Abstract

Machine learning is playing an increasingly important role in medical image analysis, spawning new advances in the clinical application of neuroimaging. There have been some reviews of machine learning and epilepsy before, but they mainly focused on electrophysiological signals such as electroencephalography (EEG) or stereo electroencephalography (SEEG), while ignoring the potential of neuroimaging in epilepsy research. Neuroimaging has its important advantages in confirming the range of epileptic region, which means a lot in presurgical evaluation and assessment after surgery. However, EEG is difficult to locate the epilepsy lesion region in the brain. In this review, we emphasize the interaction between neuroimaging and machine learning in the context of the epilepsy diagnosis and prognosis. We start with an overview of typical neuroimaging modalities used in epilepsy clinics, MRI, DTI, fMRI, and PET. Then, we introduce three approaches for applying machine learning methods to neuroimaging data: i) the two-step compositional approach combining feature engineering and machine learning classifiers, ii) the end-to-end approach, which is usually toward deep learning, and iii) the hybrid approach using the advantages of the two methods. Subsequently, the application of machine learning on epilepsy neuroimaging, such as segmentation, localization and lateralization tasks, as well as tasks directly related to diagnosis and prognosis are introduced in detail. Finally, we discuss the current achievements, challenges, and potential future directions in this field, hoping to pave the way for computer-aided diagnosis and prognosis of epilepsy.

1 Introduction

Epilepsy is a neurological disease characterized by abnormal neurophysiological activity leading to epileptic seizures or abnormal behavior, accompanied by varying degrees of loss of sensation or consciousness. Unlike a single-source disease, epilepsy is usually associated with a set of chronic recurrent transient brain dysfunction syndromes \cite{1}. People with intractable epilepsy usually suffer from severe health problems and may lose the ability to take care of themselves. In 2017, The global
lifetime epilepsy incidence rate was 7.60‰, which caused a huge global disease burden [2]. Therefore, the diagnosis and prognosis of epilepsy are important research topics. At present, advances in machine learning and neuroimaging have brought fresh air to this long-lasting research field.

The pathophysiological cause of epileptic seizures is the abnormal discharge of neurons, manifested as high-amplitude bursts on the Electroencephalogram (EEG). In order to clarify the concept, here we regard seizure as a transient brain dysfunction caused by excessive synchronous firing of neurons, and the epileptogenic foci are the sites of epileptic attack. The detection and quantification of epileptogenic foci are essential for the diagnosis of epilepsy. Although about 70% of patients with epilepsy can obtain effective seizure control through anti-epileptic drugs [3], the remaining 30% of patients have failed seizure control, leading to drug-resistant epilepsy or intractable epilepsy. Intractable epilepsy has a high mortality rate and a poor prognosis, requiring surgical treatment [1]. Surgical treatment of epilepsy can be divided into two categories, palliative surgery, and radical surgery, according to whether the surgery is targeted on the epileptic foci [4]. Palliative surgery (i.e. corpus callosotomy or neuromodulation) aims at the seizure-related neural circuits, rather than directly at the epileptogenic foci [5], while radical surgery (i.e. radio frequency thermocoagulation, resection, and dissection) directly deals with epileptogenic foci [6]. All operations require precisely locating the epileptogenic foci, and neuroimaging modalities are the doctor’s main diagnostic tool. Neuroimaging has its important advantages in confirming the range and size of epileptogenic foci comparing to the EEG, which means a lot in presurgical evaluation and assessment after surgery. Therefore, there is a great need for automated analysis of neuroimaging to help clinicians.
The clinical workflow of epilepsy diagnosis and presurgical evaluation is illustrated in Figure 1(a). Patients with suspected epilepsy are first screened by non-invasive techniques for diagnosis, and then those who are diagnosed with epilepsy are usually recommended to take anti-epileptic drugs. For patients with intractable epilepsy, clinicians have to conduct further comprehensive evaluation, including locating the epileptogenic foci and judging whether they contain the eloquent cortex, which – if removed – will result in loss of sensory processing or linguistic ability, or paralysis. This routine evaluation procedure before surgical treatment is called presurgical evaluation [7, 8]. Palliative surgery might be suggested for intractable epilepsy patients whose epileptogenic foci involve the eloquent cortex, whereas radical surgery is considered for those whose epileptogenic foci are not in the eloquent cortex. In the latter case, clinicians need to accurately locate the epileptic source to be removed while preserving the functional eloquent cortex to the greatest extent [9]. Therefore, more advanced and even invasive screening techniques might be involved. On the one hand, epileptic seizures can be directly located by electrophysiological techniques, such as non-invasive electroencephalograph (EEG) and invasive electrocorticography (ECoG) [10]. On the other hand, brain lesions, presumably indirectly or directly leading to clinical seizures, can be detected by neuroimaging techniques, such as magnetic resonance image (MRI) [11] and positron emission tomography (PET) [12]. In general, when the epileptogenic foci are identifiable in neuroimaging, the chance of no seizures after radical
surgery increases by about 2-3 times [13].

However, the clinical workflow is laborious and the outcome that finally achieved with all those medical data is sometimes full of uncertainty because of the eye fatigue of clinicians [14]. Due to the importance and difficulty of presurgical evaluation, technicians are often expected to help clinicians analyze various neuroimaging data in the epilepsy department. The workflow for neuroimaging technicians is shown in Figure 1(b). Their ultimate tasks are complementary diagnosis and computer-aided prognosis.

Voxel-based morphometry (VBM) methods are the traditional computer-aided ways for neuroimaging analysis [15]. Voxel-wise statistical comparisons between normalized brain images are always needed. However, VBM methods only capitalized on superficial information of brain images and sometimes make mistakes due to improper registration. Advances in machine learning made it possible to deeply analyze the images.

Previous reviews mainly focused on the machine learning applied to electrophysiological data (such as EEG) for epilepsy [16, 17, 18], very few reviews have paid attention to epilepsy neuroimaging so far [19, 20]. In this review, other than electrophysiology, we emphasize the role of neuroimaging in epilepsy and the application of machine learning to epilepsy neuroimaging. We will introduce the neuroimaging techniques and machine learning models used in epilepsy study, to highlight the potentials of the machine learning applications in computer-aided diagnosis and prognosis.

We searched Pubmed, Scopus and Google scholar for papers with the keywords ‘machine learning’, ‘deep learning’, ‘epilepsy’, ‘CT’, ‘MRI’, ‘SPECT’ and ‘PET’ in the title or abstract. We surveyed more than 120 papers and checked the citations of the selected papers. Then, we excluded articles that used epilepsy datasets for super-resolution or other non-clinical related tasks and that were ancient. The latest update to the included papers is on February 11, 2021.

The rest of this review is structured as follows. We first present the neuroimaging modalities that are commonly used in epilepsy (Section 2). Next, we briefly introduce three categories of approaches in machine learning, including the compositional approach using traditional machine learning methods, the deep learning oriented end-to-end approach, and the hybrid approach combining the first two approaches (Section 3). We then present the common machine learning tasks for epilepsy and list previous studies on each task (Section 4). Finally we discuss the achievements and challenges in the field (Section 5), to call for more attention on the machine learning on neuroimaging for epilepsy.
2 Neuroimaging tools for epilepsy

The development of medical imaging technology, especially neuroimaging, opens a window for studying the brain through imaging the structure and examining the functional dynamics. The widely-used image modalities are listed in Figure 2. Various non-invasive neuroimaging techniques can be used to monitor brain structure and function, including T1-weighted MRI (T1w MRI), T2-weighted MRI (T2w MRI), diffusion tensor imaging (DTI), functional MRI (fMRI) and PET. Additional semiology video is usually recorded while EEG monitoring. In the following sections, we will mainly focus on neuroimaging.

A typical MRI system consists of the following components: a magnet, a gradient coil, an RF transmitting coil, an RF receiving coil, and a signal processing and image reconstruction section. The nuclear spin of a hydrogen atom in the human body can be equivalent to a small magnetic needle. In a strong magnetic field, the nuclei of hydrogen atoms change from a disordered thermal equilibrium state to a partial direction of the main magnetic field, and the difference forms a net magnetization vector. The hydrogen nuclei precess around the main magnetic field. Gradient coils generate magnetic fields whose strength varies with spatial position and are used for spatial coding of signals. The radiofrequency transmitting coil flips the hydrogen nuclei from the direction of the main field to the transverse plane and precession around the main field. The image is obtained by signal
processing and image reconstruction process after the induction of current signal in the RF receiving coil. Fine-tuning the parameters like flip angle or pulse interval can obtain various sequences, and each sequence provides images that highlight different tissues of brain, such as T1w, T2w, and T2w-FLAIR MRI [21]. Specifically, T1w MRI maps the anatomical structure of the brain; T2w MRI captures the aberrant zone in the white matter; T2w-FLAIR MRI provides high contrasts between the gray matter and cerebrospinal fluid, aiding detection of patients with focal cortical dysplasia (FCD) [22]. It has been reported that the combination of conventional visual analysis and morphometric MRI analysis has significantly higher diagnostic sensitivity in both subgroups of FCD (94% for FCD IIa; 99% for FCD IIb) [23].

Unlike the traditional structural MRI, diffusion imaging leverages the extent, directionality and organization of the motion of free water to provide image contrast [24]. Diffusion-weighted imaging (DWI) detects water diffusion through the transverse magnetization direction, resulting in a phase shift caused by signal attenuation. As an improvement of DWI, DTI reflects the direction of white matter fiber bundles. Diffusion kurtosis imaging (DKI) depicts the molecular weight of water that diffuses out of the Gaussian distribution in the tissue. The Kurtosis information reflects the non-Gaussian characteristics caused by the complex structure of multiple microcellular compartments [25]. Fractional anisotropy (FA) and mean diffusion (MD) maps are commonly used parameter maps derived from DTI and DKI, while the mean kurtosis (MK) map is merely obtained from DKI. In particular, FA measures the degree of directionality, while MD measures the average diffusion along all diffusion directions. MK describes a more complex spatial distribution, that is, the average of the diffusion kurtosis along all diffusion directions. They are important imaging biomarkers for detecting heterogeneous samples [26].

In recent years, brain imaging has been extended from structure to function, and some imaging systems based on brain function have been designed, including functional MRI (fMRI) [27] and PET [28]. Magnetic resonance imaging is used to detect the changes in cerebral blood flow and metabolism caused by neural activity because of the paramagnetism of blood. Thus fMRI can reflect the activities of the brain tissues. PET utilizes radiotracers to observe the local uptake-related variation, which could reflect the abnormal metabolism in brain. For instance, as a complement, PET can localize the regional interictal hypometabolism, guide neuroradiologists to look for lesions [29].

Although EEG directly reflects the abnormal neural activities in epilepsy and EEG is therefore more appealing for epilepsy detection, neuroimaging is largely underestimated in the epilepsy-related machine learning tasks.
3 Machine learning methods

In essence, machine learning, as a data-geared method, builds a myriad of mathematical models that can learn from the structured training data to make predictions or decisions in novel contexts and the newly-presented data, without being explicitly programmed to perform that task [30]. A wide range of machine learning models have been applied to neuroimaging to aid the diagnosis and prognosis of epilepsy [31, 32, 33, 34, 35, 36]. With the growth of machine learning applications in epilepsy, it is necessary to review and summarize methods, tasks, scientific findings, and their interpretations. Here, we categorize the machine learning methods into three classes: the compositional approach, the end-to-end approach and the hybrid approach. The compositional approach mostly performs hand-craft feature engineering, following a classification or regression task solved with conventional machine learning algorithms. The end-to-end approach skips the feature engineering and directly applies deep neural networks to a specific task. The hybrid approach, as its name shown, is a combination of both compositional and end-to-end approaches, which applies an end-to-end model (most likely an unsupervised model, e.g. autoencoder) for feature extraction and then a supervised model to perform the task.

There are a myriad of open-source tools for machine learning and especially for processing neuroimaging of epilepsy. Firstly, Matlab, Scikit-learn, Keras, TensorFlow, PyTorch, Caffe, and Theano are some well-known toolkits to implement machine learning models. Secondly, the codes for neuroimaging processing related to epilepsy is available on the Github.

3.1 Compositional approach

The compositional approach consists of two steps, a manually feature engineering step and a machine learning step (Figure 3). The feature engineering step extracts the hand-crafted features from brain images. The machine learning step then inputs those features to a machine learning model for a certain task, such as classification (to detect the impaired or normal brain) \[33\] or regression (to predict the severity of epilepsy) \[37\]. The machine learning model applied in compositional approach is usually a simple classifier, rather than the deep neural network.

3.1.1 Feature engineering

Feature engineering is a necessary step in the conventional machine learning models, because effectively extracting hidden features from the medical images would largely help subsequent classification. In Table 1 we named some features extracted from each neuroimaging modality relevant to epilepsy. The extracted features are usually with large redundancy as we would like to maintain as much information as possible in the original medical images. Thus, feature selection for removing the invalid features and distilling the relevant features is our next step. The dimension reduction techniques, such

as Principal components analysis (PCA), have been widely used to transfer data from the original high-dimensional space into a low-dimensional space with minimal information loss by selecting the most distinguishable features or create new features [47]. PCA aims at mapping the high-dimensional features to a low-dimensional space through some linear projections via maximizing the variance of the data on the projected dimension. In this way, a lower-dimensional representation of features contains the intrinsic characteristics of the original dataset.

After feature engineering, the selected features will input to the machine learning models for the real-world tasks. To be noted, the performance of conventional models, such as support vector machine (SVM) and shallow neural networks, relies heavily on the extracted features.

3.1.2 Linear discrimination analysis

Linear discrimination analysis (LDA, also called Fisher linear discrimination analysis) is a very classic supervised method in machine learning problems such as data dimensionality reduction, feature extraction, and pattern recognition. LDA was first described for a two-class problem by Ronald A. Fisher [48], and later generalized as multi-class linear discriminant analysis. Different from the variance maximization theory of PCA, the main idea of LDA is to project the data from a high-dimensional space onto a lower-dimensional space so that the same classes are clustered together while the different
classes are far apart. Firstly, the mean of class $i$ is given by:

$$u_i = \frac{1}{n_i} \sum_{x \in \text{class } i} x$$ \hspace{0.5cm} (1)$$

The overall sample mean is given by:

$$u = \frac{1}{m} \sum_{i=1}^{m} x_i$$ \hspace{0.5cm} (2)$$

According to the definition of the between-class scatter matrix $S_b$ and the within-class scatter matrix $S_w$, the following formula can be obtained:

$$S_b = \sum_{i=1}^{c} n_i (u_i - u) (u_i - u)^T$$ \hspace{0.5cm} (3)$$

$$S_w = \sum_{i=1}^{c} \sum_{x_k \in \text{class } i} (u_i - x_k) (u_i - x_k)^T$$ \hspace{0.5cm} (4)$$

Minimizing the within-class distance and maximizing the between-class distance simultaneously via the maximization of the following objective function:

$$J_{\text{fisher}}(w) = \frac{w^T S_b w}{w^T S_w w} = \frac{\sum_{i=1}^{c} n_i w^T (u_i - u) (u_i - u)^T w}{\sum_{i=1}^{c} \sum_{x_k \in \text{class } i} w^T (u_i - x_k) (u_i - x_k)^T w}$$ \hspace{0.5cm} (5)$$

where the optimal transformation $w$ would maximize the objective function.

LDA is a pre-processing step in Machine Learning and applications of pattern classification. The variants of LDA include quadratic discriminant analysis (QDA) [49], flexible discriminant analysis (FDA) [50], and regularized discriminant analysis (RDA) [51].

3.1.3 Random forest

Random Forest (RF) is a combination of decision trees, so each tree depends on the value of an independently sampled random vector and has the same distribution for all trees in the forest [52]. RF creates Bagging [53] ensemble based on decision tree learner, and further introduces random attribute selection in the training process of decision tree. Specifically, when selecting attributes, traditional decision tree selects an optimal attribute from the attribute set of the current nodes. However, for RF, a subset containing $k$ attributes is randomly selected from the attribute set of the nodes in the decision tree, and then an optimal attribute is selected from this subset for division.

3.1.4 Support vector machines

As non-probabilistic binary linear classifiers, SVM aims to find a hyperplane in the N-dimensional space to separate the samples where N is the number of features [54]. SVMs can perform both
the classification and regression tasks, which are first designed for two-class classification but later extended to multi-class classification. Support vector regressions (SVRs) are known as regression problems. However, SVM and SVR possess the same properties, as the target variable in case of regression comprises real numbers, maximum margin separation is challenging in SVR. In SVR, there is a margin of tolerance \( \epsilon \), which should be defined prior to solving the optimization problem. The SVR problem for the training data set of \( m \) points \( \{x_i, y_i\}_{i=1}^{m} \) is given by:

\[
\begin{align*}
\min & \quad \frac{1}{2} \|w\|^2 + C \sum_{i=1}^{m} (\xi_i + \xi_i^*) \\
\text{subject to} & \quad y_i - (w^T x_i + b) \leq \epsilon + \xi_i \\
& \quad (w^T x_i + b) - y_i \leq \epsilon + \xi_i^* \\
& \quad \xi_i, \xi_i^* \geq 0
\end{align*}
\]

where \( w \) is the weight vector, \( b \) is the bias term corresponding to the hyperplane \( f(x_i) = w^T x_i + b \) with \( C \) as the regularization parameter. \( \xi_i \) and \( \xi_i^* \) are the slack variables.

The kernel function of SVM is to take data as input and transform it into the required form and define it as follows:

\[
K(\bar{x}) = \begin{cases} 
1 & \text{if } \|\bar{x}\| \leq 1 \\
0 & \text{otherwise}
\end{cases}
\]

where the value of this function is 1 inside the closed ball of radius 1 centered at the origin, and 0 otherwise. Different SVMs use different types of kernel functions. Polynomial kernel is popular in image processing and defines as follow:

\[
k(x_i, x_j) = (x_i \cdot x_j + 1)^d
\]

where \( d \) is the degree of the polynomial. Gaussian kernel is a general-purpose kernel; used when there is no prior knowledge about the data. Equation is:

\[
k(x, y) = \exp \left( -\frac{\|x - y\|^2}{2\sigma^2} \right)
\]

Gaussian radial basis function (RBF) is a general-purpose kernel; used when there is no prior knowledge about the data. Equation is:

\[
k(x_i, x_j) = \exp \left( -\gamma \|x_i - x_j\|^2 \right)
\]

where \( \gamma > 0 \). In SVM, there is a margin of tolerances \( \epsilon \), which should be defined prior to solving the optimization problem.

So far SVM has been extensively used in various applications and the extensions and variants of SVM were proposed, such as, one-class SVM (OC-SVM), least square SVM (LS-SVM), fuzzy SVM, weighted SVM, transductive SVM, and twin SVM.
3.1.5 Shallow neural networks

Neural network refers to the machine learning models that have a layered network architecture with the layer composed of many artificial neurons. The neurons are interconnected between layers, and the connection strength between neurons is the learning parameter. The training process is supervised. Specific to the complex medical imaging tasks, a large number of studies have proven that neural networks achieve superior performance effectively \[66\]. Forming the groundwork for results connected to the deep neural network (DNN) \[67\], the shallow neural network rapidly learns to build a neural network with only one hidden layer flexibly with forward propagation and backpropagation \[68\] on large datasets.

The shallow neural network, also called the artificial neural network, is consist of neurons, weights, and bias. Furthermore, neurons have three types, including input units, hidden units, and output units. When the input vector is fed into the network as input units, it will propagate through the network to the output units, which represents the probability of a specific class. Additionally, the expression of each neuron in hidden units is as follows:

\[
y = \sigma \left( \sum_{i=1}^{n} w_i x_i - b \right)
\]

In this equation, \(w_1, ..., w_n\) are the weights and \(b\) is the bias. Also, \(\sigma()\) is the activation function that provides a non-linear element, enabling the shallow neural network suffices to approximate any well-behaved functions like bounded continuous functions \[69\].

The loss function is usually be defined according to the specific task, for example, using the cross-entropy loss for classification task, and using the root mean squared error (RMSE) loss for the regression task. To be noted, many other loss functions with various regularization terms have been proposed. The design of loss function is still an on-going research topic in machine learning field. As soon as the network structure and the loss function are designed, the network parameters \(\theta\), including weights and bias, can be learned by error backpropagation algorithm \[68\].

3.2 End-to-end approach

The end-to-end approach trains a learning system with multiple functional layers \[70\], such as a deep neural network with complex nonlinear mapping. Comparing to the compositional approach, a merit of the end-to-end model is that the raw data can be directly input into the model without complicated preprocessing operations on the neuroimaging. Notwithstanding the convenience of the end-to-end models, they have some limitations such as the demand for giant data size and the weak interpretability \[71\].
End-to-end models for diagnosis and prognosis of epilepsy include the supervised learning models and the unsupervised learning models (Figure 4). The supervised learning models require labels (such as disease or health, the degree of severity, the types of epilepsy). They can be trained to reveal a relationship between the features of data and the label, hoping to be generalized to the newly generated data without its label [72]. The unsupervised learning models do not require labels and can capture the patterns of probability densities or neuronal predilections by the intrinsic characteristics of features [73].

Figure 4: The end-to-end machine learning approach. An example of a supervised learning model (a) and an unsupervised learning model (b) used for neuroimaging analysis.

3.2.1 Convolutional neural networks

Convolutional neural network (CNNs) [74, 75] are the most popular machine learning method nowadays, which have been widely applied to image processing. The great capability of CNNs to extract complex hidden features from high dimensional data with deep convolutional structures has enabled its use as feature extractors in medical classification [76] and segmentation [77, 78]. A CNN usually consists of a series of layers with each layer following a differentiable activation function. A variety of activation function has been proposed, such as sigmoid, tanh, softmax, Rectified Linear Unit (ReLU) [78, 79], and leaky ReLU [75]. Figure 4(a) illustrates a typical CNN architecture with three types of neural layers: convolutional layers, pooling layers, and fully-connected layers. The convolutional layers are interspersed with pooling layers, eventually leading to the fully connected layers. The convolutional layer takes a small patch of the input images (i.e. 3 × 3 × 3), called the local receptive field, and then utilizes various learnable kernels to convolve the receptive field to generate multiple feature maps. A pooling layer performs the non-linear downsampling to reduce the input volume’s spatial
dimensions for the next convolutional layer. The fully-connected layer pools the 2D feature maps into a 1D feature vector. The local response normalization is a non-trainable layer and performs a kind of “lateral inhibition” by normalizing over the local input regions.

In practices, a major issue in training deep models is the over-fitting, arising from the gap between a limited number of training samples and a large number of learnable parameters. Overfitting during training can reduce the performance on the test dataset. Many approaches therefore focused on avoiding overfitting, such as dropout and batch normalization. Dropout is a typical deep learning technique, referring to randomly drop a fraction of the units or connections during each training iteration [80]. It has been demonstrated that dropout can considerably avoid over-fitting. Batch normalization as an additional regularization performs normalization in each mini-batches by the running average of mean-variance statistics. Batch normalization can drastically speed up convergence in training and improves the generalization performance [81].

Diagnosis and prognosis of epilepsy based on the CNN framework is currently an emerging, active area of research [82]. More details will be presented in the Section 4.

3.2.2 Autoencoders

Auto-encoder (AE) is a typical unsupervised learning method, consisting of an encoder and a decoder (see Figure 4(b)). AEs learn the latent representation of input data and then capitalize to reconstruct the input data as an output. AEs involve multiple hidden layers which are stacked to form a deep network, called deep auto-encoders (DAEs). Compared with the shallow networks, DAEs are capable of discovering more complex patterns inherent in the input data thanks to the deep layers. So far a number of AE variations have been proposed, for example, denoising auto-encoders (denoising AEs) [83], sparse auto-encoders (sparse AE) [84], variational auto-encoders (VAE) [85, 86], adversarial autoencoder (AAE) [87], and stacked sparse AE (SSAE) [88]. These extensions of AEs have potential of learning the useful latent representations from neuroimaging data and of improving the robustness of medical image reconstruction, which could serve better applications for epilepsy diagnosis. For example, stacked convolutional autoencoders could be used to learn brain images’ representations [83].

3.3 Hybrid approach

More recently, the hybrid approach combining two different machine learning techniques has been brought into the epilepsy study [33, 46]. This formation has high flexibility to improve the performance. The hybrid approach can perform by extracting the hidden features as the latent representation via the end-to-end model rather than the hand-crafted features, and then employing machine learning algorithms for classification. For instance, convolutional autoencoders were stacked to form the
siamese network for learning the representation of each patch at the same spatial localization in healthy brain MRIs. Then in testing stage, the representations can further distinguish the abnormal patches with FCD lesions and the normal ones. Besides the unsupervised end-to-end model, supervised deep neural networks are also capable for hidden feature extraction. As an example, Jiang et al. integrated four sets of features that were extracted from four classic deep neural networks (ResNet - 50, VGGNet - 16, Inception - V3, SVGG - C3D) and classified the fused feature binarily by a full-connected layer.

4 Applications

Machine learning system learns the internal representation of multiple dimensions of numerical features for classification or regression. Then the new-come instance will be identified by its representation. Researchers have exploited multiple machine learning applications based on different objectives. Specifically, some researches focused on the segmentation, the localization and the lateralization which belong to the neuroimaging processing tasks (See section 4.1). Some researches focused on the computer-aided diagnosis tasks (See section 4.2). Finally, part of researches placed emphasis on computer-aided prognosis tasks (See section 4.3).

Figure 5: An example of U-NET for segmentation of brain tissues. This framework is adapted from an open-source project.

4.1 Neuroimaging processing

Neuroimaging processing tasks are aiming at certain regions including tissues that are in the fixed regions of all brains and abnormalities that are different from the ones in the normal brains. They sometimes output the masks. Among the methods, U-net, named for its network shape, is a
commonly used tool for neuroimaging processing. It is specialized in generating masks in segmentation and localization tasks for epilepsy applications \[91, 92\]. Additionally, the structure of U-net is shown in (Figure 5\[89\]). U-net consists of an encoder to learn the representation of image and a decoder to reconstruct the mask corresponding to original image. The encoder can be any existing deep neural network structure, which enables U-net to adjust the structure according to the application.

4.1.1 Segmentation

The segmentation task aims to generate a mask of the target region (i.e. the region of interests) on a given brain image. This mask is usually output by the supervised deep learning models. In training stage, the annotation of the mask requires cumbersome label work by clinical experts. Dice coefficient or also called Dice similarity coefficient, as a measure of the similarity between two sets of data, is the most broadly used metric to evaluate the performance of image segmentation algorithms. The higher the dice coefficient is, the better the performance is.

Some deep learning models have been applied to segment specific regions with epilepsy neuroimaging data set. Onofrey et al. applied a dictionary learning-based registration approach to segment the post-surgical brain surface from the fusion of CT and MRI data. Specifically, the prior-surgery MRI was used to guide the surgical resection of epileptic tissue, whereas SEEG recordings with the post-surgery CT image as the standard of epileptic areas. The dice coefficient between segmented result and the standard was 94\% \[93\]. Also, segmentation of certain functional regions, especially the hippocampus, is of special interests in epilepsy. The abnormalities in volume and shape of hippocampus have been reported as biomarkers for diagnosis of epilepsy \[94\]. There was a job training end-to-end model by epilepsy dataset to segment hippocampus. Carmo et al. designed CNN based on the U-net architecture to obtain the segmentation mask of hippocampus, with dice coefficient being 77\%. A native database HCUnicamp was used in their study, which was collected by personnel from the Brazilian Institute of Neuroscience and Neurotechnology (BRAINN), containing 132 patients with epilepsy \[91\].

4.1.2 Lesion Localization

Applying to the localization tasks, machine learning models also generate a mask to indicate the aberrant region. Some of the representative work are listed in Table 2. Among various localization tasks, the localization of lesions on the cortex is one of the most important. The accurate localization of the pathological lesions will greatly inform the neurosurgeon; in particular, the treatment-resistant epilepsy is often associated with lesions in the brain. Benefiting from the advances in computer vision field, a variety of deep learning methods have been proposed and effectively applied to the task of
localizing epileptogenic lesions.

The field of FCD localization has aroused special interest of researchers due to its high incidence and misdiagnosis rate. The subtle lesions could be manifested on MRI as cortical thickening, blurring of the grey matter-white matter interface and so on \[95\]. FCD lesions may be seen as normal by clinicians on structural MRI in despite of the positive histological verification. Studies of this task commonly used two evaluating indicators. Sensitivity refers to the proportion of patients with lesions are accurately detected among all patients. Specificity is the one’s complement of the proportion of control instances that are classified into the patients among the controls. Also, the studies using this two indicators would define the overlapped standard between the localization outcome and ground truth.

Compositional methods have been widely used in this field. The earliest compositional method selected six feature maps to locate the clusters of candidate lesion voxels based on the one-class SVM via ranking T1w MRI voxels by size and suspicion degree \[96\]. This method detects two patients’ FCD lesions without bias \[96\]. Subsequent study by the same team captured more distinguishing features and reached general results to locate the FCD lesions. In 3 MRI-positive cases, the detection rate was 100%, while in 10 MRI-negative cases, the detection rate was 70% \[97\]. Further, tree-structured hierarchical conditional random field was utilized to identify the segmented abnormal cortical surface regions patch-wisely by thresholding the posterior probabilities, and it located the FCD region of MRI-positive with 90% accuracy and MRI-negative with 80% accuracy. The accuracy of MRI-negative cases was the highest in the FCD localization field \[98\].

Three studies chose the shallow neural network as the classifier in compositional method \[22, 99, 39\]. With regard to features, FreeSurfer processing software is a commonly adopted brain features extracted tool \[\text{http://surfer.nmr.mgh.harvard.edu/}\] for the compositional models. Adler et al. added novel feature (local cortical deformation) to the FreeSurfer’s features, aiming at the developing cortex of children. The sensitivity improved from 53% to 73% with incorporation of novel features \[22\]. Jin et al. combined the surface-based morphometry feature sets extracted by FreeSurfer from T1w, T2w and FLAIR MRI, effectively localizing the FCD with 73.7% sensitivity and 90% specificity \[99\]. Addtionly, the morphological and intensity features could be extracted to localize the FCD regions with up to 73.5% sensitivity and 100% specificity by wagsty et al. \[39\].

More recently, end-to-end models were performed in the FCD localization area. Gill et al. leveraged MRI vertex and voxel respectively to localize the FCD region by decision tree (DT) and CNN \[100, 101\], among which CNN outperformed compositional method with 91% sensitivity and 95% specificity. Furthermore, the customized U-Net was used to localize the FCD lesions using only FLAIR MRI in
2019 with 82.5% accuracy [92].

Besides the FCD lesion, diffusion images can identify the white matter tracks involved in epileptic abnormality. Xu et al. designed a CNN with a combined focal and central loss and a soft attention scheme, and applied it to DWI data, achieving a clinically acceptable accuracy of 73%-100% to detect the white matter pathway connected to eloquent areas [102]. A following-up study from the same group applied the CNN method to the DWI to localize the pediatric eloquent cortex [103]. In addition, MD map and the fusion of FA and MK maps extracted from DKI were segmented into hippocampus masks to perform abnormal identification of certain brain regions. This work can indirectly locate anomalies in the hippocampus. They classified the patients with hippocampus epilepsy and the healthy subjects through a deep CNN to localize the abnormal hippocampus with the accuracy of 90.8% [44].

FMRI during a task or at resting state can pinpoint the abnormal regions involved in a functional network, such as language network. Torlay applied Extreme Gradient Boosting algorithm (XGBoost) on fMRI data to identify the atypical patterns of language networks on a phonological and semantic language task in patients with focal epilepsy [45]. Resting-state fMRI has been reported to be helpful to localize the eloquent function like sensorimotor cortex [104], which is essential in the presurgical evaluation.

### 4.1.3 Lateralization

Lateralization is an important task which involves two different purposes, one is to identify the hemisphere where the epileptogenicity is localized, another is to identify the hemisphere of the eloquent cortex, such as language regions. The former is helpful for lesion localization and epilepsy diagnosis. For example, the hippocampal atrophy usually lateralizes toward the focus in drug-resistant temporal lobe epilepsy (TLE). The latter is essential for the surgery treatment as the eloquent cortex must be maintained during the treatment. Some results are listed in Table 3.

The structural images have been widely used in laterlization task. For instance, Kim et al. manipulated linear discrimination analysis (LDA) to classify the left- or right-sided seizure focus with manually extracted features after the segmentation of hippocampus in MRI [40]. Similarly, the LDA classifier can be replaced by SVM or DNN for higher accuracy [106, 34]. SVM on the features from the graph theoretical network properties of DTI structural connectomes has been used to successfully lateralize the epileptogenicity in TLE by classifying the right TLE, the left TLE and the control group [107]. Another study showed that even in visually MRI-negative TLE, the seizure laterality can be predicted by traning an random forest (RF) classifier comprising an ensemble of 5000 decision trees using a set of 117 features from their structural brain images [108].

Besides the structural images, the functional images can be utilized to lateralize the dominant hemisphere. Yang et al. extracted features from rs-fMRI within local brain regions, between brain regions, and across the whole network. Then the random forest was used to reduce the dimension and SVM was employed to classify the laterality of TLE patients with 83% accuracy [109]. Gazit et al. suggested that using the selected features in verb-generation fMRI task, and then choosing the probabilistic logistic regression method could help to lateralize the language regions of patients with epilepsy [110].

### 4.2 Epilepsy Diagnosis

Researchers characterize the latent epileptic subjects and reveal the essentiality of the features, which can guide the clinicians and improve the diagnostic assessment workflow. On the one hand, these tasks were directed to save the unnecessary time of the well-trained doctors. On the other hand, the algorithms with high sensitivity increase the chance of detecting potential ‘invisible’ regions that may be ignored by the human experts. We listed some work relevant to epilepsy diagnosis in Table 4.

The good old-fashioned compositional methods had been widely applied to classify the patients and the healthy controls [32, 31, 111, 112, 113]. It may also identify the most contributed features corresponding to specific disease in such process. For example, SVM was utilized to distinguish patients with tonic-clonic seizures from the normal cohort by using two hand-crafted MRI features (Gray matter volume and fALFF) and fALFF got better performance with accuracy of 83.72% [31]. Moreover, taking both DTI (MD and FA) and DKI (MK) features into consideration, MK reached the best accuracy among three features based on SVM with accuracy of 82% [113]. However, in other studies, the feature engineering step from neuroimaging data produced large amount of features which can be easily extracted by the existing toolboxes. Usually, PCA can be used to reduce the dimension of features and then SVM can gain more discernible results with 88.90% accuracy [32]. Similar
compositional method has also been applied on PET image, in which the hemisphere symmetry tensor feature was built and extracted by multi-linear PCA. Then they manipulated SVM to classify the abnormal images and the normal ones [111].

End-to-end models have been brought into the epilepsy detection since 2018 [76]. The first application of CNN for the recognition of epilepsy by Pominova [76] used the structural MRI and fMRI separately to classify the subjects with epilepsy. This work confirmed the feasibility of CNN in an end-to-end fashion which directly inputs the high dimensional neuroimaging data without feature engineering. Later, Yan et al. presented a 3D CNN on the raw MRI image data to predict the benign epilepsy with centrotemporal spikes and achieved 89.80% accuracy [114]. Jiang et al. fused the features extracted from 2D and 3D PET ROIs respectively by three natural images pretrained networks (ResNet - 50, VGGNet - 16, Inception - V3), and a pulmonarynodules CT pretrained network (SVGG - C3D). Then, a fully connected layer was applied as a binary classification [46]. Recently, deep learning method was applied to PET for the first time. Zhang et al. developed a novel Siamese CNN which is able to track the metabolic symmetricity of PET because the epileptic focus is strongly correlated to the high-dimensional inter-hemispheric symmetricity changes. Their proposed model had a high detection accuracy of 90% [115].

Besides the end-to-end supervised models, the unsupervised machine learning approaches have been used to automatically extract the latent representation of brain images, which can be further input to a classifier. Alaverdyan applied the unsupervised Siamese network to improve the latent feature extraction [116, 33]. Then the latent representation of the T1w MRI voxels inputs to an one-class SVM classifier for the outlier detection, which can determine whether it is the abnormal data. They compared the variant of siamese networks, the stacked convolutional autoencoders and the Wasserstein autoencoders, and the results suggested that the regularized siamese network has great potential to extract the hidden features and eventually achieved the best classification performance. Surprisingly, this method has even been shown to outperform human experts for the MRI-negative cases.

### 4.3 Epilepsy Prognosis

Computer-aided prognosis tasks were important in guiding clinicians to the proper treatment. Clinically, prognosis of epilepsy can be quantified with epidemiology-based mortality score in status epilepticus (EMSE), Engel classification or other clinical indexes. The machine learning application in epilepsy prognosis is to predict the treatment outcome, which could also guide the treatment decision in advance. Prognosis is usually a classification task for the postoperative states (seizure-free or persistent seizures), although it can also be a regression task to predict the levels of treatment.

outcome such as seizure frequency or EMSE. We listed some work relevant to epilepsy prognosis in Table 5.

Studies tend to capitalize on compositional models, which use the curated features to predict the outcome of surgery. For example, Memarian et al. extracted 88 features (including demographic, clinical, electrophysiological, and structural MRI features) from mesial TLE patients and achieved 95% accuracy for prognostic prediction using SVM classifier [35]. Bernhardt et al. applied K-means clustering into 4 subgroups based on the manually segmented the mesiotemporal structures (hippocampus, amygdala, and entorhinal cortex) from T1w MRI [119]. Then, the surface morphology of the patients within each class was input to supervised LDA, aiming at predicting the postsurgical outcome. The mean accuracy reached 92% among 4 classes.

Apart from the compositional machine learning methods, end-to-end DNNs have also been applied to predict the most likely outcome of the treatment [36, 120, 121]. For example, the whole-brain connectome matrix obtained from DTI were trained with binary labels (i.e. surgical success or failure). Gleichgerrcht et al. got 88.0% ratio when predicting success surgery and 79.0% ratio when predicting failure surgery [36].

5 Discussion

In short, among the various machine learning models, the feature engineering based compositional models accounted for a large proportion of the applications, while the data-driven end-to-end models for neuroimaging analysis, such as deep learning, is just emerging. Although the first study using deep learning models for epilepsy neuroimaging data only appeared in 2018 [76], deep learning has been a
success in computer vision, recommendation systems and natural language processing [122, 123]. We can envision that deep learning would play a more important role in epilepsy neuroimaging in the future. Along this line, neuroimaging will contribute to the computer-aided diagnosis of epilepsy.

However, there are obstacles when applying deep learning methods to the epilepsy neuroimaging field. The challenges of deep learning in epilepsy neuroimaging have multiple manifolds. First, labeling data is challenging. The ambiguity in diagnosing a particular epilepsy can lead to difficulties in labeling the disease type. Labeling epileptic lesions is particularly hard, unless neurologist conducts longitudinal observations and confirms seizure free after surgery. Moreover, patients with epilepsy may suffer from multiple complications, making it difficult to use single-hot vector labels to train machine learning models. As the loss function defined by the discrepancy between the network output and the label is the key to the supervised learning algorithm based on gradient descent, noisy labels will inevitably bring serious negative effects. The consequences of mislabeling data can be fatal. Second, the imbalance between classes is another challenge in epilepsy medical images. The fact that different types of epilepsy have different frequency of occurrence leads to an imbalance between epilepsy types. For example, temporal lobe epilepsy (TLE) is common, while focal epilepsy on the motor cortex is relatively rare [124]. Therefore, the samples in the diagnosis task are tilted towards TLE, which might largely bias classification results. Third, neuroimaging requires high spatial resolution in order to detect subtle abnormalities, and neuroimaging also need a large field of view for locating abnormal brain areas of all spans. These two are difficult to meet in a single brain imaging modality. As a result, there are more and more modalities of epilepsy images, adding difficulties for modeling. Finally, due to the diversity of neuroimaging equipment and patient conditions, medical images are usually heterogeneous; therefore improving the generalization ability of machine learning models is very challenging. In fact, comprehensive validations of the generalizability and reliability of machine learning algorithms come at a cost. Few fully validated methods are ready for clinicians when encountering MRI negative images, so the algorithm can hardly be trusted in clinical applications. This distrust is further amplified by the shortcomings of machine learning without a clear physical explanation. When algorithm developers boast of their high accuracy rate, it is still difficult for clinicians to understand why it is a success, neither those few failed samples explain why they failed or when will fail.

The cutting-edge machine learning models provide potential tools for addressing the above challenges. For example, generative adversarial networks (GAN) [125, 126, 127] might be beneficial for data augmentation to address the problem of unbalanced neuroimaging samples [128]. Likelihood-based generative models (e.g., VAEs [85, 86], Pixel CNN [129] and Glow [130]) have been reported to be highly robust to the anomaly data and out-of-distribution (OOD) inputs and therefore can
be used to detect the anomaly samples. The anomaly detection has wide medical applications. For instance, when an untypical disease is not seen in the training samples, likelihood-based generative models equipped with medical OOD detection might deal with noisy labels and largely improve the robustness [131] [132] [133] [134]. The recent advancements in graph convolutional networks (GCN) can work with the non-regular data structures. In contrast to the node classification tasks of medical image analysis [135] [136], GCN can can handle unstructured data [137]. As a generalization of CNN, GCN is compatible with data in non-Euclidean domain. Segmentation [138], localization [139] and prediction [140] tasks has been reported beneficial from GCN, although the performance of GCN in epilepsy data is still needed to be tested.

On the other hand, the challenges and special needs in epilepsy applications can greatly motivate the development of machine learning methods. For example, Zhao et al. [105] came up with a new approach to solve the problems of patients’ heterogeneity by combining a restricted Boltzmann machine with a Bayesian non-parametric hybrid model. The heterogeneity of patients with epilepsy requires personalized medical care, which calls for accurate diagnosis of the stratification of each patient, such as the cause of epilepsy, the location and symptoms of epilepsy [141] [142]. Since the prognosis of epilepsy is vital for the patient’s quality of life, the longitudinal medical records of each patient should be recorded and analyzed. These are strong drives of machine learning theory and method.

6 Conclusion

Just as machine learning, especially deep learning, brings benefits to machine vision and natural language processing, machine learning on neuroimaging promises to extend those same benefits to epilepsy diagnosis and prognosis prediction. However, clinic-oriented machine learning applications has its unique context, such as the small data size, the low certainty in labeling, and the large heterogeneity across patients. It requires more efforts from multi-disciplinary experts on learning theory, neuroimaging and epilepsy clinical applications.
