Abstract

Two-dimensional (2D) magnetism has been highly sought after since the discovery of graphene, the first and most studied of all the 2D materials. However, experimental evidence for ferromagnetic ordering in isotropic 2D crystals has been missing until a three-atoms thick CrI$_3$ was shown to retain ferromagnetic ordering at finite temperatures down to a monolayer. However, 2D ferromagnetic materials discovered so far are having a transition temperature which is much lower than room temperature and hence are not useful for device applications. Here, we demonstrate successful isolation of a non-van der Waals 2D material derived from naturally occurring pyrite mineral (FeS$_2$) by means of liquid phase exfoliation in organic solvent. It is evident from the magnetic measurements that 2D FeS$_2$ is ferromagnetic with long-range magnetic ordering extending even up to the room-temperatures, whereas bulk pyrite precursor is weakly paramagnetic. Transmission electron microscopy together with Raman spectroscopy and XPS measurements confirm the crystallinity and purity of 2D FeS$_2$. Atomic force microscopy affirms the 2D nature of exfoliated flakes. Theoretical density functional theory calculations corroborate the experimental findings along with the stability of exfoliated 2D sheets which is of prime importance in the case of non-van der Waals exfoliation.

Key Words: Non-van der Waals exfoliation, Pyrite, 2D Materials, 2D Ferromagnetism
Introduction

2D atomic crystals provides unique opportunities for studying fundamental physics as well for technological advancements. (1) The discovery of CrI\textsubscript{3}, a van der Waals (vdW) 2D material that retains ferromagnetic ordering down to a monolayer is groundbreaking and laid the foundation for wide research in 2D ferromagnetic materials and their heterostructures. (2) 2D magnetic crystals are susceptible to external stimuli such as mechanical stress, electric field, light incidence and chemical modifications which can be exploited effectively to engineer their magnetic properties for device applications. (3) In addition to that, ability to form heterostructures makes them excellent candidate materials to study proximity effects by stacking with other vdW 2D electronic, valleytronic and photonic crystals. Such heterostructures may results in new and novel phenomena such as multiferroicity, unconventional superconductivity and quantum anomalous Hall effect. (4-7) More vdW 2D atomic crystals emerged namely Cr\textsubscript{2}Ge\textsubscript{2}Te\textsubscript{6} which is found to be ferromagnetic down to bilayer and Fe\textsubscript{3}GeTe\textsubscript{2} – an itinerant 2D ferromagnet. (8, 9) The critical temperatures of these ferromagnetic 2D crystals are way below the room-temperature which limits their potential technological applications. Ongoing investigations are aimed at discovering new 2D atomic crystals having a critical temperature above room-temperature and also at lifting the critical temperature of already existing vdW 2D ferromagnetic crystals close to room-temperatures. (10-12)

In addition to the exploitable robust properties, the prerequisite criteria of a potential 2D material for future applications are the abundance, the environmental friendliness and the cost effectiveness of its bulk precursor. Naturally occurring minerals are the tangible choice of precursor materials that satisfies all the three aforementioned requirements. The obvious examples are vdW materials such as graphite and molybdenite from which graphene and 2D molybdenum
disulfide (MoS$_2$) – two of the most explored materials in the entire 2D family were isolated. Very recently, 2D materials derived from naturally occurring minerals are again coming back into the limelight in the form of franckeite. Non-van der Waals (n-vdW) 2D materials are gaining popularity owing to their huge potential in catalytic applications. Recent investigations show that iron-based naturally occurring minerals are good precursor materials for envisaging new and novel n-vdW 2D materials for magnetic and catalytic applications. Liquid phase exfoliation in a suitable organic solvent is proved to be an effective method for exfoliation of these n-vdW mineral ores which was already an established method for exfoliation of vdW 2D materials.

Pyrite (FeS$_2$) is the abundant and the most common form of sulfides and is widely explored for photovoltaic applications. A small bandgap energy (~0.95 eV) and reasonably good optical absorption coefficient (~ 6 x 10$^5$ cm$^{-1}$) qualify pyrite to be used as an excellent candidate material to absorb broad spectrum of solar light. Besides photovoltaic applications, pyrite is also an excellent cathode material in lithium-ion batteries. These remarkable properties along with cost-effectiveness, eco-friendliness and abundance makes it a perfect material for nano-engineering with a view to enhance performance and to check new phenomena, especially confinement effects in the 2D regime. Moreover, layered manganese containing sulfides and selenides (MnX$_2$; X=S, Se) with pyrite-type structure were already demonstrated to have high temperature ferromagnetism down to monolayers whereas their bulk counterparts are low temperature antiferromagnetic materials. Pristine FeS$_2$ is diamagnetic and the prospect of electrically induced ferromagnetism in ‘zero-spin’ FeS$_2$ via ionic-liquid gating is one the recent advancements. However, naturally occurring pyrite has a weak paramagnetism and was attributed to the presence of magnetic impurities. In this work, we successfully isolated an
ultrathin 2D ferromagnetic crystal FeS$_2$ from a non-layered naturally occurring mineral ore pyrite (Iron (II) sulfide) by means of liquid exfoliation. Our findings suggest that 2D FeS$_2$ is ferromagnetic even at room-temperatures whereas the bulk natural ore is weakly paramagnetic. Theoretical calculations based on \textit{ab initio} density functional theory (DFT) were performed to check the preferential crystal orientations, stability and magnetic ground state of 2D FeS$_2$ and are found to be in good agreement with the experimental findings.

\textbf{Results and Discussions}

Pyrite (FeS$_2$) has an isometric structure consisting of Fe$^{2+}$ ions surrounded by six octahedrally coordinated sulfur ions. Pyrite is characterized by the presence of dianion $S^{2-}_2$ along with iron atoms occupy fcc sites with halite(NaCl) structure with $Pa\bar{3}$ space group.\footnote{From the surface energy calculations along with competing interlayer spacing and surface broken-bond density considerations, it is apparent that pyrite has three favorable cleavage/parting planes – (100), (110) and (111).\footnote{Exfoliation energy was theoretically calculated for three atomically thin 2D sheets of pyrite cleaved along these energetically favorable planes using density functional theory (DFT) and are summarized in \textbf{Figure 1}. The DFT simulations for (100), (111), and (110) planes (one layer) give values of 0.48 eV/atom, 0.19 eV/atom, and 0.50 eV/atom respectively, suggesting that the (111) is the easier to exfoliate. A (111) faceted 2D FeS$_2$ sheet consists of a layer of Fe atoms sandwiched between two layers of sulfur atoms. These observations motivated us to examine the experimental validity of the findings and are described in the following section.}

The bulk precursor mineral pyrite is an electron probe micro-analysis (EPMA) natural standard obtained from Earth, Environmental and Planetary Science Department, Rice University. It is compositionally homogeneous and inclusion-free. Powder X-ray diffraction (XRD) was carried out on ground pyrite ore to confirm the crystallinity and purity and is shown in Figure 2A.
Figure 1. Feasibility of liquid exfoliation of Iron pyrite (FeS₂). (a) Bulk iron pyrite crystal (b) Based on the cleavage and parting in the bulk crystal, three planes are likely to be exfoliated and are (100), (111) and (110). (c) The energy required for exfoliation is calculated and (111) plane is found to show the least energy and hence is expected to be abundant in the exfoliated samples.

(top). The peaks are well matching with the FeS₂ pyrite phase (JCPDS No. 65-3321). (33) Two-dimensional (2D) FeS₂ nanosheets were obtained by liquid exfoliation of powdered pyrite mineral ore in dimethylformamide organic solvent for several hours (~ 25 hrs)(see SI 1 and the
experimental section for more detailed explanation of the synthesis procedure). FeS$_2$ 2D sheets collected via ultracentrifugation followed by vacuum filtration of the supernatant were also subjected to powder XRD analysis. The acquired result is depicted in Figure 2a (bottom) which is again comparable to bulk crystal (JCPDS No. 65-3321) but with broad peaks and different intensity ratios for various crystal orientations. 2D confinement effects were also observed in the UV absorption studies as the bandgap of exfoliated samples are high compared to the bulk counterparts. The photoluminescence studies are indicative of the direct bandgap nature of the exfoliated samples. Please see SI 2 for the U-Vis, Tac plot and PL spectra.

The Phase purity of both bulk and 2D nanosheets was confirmed by Raman Spectroscopy (Figure 2b) with peaks centered at 340 and 375 cm$^{-1}$ corresponding to $E_g$ and $A_g$ symmetry modes of pyrite.(34) Peaks corresponding to other iron sulfides phases such as troilite, marcasite and pyrrhotite are absent. Raman signature of exfoliation is evident in the intensity ratio of $A_g$ and $E_g$ modes ($I_{A_g}/I_{E_g}$). For bulk pyrite, $I_{A_g}/I_{E_g}$ is greater than unity whereas 2D nanosheets has $I_{A_g}/I_{E_g}$ value lesser than unity. This is straightforward to understand since $A_g$ modes are due to out of plane vibrations whereas $E_g$ modes are from in-plane vibrations. In n-vdW 2D crystals, the in-plane vibrations are predominant as compared to out of plane modes.(20) Another important feature in the Raman spectrum of 2D FeS$_2$ is the presence of low frequency (< 200 cm$^{-1}$) shear modes which is a clear indication of interlayer coupling which is absent in bulk 3D pyrite crystal.(35) X-ray photoelectron spectroscopy (XPS) measurements are carried out in order to elucidate the oxidation state of Fe and S and their atomic ratio (survey spectra, SI 3) and are given in Figure 2c-d. Iron and sulfur peaks in 2D FeS$_2$ corresponds to binding energies expected for pyrite; Fe2p3/2 at 707.0 and S2p3/2 and S 2p1/2 peaks at 162.6 and 163.9 eV respectively whereas a low intensity Fe2p3/2 about 709.0 is due to surface Fe$^{2+}$ states.(36, 37)
Figure 2. Structural and elemental analysis: (a) X-ray diffraction spectrum of bulk (top) and 2D FeS$_2$ (bottom) - the diffraction peaks are less intense and broad for the exfoliated samples compared to the bulk counterpart. Also, the intensity ratio of the diffraction peaks is different due to the 2D confinement effects. (b) Raman spectra of bulk (top) and 2D FeS$_2$ (bottom). The Raman peak intensities are varied from bulk to 2D and the lower frequency Raman modes present in exfoliated sheets are characteristic of 2D nature. (c) High resolution XPS spectra corresponding to Fe2p and (d) S2p of 2D FeS$_2$. (e) AFM topography image and (f) the corresponding line scan curves.
The 2D sheets were transferred on to a Si/SiO$_2$ substrate by drop-casting and thickness of individual sheets were measured using an atomic force microscope (AFM) and one of the images was given in Figure 2e. It is evident from the AFM micrograph that the exfoliated FeS$_2$ is ultrathin with around 1 nm thickness given by the corresponding line profile (Figure 2f) and has a lateral dimension of a few microns. More AFM images and analysis are appended in the SI 4.

Low and high magnification transmission electron microscope (TEM) images, high-resolution TEM (HRTEM), fast Fourier transform (FFT), inverse fast Fourier transform (IFFT) and energy dispersive spectroscopy (EDS) images are presented in Figure 3. The low magnification (Figure 3a,b) and high magnification (Figure 3 c & d) TEM images signifies well exfoliated 2D sheets and the contrast confirms the ultra-thin nature (Figure 3a) and its high homogeneity is evident in the high angle annular dark field (HAADF) image (Figure 3b). The higher magnification image in (Figure 3d) shows highly ordered regions along with its respective FFT in the inset demonstrating that the orientation of atoms in this selected area is along the (111) plane. The IFFT of that selected area yields an HRTEM (Figure 3e) confirming that (111) is the preferential orientation of the exfoliated 2D sheets. The TEM analysis reinforces the finding through the exfoliation energy calculations employing DFT that the exfoliation energy is least for (111) oriented planes. The modeled (111) projection plane using Vesta® software was made using the CIF file for pyrite with the $P\bar{a}3$ space group and the group number 205 corresponding to the halite (NaCl) structure. The Vesta® projection is superimposed on the atomic resolution micrograph. The orientation of the zone axis direction is [111]. TEM EDAX (Figure 3g-j) confirms the purity of the nanosheets also supported by EPMA analysis given in the supporting information(SI 6) . Extended TEM images and analysis are also provided in the supporting information (SI 5 ).
Figure 3. Transmission electron microscopy (a) Low magnification showing the overall area of the flakes (b) moderate and (c, d) high magnification micrographs of exfoliated FeS2 samples. The corresponding FFT patterns (d inset) confirms (111) orientation of the exfoliated sheets. It was also observed that majority of the exfoliated flakes are of (111) orientation indicating the preferential plane of exfoliation as hypothesized in the exfoliation energy calculations (e) high-resolution micrograph with atomic resolution (f) FeS2 projection modeled in Vesta® software and superimposed over a zoom-in portion from (e) demonstrating perfect match between simulated and IFFT structures. (g) EDX mapping area (h) the elemental mapping (EDAX, combined) of the exfoliated samples. (i) The S element mapping and (j) the Fe element mapping.

Magnetic measurements were carried out in a superconducting quantum interference device (SQUID) magnetometer. The zero-field-cooled (ZFC) and field-cooled (FC) susceptibility versus temperature curves for the bulk pyrite show a weak paramagnetic behavior (Figure 4a) independent of temperature as we could see from the dM/dT curve (Figure 4a inset) which is
further confirmed by M-H hysteresis measurements at various temperatures (10 K, 150 K and 300 K) (Figure 4c). Bulk pyrite without any impurity is expected to be nonmagnetic but the paramagnetic behavior observed here could be due to the presence of magnetic impurities such as Co in ppm levels as listed in the EMPA mass percentage analysis in SI 6, Table S1. However, the exfoliated samples are found to be free from any impurities (Figure 3g, SI 15 and SI 6, Table S2).

Figure 4. Magnetization measurements. FC-ZFC measurements at 0.5 T for the (a) bulk pyrite and (b) 2D counterpart with the differential (δ M/ δ T) plot of the FC and ZFC curve shown in the top inset. Pure pyrite crystal is nonmagnetic, but here due to the presence of impurities, bulk pyrite ore crystals show an antiferromagnetic ordering. However, exfoliated FeS2 crystals are free from any impurities and show a ferromagnetic ordering. Corresponding M-H hysteresis measurements (c & d respectively) at three different temperatures (10 K, 150 K and 300 K).
Interestingly, 2D pyrite has a robust ferromagnetic ground state as one could clearly see from the clear diverging ZFC-FC curves (Figure 4b) and M-H loops (at 10 K, 150 K and 300K) with excellent degree of saturated magnetization. This is well in accordance with the theoretical calculations by Zhang et. al according to which a quasi-two-dimensional (111) oriented tri-layer structure with one Fe layer sandwiched by two S layers with the sequence of S-Fe-S has a stable ferromagnetic ground state.(38)

To elucidate the magnetic behavior of 2D FeS$_2$ system, we performed spin-polarized simulations in a density functional theory (DFT) level,(39-43) considering a layer of 2D FeS$_2$ oriented in [100], [111], and [110] directions, with initial unit cells containing 6 (2 FeS$_2$ formulas), 12 (4 FeS$_2$ formulas), and 12 (4 FeS$_2$ formulas) atoms, respectively (see the Supplementary Information for the initial unit cells together with their initial lattice parameters SI 7, Table S3). As we are considering 2D layers, the c unit cell axis was chosen to be 14.00 Å for all systems in order to avoid spurious interactions between neighboring structures due to the periodic boundary conditions. We performed the geometry optimizations for each system considering three different magnetic states: nonmagnetic, ferromagnetic, and antiferromagnetic. After the geometry optimizations, the most stable 2D FeS$_2$ oriented in [100] and [110] directions are the antiferromagnetic one, being ~100 and 63 meV/atom lower than the ferromagnetic one, and ~240 and 285 meV/atom lower than the nonmagnetic one, respectively. As for 2D FeS$_2$ oriented in [111] direction, it is seen that the ferromagnetic state is the most stable, being approximately 12 and 17 meV/atom lower than the antiferromagnetic and nonmagnetic states.

In Figure 5a, it is presented the geometry optimized unit cell of the most stable 2D FeS$_2$ oriented in [100], [111], and [110] directions, i.e., in their antiferromagnetic, ferromagnetic, and antiferromagnetic states, respectively. The resulted lattice parameters (a and b) for these structures
Figure 5. DFT modelled structures, density of states (DOS) and spin density and magnetization per unit cell: (a) Optimized geometry in a top and side view, (b) spin density in a top of view, (c) the total density of states (DOS) from -8.0 to 4.0 eV, and (d) schematic of net magnetization per unit cell of 2D FeS$_2$ oriented in [100], [111], [110] directions in their antiferromagnetic, ferromagnetic, and antiferromagnetic states, respectively.

are 5.58 x 5.58 Å ($\alpha=\beta=\gamma=90^\circ$, point/space group C2v/Pba2), 6.40 x 6.70 Å ($\alpha=\beta=90^\circ$, $\gamma=122^\circ$, point/space group C1/P1), and 5.35 x 8.10 Å ($\alpha=\beta=90^\circ$, $\gamma=94^\circ$, point/space group C1/P1) for 2D FeS$_2$ oriented in [100], [111], and [110] directions, respectively. As for the thickness, we found values of 3.5 and 3.8 Å for 2D FeS$_2$ oriented in [111] and [110] directions, while the oriented in [100] is one atom thick (see Figure 5a). Regarding the bond lengths, we have values around 2.14-2.18 Å for Fe-S and ~2.19 Å for S-S, which are shorter than the same reported for bulk FeS$_2$. (38,
44) The complete set of data obtained for each 2D FeS$_2$ optimized in different magnetic states are presented in the Supplementary Information SI 7.

In Figures 5b and 5c we present, respectively, the spin density (different colors indicated the spin up and down configurations) and the density of states (DOS) of the 2D FeS$_2$ oriented in [100], [111], and [110] directions in their antiferromagnetic, ferromagnetic, and antiferromagnetic states, respectively. The spin density shows that the major contribution to the magnetic response of each system comes from the Fe atoms with magnetic moments varying between 1.1 to 2.0 $\mu_B$, (see Supplementary Information, Table S4-12). As for the DOS, it is interesting to notice that both ferromagnetic as well as antiferromagnetic states indicate a metallic behavior. In Figure 5d we present an schematic view of the net magnetization per unit cell for 2D FeS$_2$ oriented in [100] and [110] directions. In general, our DFT simulations indicates that the 2D FeS$_2$ oriented in [111] direction is the easier to exfoliate and its ferromagnetic state is lower than the antiferromagnetic and nonmagnetic ones, which is in a good agreement with the experimental observations. However, more investigations are essential to unravel the origin of ferromagnetism in 2D FeS$_2$ and the type of exchange interaction responsible for the long-range magnetic ordering.

Conclusions

In short, we have successfully isolated a n-vdW 2D FeS$_2$ from natural iron sulfide (pyrite FeS$_2$) by means of liquid-phase exfoliation. Theoretical DFT calculations confirm that 2D FeS$_2$ is found to be ultrathin and stable down to a monolayer. A (111) faceted monolayer FeS$_2$ is found to be exfoliated quite easily and consist of a three atom-thick layer with a layer of iron atoms is sandwiched in between two layers of sulfur atoms. Few layered 2D FeS$_2$ nanosheets are experimentally found to be retaining the crystallinity of the parent pyrite structure and are observed to be ferromagnetic even at room-temperature whereas its bulk precursor has a weak paramagnetic
behavior. The ferromagnetic ground state of (111) faceted 2D FeS$_2$ is further confirmed by density functional theory calculations. The paramagnetic to ferromagnetic transition while exfoliating a n-vdW FeS$_2$ down to two-dimensions could have excellent implications in the fundamental magnetism as well as in future spintronic applications.

**Materials and Methods**

**Exfoliation of 2D FeS$_2$ from bulk mineral ore pyrite:** Pyrite mineral (SI 4) ore was obtained from Department of Earth, Environmental and Planetary Sciences, Rice University and was ground to small grains of several microns. 20 mg of the powder was dispersed in 200 ml of N, N – dimethylformamide (DMF) solvent and subjected to ultrasonic bath cavitation for approximately 25 hours. A red-colored dispersion of the FeS$_2$ 2D sheets was obtained as a result of extensive sonication. Ultracentrifugation of the solution was performed at an RCF value of 10000 ($ \times g$) for 15 minutes and the supernatant was filtered to obtain a pale red dispersion of ultrathin sheets of 2D FeS$_2$. The solution thus obtained was vacuum filtered to obtain few milligrams of 2D FeS$_2$ which was used as such for further characterizations.

**Analytical Techniques:** The Electron Probe Micro-Analysis (EPMA) was performed at Rice University, Department of Earth, Environmental and Planetary Sciences Science using a Jeol JXA 8530F Hyperprobe, equipped with a field emission assisted thermo-ionic (Schottky) emitter and five Wavelength Dispersive Spectrometers (WDS). The analytical conditions used were 15 kV accelerating voltage, 20 nA beam current. Powder X-ray diffraction was obtained using a Rigaku Smart-lab X-ray Spectrometer. The Raman measurements were obtained employing Renshaw inVia Raman microscope with a 50x objective using He-Ne laser of wavelength 632.8 nm with a spot size of 1µ and the elemental analysis was performed in PHI Quantera XPS machine. AFM images of the pyrite flakes were obtained in tapping mode using a Park NX-10 microscope. The
imaging was carried out using silicon nitride cantilevers, in air and at room temperature. The samples for the AFM images were prepared by drop-casting diluted dispersions onto Si/SiO$_2$ substrates. The low-resolution TEM and HRTEM images were obtained from an advanced Titan transmission electron microscope. For DC magnetic measurements, a magnetic property measurement system (MPMS 3) by Quantum Design was used.

**Theoretical tools:** The density functional theory (DFT) simulations were performed with a projector augmented wave potential (PAW) in a generalized gradient approximation (GGA) with the Perdew, Burke, and Ernzerhof (PBE) exchange-correlation functional. A Monkhorst-Pack $k$-mesh of $4 \times 4 \times 1$ was used to sample the Brillouin zone for geometry optimizations. To evaluate the electronic properties, we increase the Monkhorst-Pack $k$-mesh to $12 \times 12 \times 1$. The Kohn–Sham orbitals were expanded in a plane-wave basis set with a kinetic energy cutoff of 70 Rydberg ($\sim 950$ eV) and a Hubbard parameter $U = 2.0$ eV was used for Fe atoms. This value was used in other 2D Fe structures (hematene). The DFT simulations were performed with the computational code Quantum Espresso. The exfoliation energies were estimated using the proposed method by J. H. Jung et al.
