + Y_{2,lm})^2 \leq 2(Y_{1,lm}^2 + Y_{2,lm}^2)$, we write

$$s_n^2 \leq \frac{1}{n} \sum_{l=1}^{n} \alpha_l^2 \leq \frac{4}{n} \sum_{l=1}^{n} \left( \frac{1}{n\sigma_f^2} \sum_{m \neq l} Y_{1,lm}^2 + \frac{1}{n\sigma_f^2} \sum_{m \neq l} Y_{2,lm}^2 \right)^2$$

$$\leq 8 \times \frac{1}{n} \sum_{l=1}^{n} \left( \frac{1}{n\sigma_f^2} \sum_{m \neq l} Y_{1,lm}^2 \right)^2 + 8 \times \frac{1}{n} \sum_{l=1}^{n} \left( \frac{1}{n\sigma_f^2} \sum_{m \neq l} Y_{2,lm}^2 \right)^2.$$

To estimate $Z_1$, we use:

$$Z_1 = \frac{1}{n} \sum_{l=1}^{n} \left( \frac{1}{n\sigma_f^2} \sum_{m \neq l} \sum_{i,j,k,t} \hat{a}_i \hat{a}_j r_i r_j (r_i - 1)(r_j - 1) g_2^{(i)}(l,m) g_2^{(j)}(l,m) \rho_{s_i + s_j} \right)^2.$$

Using the fact that

$$\frac{1}{\rho_{s_i + s_j}} g_2^{(i)}(l,m) g_2^{(j)}(l,m) \leq \frac{1}{2} \left( \frac{1}{\rho_{s_i}} g_2^{(i)}(l,m)^2 + \frac{1}{\rho_{s_j}} g_2^{(j)}(l,m)^2 \right),$$

by the same arguments in the proof of Theorem 4, it is easy to check that $Z_1 = O_P(\rho_n^{-1}).$

For $Z_2$, let $c_{ijk} = a_{ij} a_{kt} r_i r_j r_k r_t / \rho_{s_i + s_j + s_k + s_t}$ and $\hat{c}_{ijk} = \hat{a}_{ij} \hat{a}_{kt} r_i r_j r_k r_t / \rho_{s_i + s_j + s_k + s_t}$. Consider the estimate:

$$Z_2 \leq \frac{2}{n\sigma_f^2} \sum_{l=1}^{n} \left( \frac{1}{n} \sum_{m \neq l} \sum_{i,j,k,t} (\hat{c}_{ijk} - c_{ijk}) \hat{g}_1^{(i)}(l) \hat{g}_1^{(j)}(m) \hat{g}_1^{(k)}(l) \hat{g}_1^{(t)}(m) \right)^2.$$

$$+ \frac{2}{n\sigma_f^2} \sum_{l=1}^{n} \left( \frac{1}{n} \sum_{m \neq l} \sum_{i,j,k,t} c_{ijk} \hat{g}_1^{(i)}(l) \hat{g}_1^{(j)}(m) \hat{g}_1^{(k)}(l) \hat{g}_1^{(t)}(m) \right)^2.$$
We will start by establishing the order of the \( Z_2^{(2)} \) term. Observe that:

\[
\frac{1}{n} E \sum_{\ell} \left( \frac{1}{n} \sum_{m \neq \ell, i, j, k} c_{ijkt} \hat{g}_1^{(i)}(\ell) \hat{g}_1^{(j)}(m) \hat{g}_1^{(k)}(\ell) \hat{g}_1^{(t)}(m) \right)^2
\]

\[
\leq \frac{d^4}{n^2} \sum_{\ell} \sum_{m \neq \ell, i, j, k} c_{ijkt}^2 E \left[ \hat{g}_1^{(i)}(\ell)^2 \hat{g}_1^{(j)}(m)^2 \hat{g}_1^{(k)}(\ell)^2 \hat{g}_1^{(t)}(m)^2 \right]
\]

\[
\leq \frac{d^4}{n^2} \sum_{\ell} \sum_{m \neq \ell, i, j, k} c_{ijkt}^2 \left( E \left[ \hat{g}_1^{(i)}(\ell)^4 \hat{g}_1^{(j)}(m)^4 \right] E \left[ \hat{g}_1^{(k)}(\ell)^4 \hat{g}_1^{(t)}(m)^4 \right] \right)^{1/2}
\]

\[
\leq \frac{d^4}{n^2} \sum_{\ell} \sum_{m \neq \ell, i, j, k} c_{ijkt}^2 \left( E \left[ \hat{g}_1^{(i)}(\ell)^8 \right] E \left[ \hat{g}_1^{(j)}(m)^8 \right] E \left[ \hat{g}_1^{(k)}(\ell)^8 \right] E \left[ \hat{g}_1^{(t)}(m)^8 \right] \right)^{1/4}
\]

Due to Lemma E.3 and Eq [A.80] since \( d \) is finite, we see that the above is \( O(1) \). To complete our bound for \( Z_2 \), observe that:

\[
P(Z_2^{(2)} > M)
\]

\[
\leq P \left( \max_{i,j,k,t} (\hat{c}_{ijkt} - c_{ijkt})^2 \frac{2}{n \sigma^2} \sum_{\ell} \left( \frac{1}{n} \sum_{m \neq \ell, i, j, k} \left| \hat{g}_1^{(i)}(\ell) \hat{g}_1^{(j)}(m) \hat{g}_1^{(k)}(\ell) \hat{g}_1^{(t)}(m) \right| \right)^2 > M \right)
\]

Since \( \max_{i,j,k,t} (\hat{c}_{ijkt} - c_{ijkt})^2 \) is lower-order and the second term in the product inside the probability statement may be viewed as a variant of \( Z_2^{(1)} \) with \( c_{ijkt} = 1 \), we can conclude \( Z_2 = O(1) \). Combining \( Z_1 \) and \( Z_2 \), we have, with probability tending to one, \( s_n^2 \leq C \rho_n^{-1} \) and \( l_{5,n} = l_{4,n} + s_n \leq C' \rho_n^{-1} \) for some universal positive constants \( C \) and \( C' \).

Thus, from Eq [A.76] and Lemma E.2 we have Eq [31].

We now state and prove Lemma E.3 which we had used in the proof of the above theorem.

**Lemma E.3.** Under the sparsity conditions in Assumption 2,

\[
E(\hat{g}_1(l)^8) = O(\rho_n^{s_n})
\]

**Proof.** We decompose \( \hat{g}_1(l) \) into

\[
\hat{g}_1(l) = \hat{H}_1(l) - h_1(l) + g_1(l) - (\hat{T}_n - \theta).
\]

Then for some constant \( C \),

\[
\hat{g}_1(l)^8 \leq C \{ (\hat{H}_1(l) - h_1(l))^8 + g_1(l)^8 + (\hat{T}_n - \theta)^8 \}.
\] (A.78)
\(g_1(l)^8\) is \(O(\rho_n^{8s})\). Now for \((\hat{T}_n - \theta)^8\),

\[
(\hat{T}_n - \theta)^8 \leq C((\hat{T}_n - T_n)^8 + (T_n - \theta)^8),
\]

where \((T_n - \theta)^8 = \Theta(\rho_n^{8s})\) by boundness of graphon and we investigate \(E((\hat{T}_n - T_n)^8)\). Let \(S_r\) denote all \(r\)-node subsets from node \(\{1, \ldots, n\}\),

\[
E((\hat{T}_n - T_n)^8) = \frac{\sum_{S_1, \ldots, S_8 \in S_r} E[\{\hat{H}(S_1) - h(S_1)\} \ldots \{\hat{H}(S_8) - h(S_8)\}]}{\binom{n}{8}}.
\]

Consider any term in the above sum where each of the four pairs of the subsets have \(p_i, i = 1, \ldots, 4\) nodes, \(d_i, i = 1, \ldots, 4\) edges in common. In this case there are \(8r - \sum p_i\) choices of nodes and the number of edges are at least \(8s - \sum d_i\). First note that \(p_i \geq 2\), to have non-zero contribution. For acyclic graphs, \(d_i \leq p_i - 1\) and for general subgraphs with a cycle, \(d_i \leq \binom{p_i}{2}\). Thus, for \(p_i \geq 2\), we have:

\[
O\left(\binom{n^{8r - \sum p_i - \sum d_i}}{\binom{n}{8}}\right) = O(\rho_n^{8s}) \times O\left(\frac{1}{\binom{n^{\sum p_i - \sum d_i}}{\binom{n}{8}}}\right).
\]

For acyclic graphs, it is easy to see that under our sparsity conditions the above is dominated by \(p = 2\). For general cyclic graphs, since \(\rho_n = \omega(n^{1/r})\) and \(p \leq r\),

\[
n^{p_i} \rho_n^{d_i} \geq n^{p_i(1 - \frac{2p_i}{r} - 1)} \geq n^{\frac{4p_i(r+1)}{r}} \rightarrow \infty.
\]

So, \(E((\hat{T}_n - T_n)^8) = O(\rho_n^{8s})\).

To finish bounding \(E[\hat{g}_1(l)^8]\), we look into the first term of Eq A.78. Let \(S'_r\) denote all \(r - 1\) node subsets from node \(\{1, \ldots, n\}\) excluding node \(l\),

\[
E((\hat{H}_1(l) - h_1(l))^8) = \frac{\sum_{S_1, \ldots, S_8 \in S'_r} E[\{\hat{H}(l \cup S_1) - h(l \cup S_1)\} \ldots \{\hat{H}(l \cup S_8) - h(l \cup S_8)\}]}{\binom{n^{r-1}}{8}}.
\]

Similarly, consider any term in the above sum where each of the four pairs of the subsets have \(p_i, i \leq 4\) nodes (besides node \(l\)), \(d_i, i \leq 4\) edges in common. In this case there are \(4(2r - 2) - \sum p_i\) choices of nodes and the number of edges are \(8s - \sum d_i\), (since each subset already share node \(l\)). When \(p_i \geq 1\), each pair share node \(l\) and another \(p_i\) nodes, then for acyclic graphs, \(d_i \leq p_i\), and for general subgraphs with a cycle, \(d_i \leq \binom{p_i+1}{2}\). Thus, for \(p_i \geq 1\), \(d_i \geq 0\), we have

\[
O\left(\binom{n^{4(2r-2) - \sum p_i} - \sum d_i}{\binom{n^{r-1}}{8}}\right) = O(\rho_n^{8s}) \times O\left(\frac{1}{\binom{n^{\sum p_i - \sum d_i}}{\binom{n^{r-1}}{8}}}\right),
\]

where as we showed above for acyclic graphs, under our sparsity conditions the above is dominated by \(p = 1\). For general cyclic graphs, since \(\rho_n \gg n^{1/r}\) and \(p_i \leq r\), \(n^{p_i} \rho_n^{d_i} \rightarrow \infty\). Thus, \(E((H_1(l) - h_1(l))^8)\) is also \(O(\rho_n^{8s})\).

Thus, combining all terms in Eq A.78 \(E[\hat{g}_1(l)^8]\) is \(O(\rho_n^{8s})\). \(\square\)
E.4 Comparing Bootstrap Edgeworth Expansion with the U-statistic Edgeworth Expansion

Finally, we show that the bootstrap Edgeworth expansion is close to that of the conditional expectation, which was established in Proposition E.1.

**Proposition E.4.** Suppose that \( \sigma_f > 0 \), the function \( f \) has three continuous derivatives in a neighbourhood of \( \mu \), and \( \sum_{i=1}^{d} a_i g_i^{(i)}(X_1) \) is non-lattice. Furthermore, suppose that the weights \( \xi_1, \ldots, \xi_n \) are generated from a non-lattice distribution such that \( E(\xi_1) = 1, E((\xi_1 - 1)^2) = 1, E((\xi_1 - 1)^3) = 1 \). Then we have:

\[
P^*(S_n^* \leq x) = P(S_n \leq x) + O_P \left( n^{-1/2} \right) + O_P \left( \frac{\log n}{n^{2/3} \rho_n} \right). \tag{A.79}
\]

**Proof.** Now we show that \( \tilde{\sigma}_f, \tilde{A}_1 \) and \( \tilde{A}_2 \) converge to \( \sigma_f, A_1 \) and \( A_2 \). We first show \( \tilde{\lambda}_{ij} \) and \( \tilde{\lambda}_{ijk} \) converge to \( \lambda_{ij} \) and \( \lambda_{ijk} \).

\[
\tilde{\lambda}_{ij} = r_i r_j \tilde{E} \left\{ \frac{\hat{g}_1^{(i)}(l) \hat{g}_1^{(j)}(l)}{\rho_n^* \rho_n^*} \right\},
\]

\[
\lambda_{ij} = r_i r_j E \left\{ \frac{g_1^{(i)}(X_1) g_1^{(j)}(X_1)}{\rho_n^* \rho_n^*} \right\}.
\]

Using the fact that \( E(V_1) = 0, E(V_1^2) = 1, E\{g_1^{(i)}\} = 0 \), and an analogous argument as in the proof of Lemma 3.1d) in [Zhang and Xia (2020)], we have:

\[
\tilde{\lambda}_{ij} - \lambda_{ij} = O_P \left( n^{-1/2} \rho_n^{-1/2} \right).
\]

Similarly, expanding \( \tilde{\lambda}_{ijk} \) and \( \lambda_{ijk} \), using the fact that \( E(V_1^3) = 1, E\{g_1^{(i)}\} = 0, \)

\[
\tilde{\lambda}_{ijk} - \lambda_{ijk} = O_P \left( n^{-1/2} \rho_n^{-1/2} \right).
\]

Using the same argument in the proof of Lemma 6, we have

\[
\tilde{E}\{g_1^{(i)}(l)g_1^{(j)}(m)g_2^{(k)}(l, m)\} - E\{g_1^{(i)}(X_1)g_1^{(j)}(X_m)g_2^{(k)}(X_1, X_m)\} = O_P(n^{-1/2} \rho_n^{-1/2}).
\]

Furthermore, under the assumption that \( f \) has three continuous derivatives in the neighbourhood of \( \mu \), we know that

\[
\tilde{a}_i = a_i + O_P \left( n^{-1/2} \rho_n^{-1/2} \right), \quad \tilde{a}_{ij} = a_{ij} + O_P \left( n^{-1/2} \rho_n^{-1/2} \right). \tag{A.80}
\]

Thus, together with Eq (A.80), we have,

\[
\sigma_f^2 - \tilde{\sigma}_f^2 = O_P \left( n^{-1/2} \rho_n^{-1/2} \right), \quad \tilde{A}_1 - A_1 = O_P \left( n^{-1/2} \rho_n^{-1/2} \right), \quad \tilde{A}_2 - A_2 = O_P \left( n^{-1/2} \rho_n^{-1/2} \right).
\]
Finally we have,

\[ \tilde{p}_1(x) = -\{ \hat{A}_1 \tilde{\sigma}_f^{-1} + \frac{1}{6} \hat{A}_2 \tilde{\sigma}_f^{-3} (x^2 - 1) \} = p_1(x) + OP \left( n^{-1/2} \rho_n^{-1/2} \right). \]

Therefore, under the same condition of Proposition [E.1] from Eq [31] we have,

\[
P^*(S_n^* \leq x) = \Phi(x) + n^{-1/2} \tilde{p}_1(x) \phi(x) + OP \left( \frac{\log n}{n^{2/3} \rho_n} \right)
\]

\[= P(S_n \leq x) + o_P \left( n^{-1/2} \right) + O_P \left( \log n n^{-2/3} \rho_n \right).\]

\[\square\]

F Detailed Results of Confidence Interval Bias Correction for Smooth Functions of Counts

F.1 Edgeworth Expansion for Studentized Smooth Function of Counts

In order to write \( \sigma_f^2 \) as a function of \( \mu \) and \( \hat{\sigma}_f^2 \) as function of \( u \), we have to expand the vector of \( u \) by including terms such that the variance can be written as a function of the expectation. For example, for simple mean, one needs to add \( (x_1, x_2) = (x, x^2) \) for data point \( x \), since the variance is then \( x^2 - x^2 \). For i.i.d random variables, this is simple, but for U statistics, the dependence makes this more nuanced. We expand the vector of \( u \) into \( \tilde{u} \). Given \( X \), the uncentered \( \tilde{u} \) is

\[
\tilde{u} = \left\{ \tilde{I}^{(1)}_n \rho_n^{-1}, \ldots, \tilde{I}^{(d)}_n \rho_n^{-1} \right\},
\]

\[
\begin{aligned}
&= \left\{ \frac{r_1 r_2}{n \rho_n} \sum_{i=1}^n \hat{h}_1^{(1)}(X_i) \hat{h}_1^{(2)}(X_i) \right\}, \ldots, \frac{r_{d-1} r_d}{n \rho_n} \sum_{i=1}^n \hat{h}_1^{(d-1)}(X_i) \hat{h}_1^{(d)}(X_i),

&= \left\{ \frac{r_1^2}{n \rho_n} \sum_{i=1}^n \hat{h}_1^{(1)}(X_i)^2, \ldots, \frac{r_d^2}{n \rho_n} \sum_{i=1}^n \hat{h}_1^{(d)}(X_i)^2 \right\},
\end{aligned}
\]

(\text{d terms})

where

\[
\hat{h}_1(X_i) = \frac{1}{(n-1)^{1/2}} \sum_{1 \leq i_1 < \ldots < i_r \leq n, i \neq i} \hat{h}(X_i, X_{i_1}, \ldots, X_{i_r}).
\]

Denote \( \tilde{\mu} = E\tilde{u} \), and \( u^t = \tilde{u} - \tilde{\mu} \). Define \( h(\mu) = \sigma_f^2 \), \( h(\tilde{u}) = \hat{\sigma}_f^2 \) and \( c_i = \nabla h(\hat{\mu})^{(i)} \).
Proposition F.1. Define \( S'_n = n^{1/2} (f(u) - f(\mu))/\sigma_f \). Under the condition that the function \( f \) has three continuous derivatives in a neighbourhood of \( \mu \), and \( \sum_{i=1}^d a_i g_1^{(i)}(X_1) \), is non-lattice, we have:

\[
P(S'_n \leq x) = \Phi(x) + n^{-1/2} q_1(x) \phi(x) + o \left( \frac{1}{n^{1/2}} \right),
\]

where \( B_1 \) and \( B_2 \) are

\[
B_1 = A_1 \sigma_f^{-1} - \frac{1}{2} \sigma_f^{-3} \sum_{i=1}^d \sum_{j=1}^{d'} a_i c_j E \{ \mathbf{u}^{(i)} \mathbf{u}^{(j)} \},
\]

\[
B_2 = 6B_1 - 6A_1 + \frac{A_2}{\sigma_f^3}.
\]

\( A_1 \) and \( A_2 \) are defined in Proposition \( \text{[E7]} \). The regularity conditions are to ensure the remainders in the stated order uniformly in \( x \).

Proof. Now, we define \( A(\bar{u}) = A(u) = f(u) - f(\mu), B(\bar{u}) = (f(u) - f(\mu))/h(\bar{u}). \)

Then by Taylor Expansion we have,

\[
B(\bar{u}) = A(\bar{u})/h(\bar{u})^{1/2} = A(\bar{u}) \ast h(\bar{u})^{-1/2}
\]

\[
= A(\bar{u}) \left\{ h(\bar{u})^{-1/2} + (\bar{u} - \bar{\mu})^T \nabla(h(\bar{\mu})^{-1/2}) + (\bar{u} - \bar{\mu})^T \frac{H(h(\bar{\mu})^{-1/2})}{2} (\bar{u} - \bar{\mu}) + o_P \left( \frac{1}{n} \right) \right\}
\]

\[
= A(\bar{u})/h(\bar{\mu})^{-1/2} - \frac{1}{2} A(\bar{u}) h(\bar{\mu})^{-3/2} (\nabla h(\bar{\mu}))^T (\bar{u} - \bar{\mu}) + o_P \left( \frac{1}{n^{3/2}} \right)
\]

\[
= A(\bar{u})/\sigma_f - \frac{1}{2} (\bar{u} - \bar{\mu})^T \sigma_f^{-3} \nabla f(\bar{\mu}) (\nabla h(\bar{\mu}))^T (\bar{u} - \bar{\mu}) + o_P \left( \frac{1}{n^{3/2}} \right)
\]

\[
= A(u)/\sigma_f - \frac{1}{2} (\bar{u} - \bar{\mu})^T \sigma_f^{-3} \left[ \begin{array}{ccc}
    a_1 c_1 & \ldots & a_1 c_d \\
    \ldots & \ldots & \ldots \\
    a_d c_1 & \ldots & a_d c_d
\end{array} \right] (\bar{u} - \bar{\mu}) + o_P \left( \frac{1}{n^{3/2}} \right),
\]

where

\[
(\bar{u} - \bar{\mu})^T D(\bar{u} - \bar{\mu}) = \sum_{i=1}^d \sum_{j=1}^{d'} a_i c_j \mathbf{u}^{(i)} \mathbf{u}^{(j)},
\]

\[
a_{d+1} = a_{d+2} = \ldots = a_d = 0.
\]

We have \( S'_n = n^{1/2} \frac{f(u) - f(\mu)}{h(u)} = n^{1/2} B(\bar{u}). \) Thus we can write \( S'_n \) into

\[
S'_n = n^{1/2} A(u)/\sigma_f - \frac{1}{2} \sigma_f^{-3} n^{1/2} \sum_{i=1}^d \sum_{j=1}^{d'} a_i c_j \mathbf{u}^{(i)} \mathbf{u}^{(j)} + o_P \left( \frac{1}{n} \right). \quad \text{(A.82)}
\]
Since $a_i = 0$ for $i > d$, we only discuss here $u^{(i)} u^{(j)}$ for $i \leq d, j \leq d$ and $u^{(i)} u^{(j)}$ for $i \leq d, d < j \leq d'$. We first prove that

$$u^{(i)} u^{(j)} = E\{u^{(i)} u^{(j)}\} + n^{-2} \sum_{l<m} \gamma(X_l, X_m) + O_P\left(\frac{1}{n^{3/2}}\right) \quad (A.83)$$

holds for both cases, where $\gamma$ is some symmetric function of $X_l$ and $X_m$.

For $i \leq d, j \leq d$, since $u^{(i)} = u^{(i)} + \frac{u^{(j)}}{n^2} + O_P\left(\frac{1}{n^{3/2}}\right)$, $u^{(j)} = u^{(j)} + \frac{u^{(j)}}{n^2} + O_P\left(\frac{1}{n^{3/2}}\right)$, we first prove that

$$u^{(i)} u^{(j)} = \frac{u^{(i)} u^{(j)}}{n^2} + O_P\left(\frac{1}{n^{3/2}}\right)$$

for some $k, t \in \{1, \ldots, d\}$. Denote $E\{\hat{h}^k(X_l)\} = \theta^{(k)}$, Hoeffding decomposition of $\hat{h}^k(X_l)$ yields,

$$\frac{\hat{h}^k(X_l) - \theta^{(k)}}{\rho^{(n)}} = h_1^{(k)}(X_l) - \theta^{(k)} + \frac{r}{n-1} \sum_{s \neq l, 1 \leq s \leq n} \{g_2^{(k)}(X_l, X_s) + g_1^{(k)}(X_s)\} + O_P\left(\frac{1}{n}\right)$$

for some $k, t \in \{1, \ldots, d\}$.

Denote $U^{(i)} = \sum_{i=1}^{n} g^{(i)}(X_l) / n$,

$$u^{(i)} u^{(j)} = \frac{r^{k} r^{t}}{\rho^{(n)} \rho^{(n)}} \left\{ \theta^{(k)} U^{(i)} U^{(t)} + \theta^{(t)} U^{(i)} U^{(k)} + \frac{1}{n^2} \sum_{l=1}^{n} g^{(i)}(X_l) g^{(k)}(X_l) g^{(t)}(X_l) 
+ \frac{2}{n^2} \sum_{l<m} g^{(i)}(X_l) g^{(k)}(X_m) g^{(t)}(X_l) + \frac{2}{n^2} \sum_{l<m} g^{(i)}(X_l) g^{(k)}(X_m) g^{(t)}(X_l, X_m) 
+ \frac{2}{n^2} \sum_{l<m} g^{(i)}(X_l) g^{(k)}(X_m) g^{(t)}(X_l) \right\} + O_P\left(\frac{1}{n^{3/2}}\right).$$
Taking Expectation, Eq [A.83] easily follows. Now that Eq [A.83] holds, using Eq [A.72] and Eq [A.82] we have

\[ S_n' = A_1 \sqrt{n} \sigma_f - n^{-1/2} \sum_{i=1}^{d'} \sum_{j=1}^{d'} a_{ij} \mu_{ij} E\{u^{(i)}(i)u^{(j)}(j)\} \]

\[ + n^{-3/2} \sum_{l=1}^{n} \alpha(X_l) + n^{-3/2} \sum_{l<m} \beta(X_l, X_m) + \gamma(X_l, X_m) \] + O_P \left( \frac{1}{n} \right) \quad (A.85) \]

Therefore, using Lemma [E.2] we know that

\[ B_1 = A_1 \sigma_f^{-1} - n^{-1/2} \sum_{i=1}^{d'} \sum_{j=1}^{d'} a_{ij} \mu_{ij} E\{u^{(i)}(i)u^{(j)}(j)\}. \quad (A.86) \]

From Eq [A.85] we also have that Theorem 2.1 of Jing and Wang (2010) applies to \( S_n' \) under the same conditions of Proposition [E.1]. For the simplicity of calculation, we note that \( B_2 \) can be estimated using the identity \( p_1(0) = q_1(0) \) and the forms of \( A_1, A_2, \) and \( B_1 \), which gives us \( B_2 = 6B_1 - 6A_1 + \frac{2}{\sigma_f^2} \).

Thus, under same conditions of Proposition [E.1] we have

\[ P(S_n' \leq x) = \Phi(x) + n^{-1/2} q_1(x) \phi(x) + o\left(n^{-1/2}\right), \]

where \( B_1 \) and \( B_2 \) are defined above, \( q_1(x) \) is as

\[ q_1(x) = -\{B_1 + \frac{1}{6} B_2 (x^2 - 1)\}. \]

\[ \Box \]

**F.2 Estimating Confidence Interval Correction for Smooth Function of Counts**

In order correct the confidence intervals arising from the standardized bootstrap, we need to estimate \( p_1(x) \) and \( q_1(x) \). This requires the calculation of \( \sigma_f^2, A_1 \) and \( A_2 \) are straightforward. In this section, we show how to compute \( \hat{q}_1(x) \) for transitivity.

While we only show in detail the calculations of transitivity \((d = 2)\), they can be easily used as building blocks to extend to other smooth functions of counts with \( d \geq 2 \).

In the case of transitivity, the original \( u \) used for estimation of \( p_1(x) \) is of length \( d = 2 \). Recall that for estimating \( q_1(x) \) we need to expand this vector so that the variance is a function of this vector. This expanded vector (see Eq [A.81]) is of length \( d' = 5 \). Denote \( \mu_{ij} = n \times E(u^{(i)}(i)u^{(j)}(j)) \). We also have for \( T \) and \( V, r_1 = r_2 = r = 3 \), and \( s_1 = 3 \) and \( s_2 = 2 \).

To estimate \( B_1 \) and \( B_2 \), we first use the fact that \( c_k \) for \( k \) in \( 1 \leq k \leq d' \) follows Hall (2013) Section 3.10.6 as follows:

\[ c_k = 2 \sum_{i=1}^{d} \sum_{j=1}^{d} a_{ik} a_{j} \mu_{ij} - 2a_k \sum_{i=1}^{d} a_{ik} \mu^{(i)} + \sum_{i=1}^{d} \sum_{j=1}^{d} a_{i_1,a_{j_1},(k)} \quad (A.87) \]
Bestimating example, in transitivity, \( \hat{g}^{(3)} = \hat{g}^{(1)} \hat{g}^{(2)} \).

Now we simplify \( E \mathbf{u}'^{(i)} \mathbf{u}'^{(j)} \) for \( 1 \leq i \leq d, 1 \leq j \leq d' \) for the purpose of estimating \( B_1 \) and \( \alpha_1 \) in Eq \( \text{[A.86]} \) and Eq \( \text{[A.87]} \). We do not consider the case where \( i > d \) since \( a_i \) for \( i > d \) is 0. By the definition of \( \mathbf{u}' \), using Hoeffding Decomposition of \( \hat{h}^{(1)}(X_1) \) \( (i \in \{1, 2\}) \) showed in Eq \( \text{[A.84]} \), simple algebra yields,

\[
E \{ \mathbf{u}'^{(i)} \mathbf{u}'^{(j)} \} = \frac{r^2}{n \rho_n^3} E \{ g^{(1)}_1(X_1)g^{(j)}_1(X_1) \} + O \left( \frac{1}{n^{3/2}} \right), \quad 1 \leq i, j \leq 2,
\]

\[
E \{ \mathbf{u}'^{(2)} \mathbf{u}'^{(5)} \} = \frac{r^3}{n \rho_n^4} \left[ E \{ g^{(2)}_1(X_1)g^{(5)}_1(X_1)^2 \} + 2(r - 1)E \{ g^{(2)}_1(X_1)g^{(5)}_1(X_1)g^{(2)}_2(X_1, X_2) \} + \frac{2r^4}{n \rho_n^2} \mu_1 E \{ g^{(1)}_1(X_1)g^{(1)}_2(X_1) \} + O \left( \frac{1}{n^{3/2}} \right) \right],
\]

\[
E \{ \mathbf{u}'^{(1)} \mathbf{u}'^{(5)} \} = \frac{r^3}{n \rho_n^4} \left[ E \{ g^{(1)}_1(X_1)g^{(2)}_1(X_1)^2 \} + 2(r - 1)E \{ g^{(1)}_1(X_1)g^{(2)}_1(X_1)g^{(2)}_2(X_1, X_2) \} + \frac{2r^4}{n \rho_n^2} \mu_2 E \{ g^{(1)}_1(X_1)g^{(2)}_2(X_1) \} + O \left( \frac{1}{n^{3/2}} \right) \right],
\]

\[
E \{ \mathbf{u}'^{(2)} \mathbf{u}'^{(4)} \} = \frac{r^3}{n \rho_n^4} \left[ E \{ g^{(2)}_1(X_1)g^{(1)}_1(X_1)^2 \} + 2(r - 1)E \{ g^{(2)}_1(X_1)g^{(1)}_1(X_1)g^{(1)}_2(X_1, X_2) \} + \frac{2r^4}{n \rho_n^2} \mu_1 E \{ g^{(1)}_1(X_1)g^{(2)}_1(X_1) \} + O \left( \frac{1}{n^{3/2}} \right) \right],
\]

For the other two cases of \( i = 1, 2 \) and \( j = 3 \), applying the same technique, we
have
\[E\{u^{(1)}u^{(3)}\} = \frac{r^3}{n\rho_{n}^s \rho_{n}^s} \left[ E\{g_1^{(1)}(X_1)^2g_1^{(2)}(X_1)\} \right.
\]
\[+ (r - 1)E\{g_1^{(1)}(X_1)g_1^{(1)}(X_2)g_2^{(2)}(X_1, X_2)\} \]
\[+ (r - 1)E\{g_1^{(1)}(X_1)g_1^{(2)}(X_2)g_2^{(1)}(X_1, X_2)\} \]
\[+ \frac{r^4}{n\rho_{n}^s \rho_{n}^s} \mu_1 E\{g_1^{(1)}(X_1)g_3^{(2)}(X_1)\} \]
\[+ \frac{r^4}{n\rho_{n}^s \rho_{n}^s} \mu_2 E\{g_1^{(1)}(X_1)^2\} + O\left(\frac{1}{n^{3/2}}\right),\]

\[E\{u^{(2)}u^{(3)}\} = \frac{r^3}{n\rho_{n}^s \rho_{n}^s} \left[ E\{g_1^{(2)}(X_1)^2g_1^{(1)}(X_1)\} \right.
\]
\[+ (r - 1)E\{g_1^{(2)}(X_1)g_1^{(1)}(X_2)g_2^{(2)}(X_1, X_2)\} \]
\[+ (r - 1)E\{g_1^{(2)}(X_1)g_1^{(2)}(X_2)g_2^{(1)}(X_1, X_2)\} \]
\[+ \frac{r^4}{n\rho_{n}^s \rho_{n}^s} \mu_1 E\{g_1^{(2)}(X_1)^2\} + O\left(\frac{1}{n^{3/2}}\right).\]

Now we can estimate \(B_1\) from Eq [A.86] and \(c_i, 1 \leq i \leq 5\) from Eq [A.87] by estimating \(E\{u^{(i)}u^{(j)}\}\) above using \(g_1^{(i)}(X_1)\) and \(g_2^{(j)}(X_1, X_2)\), for \(i \in \{1, 2\}\). Using the fact of \(p_1(0) = q_1(0)\), we can estimate \(\hat{B}_2\) by
\[\hat{B}_2 = 6\hat{B}_1 - 6\hat{A}_1\hat{\sigma}^{-1}_f + \hat{A}_2\hat{\sigma}^{-3}_f.\]

Then we have the estimated \(\hat{q}_1(x)\),
\[\hat{q}_1(x) = -\{\hat{B}_1 + \frac{1}{6}\hat{B}_2(x^2 - 1)\}.
\]

Now we show the studentized edgeworth expansion of some statistics \(f(T, V)\) using same \(u\) as transitivity, including \(T, 3T + 5V, TV, 3T/V, (T^2V^2)\). The \(q_1(x)\) of the Edgeworth expansion of the studentized version of these statistics \(f(T, V)\) share the same \(E\{u^{(i)}u^{(j)}\}\) \(i \in \{1, 2\}, j \in \{1, \ldots, 5\}\). The only difference lies in evaluating different derivatives of \(f\) and thus having different \(\hat{c}_k, \hat{B}_1\) and \(\hat{B}_2\).

Recall that err\((F, G)\) is defined in Section 6 as the maximum of \(|F(x) - G(x)|\) over the range \([-3, 3]\), over a grid size 0.1. In the following two tables, we show this distance between the true CDF and our empirical edgeworth expansion and the normal approximation for five different smooth functions. Tables [A.1] and [A.2] show these for the standardized and studentized statistics. The empirical edgeworth expansion is estimated using a random graph with \(n = 160, \rho_n = 1\), generated from two graphons \(SBM-G\) and \(SM-G\) with the same parameters as in Section 6. The true CDF is estimated by \(10^6\) size 160 graphs generated by the same graphons with same model parameters.
Table A.1: Standardized EW Sup CDF error compared to N(0,1)

Table A.1 shows the standardized sup error \( \sup_x |\hat{F}(S_n \leq x) - F(x)| \), where \( S_n \) is the standardized statistic, \( \hat{F}(S_n \leq x) = \Phi(x) + n^{-\frac{1}{2}} \hat{p}_1(x) \phi(x) \) and \( F(x) \) is the true distribution of the standardized statistic. In Table A.2 we show \( \sup_x |\hat{F}(S_n \leq x) - F'(x)| \), where \( \hat{F}(S'_n \leq x) = \Phi(x) + n^{-\frac{1}{2}} \hat{q}_1(x) \phi(x) \) and \( F'(x) \) indicates the true CDF of the studentized statistic.

Table A.2: Studentized EW Sup CDF error compared to N(0,1)

We see that for both graphons the empirical edgeworth expansion has much lower error than the Gaussian approximation. Also, the linear combinations of the statistics typically have lower error than those which need the estimation of first and second derivatives.

### G Additional experiments

In this section we provide additional experiment results that were left out from the main text for space concerns.

We show in Figure A.6 the maximum of (absolute) difference of the bootstrap CDF \( F_n^* \) over the \([-3, 3]\) range (err(\( F_n, F_n^* \))) for two-star density from the true CDF \( F_n \) for sparsity parameter \( \rho_n \) varying from 0.05 to 1. We show the average of the expected difference over 30 independent runs along with errorbars. In Figure A.7 we show the 95% CI coverage for two-stars. The results of two-stars are similar to those of triangles in the main paper.
Figure A.6: We plot \( \text{err}(F_n, F_n^*) \) for two-star density for all methods on the Y axis, where \( F_n^*(t) \) corresponds to the appropriate resampling distribution. We vary the sparsity parameter \( \rho_n \) on the X axis. The networks in the left column are simulated from SBM-G and those in the right column are simulated from SM-G. The first row is centered at bootstrap mean and normalized by variance estimation from each method \( \sigma_n \). The second row is centered by triangles density estimated on the whole graph (MB-L-apx is centered at approximate triangle density estimated from the whole graph) and normalized by \( \sigma_n \).

Figure A.7: We present coverage of 95% Bootstrap Percentile CI with correction for two-stars of the SBM-G (left) and SM-G (right) models in \( \rho \) from 0.05 to 1.
G.1 Additional timing results

In Figure A.8 we show logarithm of running time for four-cycles count against growing $n$ for $SM-G$ model.

Figure A.8: Logarithm of running time for four-cycles in $SM-G$ against sample size $n$.
