

Revenue Maximization for Buyers with Outside Options

Yannai A. Gonczarowski* Nicole Immorlica† Yingkai Li‡
Brendan Lucier§

Abstract

We study mechanisms for selling a single item when buyers have private values for their outside options, which they forego by participating in the mechanism. This substantially changes the revenue maximization problem. For example, the seller can strictly benefit from selling lotteries already in the single-buyer setting. We bound the menu size and the sample complexity for the optimal single-buyer mechanism. We then show that posting a single price is in fact optimal under the assumption that either (1) the outside option value is independent of the item value, and the item value distribution has decreasing marginal revenue or monotone hazard rate; or (2) the outside option value is a concave function of the item value. Moreover, when there are multiple buyers, we show that sequential posted pricing guarantees a large fraction of the optimal revenue under similar conditions.

1 Introduction

In the textbook example of revenue optimization, a monopolistic seller wishes to sell a single item to a single buyer whose value is drawn from a known distribution. In this idealized economic environment, Myerson (1981) proved that the optimal mechanism simply posts a single price, which the buyer accepts if it is below her value. However, actual economic environments depart significantly from this ideal. One significant assumption is that each buyer's utility from winning no items, or more precisely, from taking her *outside option*, is normalized to zero. While this assumption is without loss when the value of the each buyer's outside option is known to the seller, it falls short of capturing scenarios in which buyers have private values for their outside options.

In this paper we relax this assumption, allowing the buyer to have a private valuation for an outside option (or, equivalently, a private cost for participation) which she forfeits by participating in the mechanism.¹ Specifically, we extend the buyer's type to include both a valuation for the item for sale and a valuation for the outside option. The seller, given a Bayesian prior over the buyer's type, chooses a mechanism to sell the item.

Upon first glance, one may wonder whether this setting is in fact equivalent to a single-dimensional setting in which the buyer's type is simply her item value minus her outside-option value. However, for private outside option values, this transformation impacts different types' choices differently. Consider a buyer with choice between paying \$3.10 for getting the item for sure or paying \$1 for getting the item with probability² 50% (or not paying anything and taking her outside option). If the buyer has a value of \$5 for the item and an outside option value of \$1, she would strictly prefer the former option (paying \$3.10 and getting the item for sure for a resulting value of $5 - 3.10 = \$1.90$). However, if the buyer has a value of $5 - 1 = \$4$ for the item and an outside option value of \$0, she would strictly prefer the latter option (paying \$1 and getting the item with probability 50% for a resulting expected value of $\frac{1}{2} \cdot 4 - 1 = \1). So there is more at play here than is conveyed by the difference between the item value and the outside-option value.

Our model can be interpreted in various ways. For example, a private value for the outside option is equivalent to a private cost for participating in the auction, where the cost is nonrefundable even if the buyers do not win any item from the auction (Celik and Yilankaya, 2009). Another interpretation is the oligopoly model with exclusive competitions (Champsaur and Rochet, 1989). For example, suppose there are multiple firms who wish to sell different items to a single buyer by holding auctions simultaneously in different locations, and the buyer can participate in at most one auction. Taking the other sellers' strategies (selling mechanisms) as exogenous, from the perspective of any seller, the utility of the buyer for participating in the other auction can be modeled as an outside option with a private value. Thus, the best response problem in this oligopoly model is the optimal mechanism for the design problem with a private value for the outside option. Finally, our model can also be viewed as a setting where buyers must make investment decisions for boosting their values for winning the auction. Without investment, the buyers have no value for winning the auction. The investments are costly for the buyers, and the investment costs are the

¹The model with a non-exclusive outside option is discussed in Appendix C.

²But recall that with the remaining 50% probability, the buyer will not get the item nor will she have access to her outside option since she chose to participate in the mechanism.

private information of the buyers. The buyers must decide whether to invest before the auction starts (Gershkov et al., 2020).³

As we show, known qualitative results regarding the form of the revenue-maximizing mechanism in the standard setting may fail to hold in the presence of a private value for a buyer’s outside option, already in the single buyer setting. Indeed, already in this setting the seller can strictly benefit by offering lotteries (see Example 1 below), in sharp contrast to the setting where the seller knows the buyer’s value for the outside option. We therefore embark on a study aimed at adapting and extending canonical results on revenue maximization to this generalized setting, for a single buyer as well as for multiple buyers.

We start by providing a payment identity for our setting, analogous to the classic one of Myerson (1981). We then build upon our payment identity to provide characterizations of the optimal mechanism in the single buyer setting, as well as to show that despite the revenue-maximizing mechanism sometimes having to offer lotteries to the buyer, its menu size is at most linear in the number of possible values that the outside option may take. We also bound the number of samples required to learn an up-to- ϵ revenue-maximizing mechanism absent direct access to the underlying distribution. These results shed light on which parts of the standard analysis and its results are robust to making the value of the outside option private. Despite these added complexities, we show that if either (1) the valuation distribution is independent of the outside option value distribution and has decreasing marginal revenue or monotone hazard rate (Definition 1); or (2) the outside option value is a concave function of the item value, then the optimal mechanism simply posts a (carefully chosen) single price for the item. Curiously, we show that under these conditions, the optimal price is in fact equal to the standard monopoly price for the (single-dimensional) distribution of the difference between the value of the item and that of the outside option, despite the example above that explicitly shows that these two problems are not equivalent.

Finally, in the multi-buyer setting, as suggested by Gershkov et al. (2020), characterizing the exact revenue optimal mechanism may not be tractable even when the outside option values are known and all buyers are symmetric. This is because the buyers do not satisfy the von Neumann–Morgenstern expected utility characterization for their preference of the lotteries, and the revenue optimal mechanism may not be symmetric even in this simplified case. In contrast, we show that even in the asymmetric setting, if for each buyer, either (1) the valuation distribution is independent of the outside option value distribution and has decreasing marginal revenue; or (2) the outside option value is a concave function of the item value, then a sequential posted price mechanism guarantees a constant fraction of the optimal revenue.⁴

³Our setting with a private value for the outside option is a special case of this setting, in which the investment decision is binary, and the valuation for winning the auction is zero if the buyer does not make a costly investment. Note that however, our model is not covered by Gershkov et al. (2020) as they only consider public investment cost.

⁴Our result for the multi-buyer setting allows the situations where some of the buyers satisfy condition (1) while the others satisfy condition (2).

1.1 Related Work

Although most work in the literature on auction design focuses on the case where the buyer has an outside option for not participating the auction with a value that is known to the seller, and this value is normalized to zero, Rochet and Stole (2002) illustrate that some general lessons from this work is not robust to the presence of a private value for the outside option when there are production costs (which our model does not have).

There is a significant body of work following up on Rochet and Stole (2002) in the economic literature. Most of this work focuses on qualitative features of the optimal mechanism when there are private values for outside options, such as showing that distortion at the top or bottom is not required. There are various extensions of the model by considering the optimal mechanisms for selling congestible goods (Jebsi and Thomas, 2006), when principals are risk-averse (Basov and Yin, 2010), or by considering the optimal income taxation rule (Lehmann et al., 2011). The novel contribution of our work is to provide a general characterization of the optimal mechanism through a payment identity and virtual value analysis, and to provide natural sufficient distributional conditions for price posting to be optimal or to guarantee a large fraction of the optimal revenue.

By having a two-dimensional (item value, outside option value) type space but (as we show) giving way for a structural understanding of the general optimal mechanism, our setting can also be thought of as relating to the line of work on so-called “one-and-a-half dimensional,” or “interdimensional,” mechanism design settings. In that domain, a buyer has one dimension representing her willingness to pay, and an additional so called “half dimension” representing a constraint on her demand. For example, in the FedEx problem (Fiat et al., 2016) the “half dimension” is the buyer’s deadline, and the buyer is only willing to accept the item before this deadline. For buyers with budgets (Che and Gale, 1998; Devanur and Weinberg, 2017), the “half dimension” is the buyer’s budget constraint, which places a cap on the maximum value she can pay for the item offered by the seller. The main focus of those papers is to provide characterizations of the optimal mechanisms, (e.g., bound their menu sizes). In our setting, a buyer’s value for her outside option can also be viewed as a “half dimension” of sorts since it only affects her decision of whether or not to participate in the auction; conditional upon participating in the auction, the value of the forfeited outside option does not affect the buyer’s utility in the auction.

Our paper also falls into the scope of designing simple and approximately optimal mechanisms (Hartline and Roughgarden, 2009). This line of work mainly focuses on the case in which all buyers have an outside option known to be of zero value. For the single-item setting, sequential posted pricing guarantees a $1 - 1/e$ fraction of the optimal revenue (Yan, 2011). For multi-item setting, sequential posted pricing guarantees a constant fraction of the optimal revenue when buyers have unit-demand valuations (Chawla et al., 2010; Cai et al., 2019) and selling items separately or as bundles guarantees a constant fraction of the optimal revenue when buyers have additive valuations (Babaioff et al., 2020; Cai et al., 2019). When buyers have non-linear utilities (e.g., budgeted utility), Feng et al. (2020) show that constant-fraction approximation results (e.g., sequential posted pricing) for linear buyers can be generalized to non-linear buyers when the type distributions of the buyers satisfies some closeness property. There are numerous results on this topic. See the survey of Roughgarden and Talgam-Cohen (2019) for a detailed discussion on the approximately

optimal mechanisms in various other settings.

Finally, our results also contribute to the literature on menu sizes of optimal and approximately optimal mechanisms (e.g., Fiat et al., 2016; Hart and Nisan, 2017; Babaioff et al., 2017; Devanur and Weinberg, 2017; Gonczarowski, 2018; Saxena et al., 2018; Devanur et al., 2020) and to the literature on the sample complexity of learning up-to- ϵ optimal mechanisms (e.g., Cole and Roughgarden, 2014; Morgenstern and Roughgarden, 2015; Devanur et al., 2016; Gonczarowski and Nisan, 2017; Hartline and Taggart, 2019; Gonczarowski and Weinberg, 2018; Guo et al., 2019).

2 Models

A seller has a single item to offer for sale to n buyers. Each buyer i has a private valuation $v_i \geq 0$ for getting the item and a private valuation c_i for her outside option when she does not participate the mechanism.⁵ Let $t_i \equiv (v_i, c_i)$ represent the private type of buyer i and let \bar{F}_i be the seller’s prior distribution over t_i with density \bar{f}_i . Let F_i and G_i be the marginal distributions of the item value and outside-option value with densities f_i, g_i . Note that a buyer’s item value and outside option value may be correlated under \bar{F}_i . Let $\bar{F} = \times_i \bar{F}_i$ be the product distribution of the buyers’ type profiles.

Mechanisms. Most papers in the mechanism design literature focus on truthful⁶ mechanisms, and (by the revelation principle) this restriction is without loss when buyers have outside options whose values are known to the seller (Myerson, 1981). However, it is not immediate that the revelation principle extends to the setting with private outside option values. Note that by assumption, a buyer forfeits her right to choose her outside option the minute she communicates with the seller. Nonetheless, we show that there exists a generalized notion of a revelation mechanism, such that any mechanism can be transformed into an *opt-out-or-revelation mechanism* with the same revenue. Formally, let $\bar{\mathbb{R}} \equiv \mathbb{R} \cup \{\psi\}$ be the augmented report space where ψ represents not participating in the auction, and any other report is an item value report. We show that it is sufficient to consider what we call opt-out-or-revelation mechanisms, i.e., mechanisms \mathcal{M} with allocation function $x : \bar{\mathbb{R}}^n \rightarrow \Delta(\{0, 1\}^n)$ and payment function $p : \bar{\mathbb{R}}^n \rightarrow \mathbb{R}^n$, such that each buyer reporting ψ (and only such buyers) receives the outside option and $x = p = 0$, and there exists an equilibrium where each buyer maximizes her utility by reporting truthfully (where a “truthful report” of ψ indicates that the buyer’s outside option value is at least her expected utility from truthfully participating). That is, there exists a profile of strategies σ such that $\sigma_i(t_i) \in \{\psi, v_i\}$ and for any buyer i and type t_i ,

$$\mathbf{E}_{t_{-i} \sim \bar{F}_{-i}}[u_i(\mathcal{M}(\sigma(t)))] \geq \mathbf{E}_{t_{-i} \sim \bar{F}_{-i}}[u_i(\mathcal{M}(b_i, \sigma_{-i}(t_{-i})))] \text{ for any } b_i \in \bar{\mathbb{R}}.$$

⁵Although it is most natural to consider non-negative values for outside options, negative values for outside options can capture the potential social benefit for the buyer to participate the auction, which is not modeled in her valuation for the item. Introducing negative values for outside options will lead to different observations for the optimality of posted pricing, which will be discussed formally in Section 4.

⁶In this paper, by truthfulness in a multi-buyer setting we will mean individual rationality and Bayesian incentive compatibility.

See Appendix A for a more detailed discussion on this generalized opt-out-or-revelation mechanism.

When there is a single buyer ($n = 1$), we say that an opt-out-or-revelation mechanism \mathcal{M} posts a price if there exists a price p such that the mechanism awards the item with probability 1 for a price of p if the buyer participates and reports a value of no less than p , and otherwise the item is not awarded and $p = 0$. With $n \geq 2$ buyers, we say that an opt-out-or-revelation mechanism \mathcal{M} is a sequential posted price mechanism if there exist prices p_i and an order over the buyers such that the mechanism awards the item with probability 1 for a price of p_i to the first buyer i —according to this order—who participates and reports a value of no less than p_i (and no other buyers are charged any price), and the item is not awarded and no buyer is charged any price if no such buyer exists.

Revenue Maximization. For any mechanism \mathcal{M} , let $\text{Rev}(t, \sigma; \mathcal{M}) = \sum_i p_i(\sigma(t))$ be the revenue of mechanism \mathcal{M} given type profile t and strategy profile σ , and let $\text{Rev}(\bar{F}, \sigma; \mathcal{M}) = \mathbf{E}_{t \sim \bar{F}}[\text{Rev}(t, \sigma; \mathcal{M})]$ be the expected revenue given distribution \bar{F} . We will omit the strategy σ in the notation if it is clear from the context. Let

$$\text{OPT}(\bar{F}) = \max_{\mathcal{M}} \max_{\sigma \in \text{BNE}(\bar{F}, \mathcal{M})} \text{Rev}(\bar{F}, \sigma; \mathcal{M})$$

be the optimal expected revenue of the seller given distribution \bar{F} under the Bayes–Nash equilibrium with highest expected revenue. Let $\phi(v) = v - \frac{1-F(v)}{f(v)}$ be the virtual value of the buyer with value v and valuation distribution F .

Definition 1. For any valuation distribution F with density function f and virtual value function ϕ ,

- F is regular if the virtual value $\phi(v)$ is non-decreasing;
- F has decreasing marginal revenue (DMR) if $f(v)\phi(v)$ is non-decreasing;
- F has monotone hazard rate (MHR) if $\phi'(v) \geq 1$ for all v .

3 Preliminary Analysis

In this section, we consider the setting where there is only a single buyer in the market. Thus we will omit the subscript i from our notation throughout the section. Note that all results in this section apply even when the distribution over types allows for correlation between valuations and outside options. In the following example, we show that the private outside option value setting is qualitatively different from the setting in which the outside option value is known to the seller, by providing a distribution over item values and outside option values—these will even be independently distributed—such that offering lotteries to the buyer can strictly improve the expected revenue compared to posting a single fixed price.⁷

⁷There is an interesting conceptual connection between this example and the observation of Deneckere and McAfee (1996) that a seller may be able to strictly increase her revenue by introducing a damaged good into the market. Note that our setting with a private value for the outside option can be converted into a

Example 1. The item value and outside option value of the buyer will be independently distributed. The item value distribution has CDF $F(v) = 1 - \frac{1}{v-1}$ for $v \in [2, 5)$ and $F(v) = 1$ for $v \geq 5$. Note that F is a regular distribution. The outside option is 0 with probability 0.15 and 2 with probability 0.85. In this example, the optimal posted-price mechanism is to post price 2, resulting in revenue 0.86. However, the mechanism that offers choice from the menu of two probability-price lotteries $(1, 3), (\frac{2}{3}, \frac{4}{3})$ has strictly higher revenue 0.9. The multiplicative gap between the optimal mechanism and optimal pricing is therefore higher than 1.038.

A classic approach to designing the revenue-optimal mechanism for a single-item setting when the value of the outside option known to the seller is to use a payment identity and virtual value analysis.

Lemma 1 (Myerson, 1981). *In the single-item single-buyer setting, if all buyers have outside option 0, for any truthful mechanism \mathcal{M} with allocation x and payment p , it holds that x is non-decreasing and the payment satisfies $p(v) = vx(v) - \int_0^v x(z) dz + p_0$ for some constant p_0 . The expected revenue given distribution F is*

$$\text{Rev}(F; \mathcal{M}) = \mathbf{E}_{v \sim F}[x(v)\phi(v)] + p_0.$$

In this section, we provide an analog of the payment identity when buyers have private outside option values. That is, we show that it is without loss to consider a truthful mechanism as if the outside option had value 0, in which case the buyer will participate if and only if her utility from participating is at least her outside option value.

Lemma 2. *It is without loss for the seller to commit to a monotone non-decreasing allocation rule $x(v)$ and payment rule $p(v) = vx(v) - \int_0^v x(z) dz + p_0$ for some constant p_0 , and for the buyer to participate and truthfully reveal v if and only if $u(v; x, p) = \int_0^v x(z) dz - p_0 \geq c$.*

Proof. In Section 2, we have shown that it is without loss to consider the opt-out-or-revelation mechanism where the buyer truthfully reveals her item value conditional on participation. By Lemma 1, the allocation satisfying the incentive constraint must be non-decreasing, and the payment satisfies $p(v) = vx(v) - \int_0^v x(z) dz + p_0$ for some constant p_0 . Finally, the utility of the buyer for participating the auction is $u(v; x, p) = v \cdot x(v) - p(v) = \int_0^v x(z) dz - p_0$, and she therefore maximizes utility by participating in the auction if and only if her utility is at least c . \square

Given any allocation rule x and corresponding payment $p(v) = v \cdot x(v) - \int_0^v x(z) dz + p_0$, let $v_x(c) = \inf_{v \geq 0} \{v \cdot x(v) - p(v) \geq c\}$, and

$$x_c(v) = \begin{cases} x(v) & v \geq v_x(c) \\ 0 & v < v_x(c). \end{cases}$$

two-item setting. In this two-item setting, one of the items would correspond to participating and winning while the other would correspond to participating and not winning—the latter having negative value with probability 1 (if the original outside option value is positive)—and the mechanism is constrained to ex-post allocate exactly one item to the buyer. Example 1 shows that price posting in our outside-option setting—which in the transformed two-item setting translates to preventing the item with negative value from being sold—may not maximize revenue. Therefore, in the transformed two-item setting, Example 1 is interpreted as showing that the seller can strictly increase her revenue by introducing a new item with negative value—a good so damaged that its value to the buyer is in fact always negative.

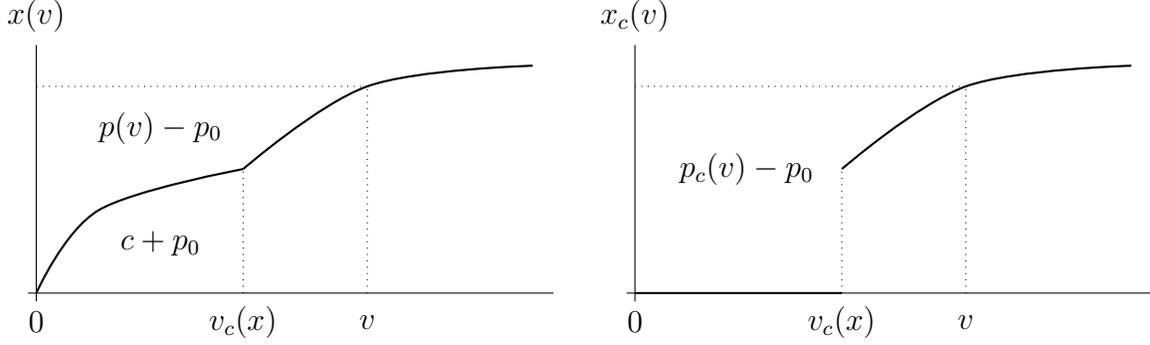

Figure 1: The figure on the left is an illustration of the payment $p(v)$ and the cutoff value $v_x(c)$ where $c - p_0 \geq 0$. The figure on the right illustrates the interim allocation rule $x_c(v)$ when the outside option is c . Here $p_c(v)$ is the incentive compatible payment rule for allocation rule $x_c(v)$. The figure illustrates that $p_c(v) = p(v) + c$ for any $v \geq v_x(c)$.

That is, $v_x(c)$ is the minimum item value at which a buyer with outside option value c will choose to participate in a mechanism with allocation rule x , and $x_c(v)$ is the resulting allocation rule taking the participation decision into account. For any joint distribution \bar{F} , let \bar{F}_c be the conditional item value distribution when the outside option is c . We define the virtual value of the buyer given conditional valuation distribution \bar{F}_c as $\phi_c(v) = v - \frac{1 - \bar{F}_c(v)}{f_c(v)}$.

Lemma 3. *Given any distribution \bar{F} with marginal outside option distribution G , and any mechanism \mathcal{M} with allocation x and payment rule p with parameter p_0 , the revenue of the seller is*

$$\text{Rev}(\bar{F}; \mathcal{M}) = \mathbf{E}_{c \sim G} [\mathbf{E}_{v \sim \bar{F}_c} [x_c(v) \phi_c(v)] - (1 - \bar{F}_c(v_x(c))) \cdot \max\{-p_0, c\}].$$

Proof. For any outside option value c , the buyer with outside option value c participates in the mechanism if and only if $v \geq v_x(c)$. First we consider the case $c + p_0 > 0$, in which case $v_x(c) > 0$. Moreover, the payment of a buyer having any value $v \geq v_x(c)$ is $v \cdot x(v) - \int_0^v x(z) dz + p_0 = v \cdot x_c(v) - \int_0^v x_c(z) dz - c$, and the payment of a buyer having any value $v < v_x(c)$ is 0 since such a buyer does not participate the auction. This is illustrated in Figure 1. Note that by Myerson (1981), we have

$$\mathbf{E}_{v \sim \bar{F}_c} \left[v \cdot x_c(v) - \int_0^v x_c(z) dz \right] = \mathbf{E}_{v \sim \bar{F}_c} [x_c(v) \phi_c(v)]$$

and thus the expected revenue given cost $c \geq -p_0$ is

$$\begin{aligned} & \mathbf{E}_{v \sim \bar{F}_c} \left[v \cdot x_c(v) - \int_0^v x_c(z) dz - c \cdot \mathbf{1}[v \geq v_x(c)] \right] \\ &= \mathbf{E}_{v \sim \bar{F}_c} [x_c(v) \phi_c(v)] - (1 - \bar{F}_c(v_x(c))) \cdot c, \end{aligned}$$

where $\mathbf{1}$ is the indicator function. For the case $c \leq -p_0$, we have $v_x(c) = 0$. Thus the payment of a buyer having any value $v \geq 0$ is $v \cdot x(v) - \int_0^v x(z) dz + p_0 = v \cdot x_c(v) - \int_0^v x_c(z) dz + p_0$, and again by Myerson (1981), the expected revenue given cost c is

$$\mathbf{E}_{v \sim \bar{F}_c} \left[v \cdot x_c(v) - \int_0^v x_c(z) dz + p_0 \right] = \mathbf{E}_{v \sim \bar{F}_c} [x_c(v) \phi_c(v)] + p_0.$$

Taking expectation over $c \sim G$ gives us the desired characterization. \square

In this paper, we focus on the problem of revenue maximization, so it is without loss to consider $p_0 \geq 0$. When outside option values are guaranteed to be non-negative, it is without loss to further assume that $p_0 = 0$.

Lemma 4. *For any mechanism with allocation and payment x, p such that $p(v) = vx(v) - \int_0^v x(z) dz + p_0$ for some constant p_0 , there exists another mechanism with allocation and payment \hat{x}, \hat{p} with weakly higher revenue and $\hat{p}(v) = v\hat{x}(v) - \int_0^v \hat{x}(z) dz + \hat{p}_0$ where $\hat{p}_0 \geq 0$. This can be strengthened to $\hat{p}_0 = 0$ if the outside option values are non-negative.*

Proof. Suppose first that $p_0 < 0$. Given any allocation x and letting $v' = \sup_v \{v \cdot x(v) - \int_0^v x(z) dz \leq p_0\}$, define

$$\hat{x}(v) = \begin{cases} x(v) & v \geq v' \\ x(v') & v < v', \end{cases}$$

$$\hat{p}(v) = v\hat{x}(v) - \int_0^v \hat{x}(z) dz.$$

One can verify that the revenue of the seller is weakly higher with allocation \hat{x} and payment \hat{p} since the types in mechanism with x and p with negative payment will not participate under the new mechanism while the types with positive payment will participate and pay the same amount.

When $p_0 > 0$ and the outside option values are non-negative, given any allocation and payment x, p , we can instead define

$$\hat{x}(v) = \begin{cases} x(v) & v \geq \sup_v \{\int_0^v x(z) dz \leq p_0\} \\ 0 & v < \sup_v \{\int_0^v x(z) dz \leq p_0\}, \end{cases}$$

$$\hat{p}(v) = v\hat{x}(v) - \int_0^v \hat{x}(z) dz.$$

The revenue of the seller is then unchanged if we use the mechanism with allocation \hat{x} and payment \hat{p} , instead of x and p , since all types of the buyer have the same allocation and payment in best response. \square

3.1 Menu Size

By the taxation principal, the optimal mechanism for the single buyer problem is essentially posting a menu of allocations and payments for the buyer to choose from. Let d be the size of the support for the outside option value distribution. Example 1 shows that it can be optimal to offer a menu of at least 2 options to the buyer when $d \geq 2$. In this section, we provide an upper bound, as a function of d , on the number of menu entries required in the optimal mechanism, i.e., on the menu size of the optimal mechanism. The main idea is to reduce the problem to d different revenue maximization problems with public budgets. The proof is deferred to Appendix B.

Theorem 1. *For selling a single item to a single buyer with private outside option, when the size of the support for the outside option value distribution is d , the menu size required for the optimal mechanism is at most $2d + 1$.*

3.2 Sample Complexity

In this section, we consider a setting in which the joint distribution \bar{F} is unknown to the seller, who instead only has access to samples from this distribution, and upper bound the number of samples required to *learn* an up-to- ϵ optimal auction. Note that our sample complexity result applies to correlated distributions as well. The proof is deferred to Appendix B.

Theorem 2. *For selling a single item to a single buyer with private outside option, for any constant $\epsilon > 0$, if the joint distribution \bar{F} is supported on $[0, 1] \times [0, 1]$, there exists an mechanism with access to $O(\epsilon^{-6} \log \epsilon^{-1})$ samples that obtains expected revenue at least $\text{OPT}(\bar{F}) - \epsilon$.⁸*

4 Optimality of Posted Pricing in the Single-Buyer Setting

Recall that as illustrated in Example 1, in general it is not revenue-optimal to post a single take-it-or-leave-it price. Nonetheless, in this section, we show that under natural assumptions on the joint distribution, posting a deterministic take-or-leave-it price is optimal for the seller. We will focus on the case in which the private outside option value is non-negative, and by Lemma 4, we set $p_0 = 0$ and omit it in the notation.

4.1 Independent Outside Options

In this section, we consider the setting where the outside option distribution is independent from the valuation distribution. In this case, we provide two sufficient conditions on the valuation distribution such that posted pricing is optimal for revenue maximization.

4.1.1 DMR Valuation Distribution

We start by analyzing the case in which the valuation distribution has decreasing marginal revenue. We begin with a technical lemma that encapsulates a useful implication of the decreasing marginal revenue property.

Lemma 5. *If the valuation distribution F has decreasing marginal revenue, then for any $c \geq 0$ and any $v \geq c$, we have that $f(v)(\phi(v) - c)$ is monotone non-decreasing in v .*

Proof. If $f'(v) \leq 0$, we have

$$\frac{\partial f(v)(\phi(v) - c)}{\partial v} = \frac{\partial f(v)\phi(v)}{\partial v} - f'(v) \cdot c \geq 0.$$

If $f'(v) > 0$, we have

$$\frac{\partial f(v)(\phi(v) - c)}{\partial v} = \frac{\partial f(v)(v - c) - (1 - F(v))}{\partial v} = f'(v)(v - c) + 2f(v) \geq 0$$

where the inequality holds for $v \geq c$. □

⁸This result is information theoretic as they may not exist polynomial time algorithm for computing the optimal mechanism for discrete distributions.

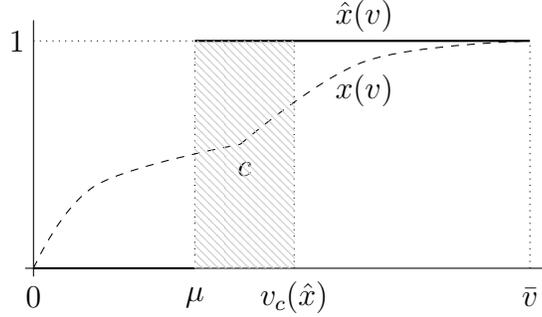

Figure 2: Given any allocation rule $x(v)$ (dashed line), \hat{x} (solid line) is the allocation rule for a posted price mechanism such that $\int_0^{\bar{v}} x(v) dv = \int_0^{\bar{v}} \hat{x}(v) dv$. The area of the shaded region is c .

Theorem 3. *With independent item values and outside option values, and with non-negative outside option values, if the item value distribution F has decreasing marginal revenue and bounded support,⁹ there exists a revenue-maximizing mechanism that is a posted price mechanism.*

Proof. Here we will prove the result for a slightly more general setting, where the outside option values can be correlated with the item values, but the conditional item value distribution \bar{F}_c has identical and bounded support, and has decreasing marginal revenue for any outside option value c .

Denote the item value upper bound by $H < \infty$. For any allocation rule x and associated payment rule p , let $\bar{v} = \sup_{v \leq H} \{x(v) < 1\}$, and $\mu = \int_0^{\bar{v}} (1 - x(z)) dz$. Note that μ is finite since $H < \infty$. Let

$$\hat{x}(v) = \begin{cases} 1 & v \geq \mu \\ 0 & v < \mu. \end{cases} \quad (1)$$

Allocation rule \hat{x} is illustrated in Figure 2. For any outside option value c , it is easy to verify that

$$\hat{x}_c(v) = \begin{cases} 1 & v \geq v_c(\hat{x}) \\ 0 & v < v_c(\hat{x}). \end{cases}$$

where $v_c(\hat{x}) = \bar{v} - \mu + c$. Moreover, $\int_0^H x(z) dz = \int_0^H \hat{x}(z) dz$ and $\int_0^v x(z) dz \geq \int_0^v \hat{x}(z) dz$ for any $v \in [0, H]$. Thus by Lemma 3, for any $c \geq 0$, the revenue of mechanism with allocation x

⁹The boundedness assumption is to avoid a situation in which no mechanism is optimal, i.e., for any mechanism, there exists another mechanism with strictly higher revenue.

given outside option value c is

$$\begin{aligned}
R(x; c) &= \mathbf{E}_{v \sim F}[x_c(v)\phi_c(v)] - (1 - \bar{F}_c(v_x(c))) \cdot c = \int_{v_x(c)}^H \bar{f}_c(v)(x_c(v)\phi_c(v) - c) dv \\
&\leq \int_{v_x(c)}^H \bar{f}_c(v)x_c(v)(\phi_c(v) - c) dv \\
&= \bar{f}_c(v)(\phi_c(v) - c) \int_0^v x_c(z) dz \Big|_{v=v_x(c)}^H - \int_{v_x(c)}^H \int_0^v x_c(z) dz d[\bar{f}_c(v)(\phi_c(v) - c)] \\
&\leq \bar{f}_c(v)(\phi_c(v) - c) \int_0^v \hat{x}_c(z) dz \Big|_{v=v_{\hat{x}}(c)}^H - \int_{v_{\hat{x}}(c)}^H \int_0^v \hat{x}_c(z) dz d[\bar{f}_c(v)(\phi_c(v) - c)] \\
&= \int_{v_{\hat{x}}(c)}^H \bar{f}_c(v)\hat{x}_c(v)(\phi_c(v) - c) dv = \int_{v_{\hat{x}}(c)}^H \bar{f}_c(v)(\hat{x}_c(v)\phi_c(v) - c) dv = R(\hat{x}; c). \quad (2)
\end{aligned}$$

The first inequality holds because $c \geq 0$ and $x_c(v) \in [0, 1]$ for any v . The third and the fourth equalities holds by integration by parts. The fifth equality holds because $\hat{x}_c(v) = 1$ for any $v \geq v_{\hat{x}}(c)$. The second inequality follows from the combination of two observations:

1. $x_c(v) = 0$ for any $v \leq v_x(c)$ and $\hat{x}_c(v) = 0$ for any $v \leq v_{\hat{x}}(c)$. This further implies that $\int_0^{v_x(c)} x_c(z) dz = \int_0^{v_{\hat{x}}(c)} \hat{x}_c(z) dz = 0$. Hence

$$\bar{f}_c(v)(\phi_c(v) - c) \int_0^v x_c(z) dz \Big|_{v=v_x(c)}^H = \bar{f}_c(v)(\phi_c(v) - c) \int_0^v \hat{x}_c(z) dz \Big|_{v=v_{\hat{x}}(c)}^H.$$

2. By the construction of \hat{x} , we have $\int_0^v x(z) dz \geq \int_0^v \hat{x}(z) dz \geq 0$ for any $v \geq 0$, which implies $v_x(c) \leq v_{\hat{x}}(c)$ for any c . Moreover, by Lemma 5, $\bar{f}_c(v)(\phi_c(v) - c)$ is non-decreasing in v for any $v \geq v_{\hat{x}}(c) \geq c$ and $v \leq H$. Hence, we have

$$\begin{aligned}
&\int_{v_x(c)}^H \int_0^v x_c(z) dz d[\bar{f}_c(v)(\phi_c(v) - c)] \\
&\geq \int_{v_{\hat{x}}(c)}^H \int_0^v x_c(z) dz d[\bar{f}_c(v)(\phi_c(v) - c)] \\
&\geq \int_{v_{\hat{x}}(c)}^H \int_0^v \hat{x}_c(z) dz d[\bar{f}_c(v)(\phi_c(v) - c)]
\end{aligned}$$

where the first inequality holds since $v_x(c) \leq v_{\hat{x}}(c)$, $\int_0^v x(z) dz \geq 0$ and $\bar{f}_c(v)(\phi_c(v) - c)$ is non-decreasing in v . The second inequality holds since $\int_0^v x(z) dz \geq \int_0^v \hat{x}(z) dz$ and $\bar{f}_c(v)(\phi_c(v) - c)$ is non-decreasing in v .

Taking expectation over c , Theorem 3 holds. \square

Intuitively, DMR is an assumption stating that the seller can always extract higher revenue (or equivalently increase virtual welfare) by allocating the item to the agent with

higher value instead of lower value when there is no outside option. In Theorem 3, we show that the extra negative impact of the outside option on revenue is decreasing as we reduce the probability of selling the item to a given agent (this is transparent from lemma 3). So by shifting the allocation from lower-value agents to higher-value agents, we simultaneously increase the virtual welfare and decrease the negative impact of outside options (as the agent will participate less often). Shifting the allocation in this way as much as possible ultimately leads to a step function corresponding to posted pricing, which must then be optimal.

Remark. In this section we have focused on the case in which the outside option value is non-negative. In Appendix D, we show that a deterministic mechanism can guarantee at least 50% of the optimal revenue when the outside option value could be positive or negative. Note that, in this context, a deterministic mechanism is equivalent to setting a price p_0 for participating the auction, and an additional price p for winning the item. The presence of the additional participation cost p_0 is intuitive: a negative outside option means that an agent has a strict incentive to participate in the auction regardless of outcome, and p_0 serves to extract a portion of that participation utility as revenue.

4.1.2 MHR Valuation Distribution

We move on to analyzing the case in which the valuation distribution has monotone hazard rate. Note that if the valuation distribution F satisfies monotone hazard rate, the derivative of the virtual value is $\phi'(v) \geq 1$ for all $v \geq 0$, and hence distribution F is regular as well.

Lemma 6 (Devanur and Weinberg, 2017). *If the valuation distribution F is regular, then $f(v)\phi(v)$ is non-decreasing in v for $v \in [0, v^*]$ where $v^* = \inf_v\{\phi(v) \geq 0\}$.*

Theorem 4. *With independent item values and outside option values, and with non-negative outside option values, if the item value distribution F has monotone hazard rate, there exists a revenue optimal mechanism that is a posted price mechanism.*

Proof. For any allocation rule $x(v)$, let $c' = \inf_{c \geq 0}\{\phi(v_x(c)) - c \geq 0\}$ and let $v' = v_x(c')$. We first focus on the case that both c' and v' are finite, i.e., there exists $c \geq 0$ such that $\phi(v_x(c)) - c \geq 0$.¹⁰ For any allocation rule $x(v)$, let

$$\hat{x}(v) = \begin{cases} 1 & v \geq v' \\ x(v) & v < v'. \end{cases}$$

Allocation \hat{x} is illustrated in Figure 3. By Lemma 3, since we set $p_0 = 0$, the expected revenue of any mechanism with allocation rule x from the buyer with outside option value $c \geq 0$ is

$$\mathbf{E}_{v \sim F}[x_c(v)\phi(v)] - (1 - F(v_x(c))) \cdot c = \int_{v_x(c)}^{\infty} f(v)(x_c(v)\phi(v) - c) dv.$$

We separate the discussion into two cases. For any outside option value c such that $v_x(c) \leq v'$, we have $v_x(c) = v_{\hat{x}}(c)$. In this case, since $\phi(v) \geq 0$ for any $v \geq v'$, allocation \hat{x} only

¹⁰Since the item value is independent of the outside option value, the virtual value function is invariant of the outside option of the buyer.

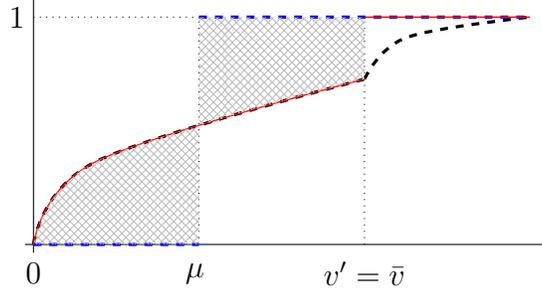

Figure 3: Given any allocation rule $x(v)$ (black dashed line), \hat{x} (red solid line) is the allocation rule that increases the allocation to 1 for value above v' and \hat{x}' (blue dashed line) is the allocation rule that corresponds to posting price μ . The two shaded regions in the figure have the same area.

increases the allocation to types with positive virtual value $\phi(v)$ compared to x , which increases the expected revenue. For any outside option value c such that $v_x(c) > v'$, we have $v_x(c) \geq v_{\hat{x}}(c) > v' \geq 0$. In this case, for any $\tilde{v} \in [v_{\hat{x}}(c), v_x(c)]$, we have

$$\phi(\tilde{v}) - c \geq \phi(v_{\hat{x}}(c)) - c \geq \phi(v') - c' = 0,$$

where the first inequality holds since $\tilde{v} \geq v_{\hat{x}}(c)$. The second inequality holds because $\phi(v) - v$ is non-decreasing in v due to the MHR assumption, and $v_{\hat{x}}(c) \geq v'$. Thus increasing the allocation to 1 for item values between $[v_{\hat{x}}(c), v_x(c)]$ only weakly increases the revenue. Therefore, the mechanism with allocation rule \hat{x} generates weakly higher revenue compared to x .

Let $\bar{v} = \sup_v \{\hat{x}(v) < 1 \text{ and } F(v) < 1\}$ and $\mu = \int_0^{\bar{v}} (1 - x(z)) dz$. We claim that μ is finite. In the case that v' is finite or the maximum value in the support is $H < \infty$, we have that $\bar{v} \leq \min\{v', H\}$ is finite, and hence μ is finite. In the case that v' is infinite and \bar{v} is infinite, let m be the value such that $\phi(m) = 0$.¹¹ Suppose μ is infinite. Then for sufficiently large c , we have

$$\phi(v_x(c)) - c \geq v_x(c) - m - c = c + \int_0^{v_x(c)} (1 - x(z)) dz - m - c > 0$$

where the first inequality holds because $\phi'(v) \geq 1$ since F is MHR, and the equality holds by the definition of $v_x(c)$. The last inequality holds since because μ is infinite, for any m there exist a sufficiently large c such that $\int_0^{v_x(c)} (1 - x(z)) dz > m$. Note that this contradicts to the condition that v' is infinite, and hence μ must be finite. Let

$$\tilde{x}(v) = \begin{cases} 1 & v \geq \mu \\ 0 & v < \mu. \end{cases}$$

This is well defined since μ is finite. Allocation \tilde{x} is illustrated in Figure 3. For any outside option value c such that $v_{\hat{x}}(c) \geq \bar{v}$, we have that $v_{\hat{x}}(c) = v_{\tilde{x}}(c)$ and the revenues are the same for both mechanisms. For any outside option value c such that $v_{\hat{x}}(c) < \bar{v}$, we have that $c < c'$

¹¹For an MHR distribution, the value m with virtual value zero is always finite (Hartline et al., 2008).

since $v_{\tilde{x}}(c') = v_x(c') = v'$ and $\bar{v} \leq v'$. In this case, let $\hat{\phi}$ be the virtual value function such that $\hat{\phi}(v) = \phi(v) - c$ if and only if $\phi(v) - c < 0$, and $\hat{\phi}(v) = 0$ otherwise. By Lemma 6, it is easy to verify that the valuation distribution with virtual function $\hat{\phi}$ has decreasing marginal revenue. we have that

$$\begin{aligned}
R(\hat{x}; c) &= \int_{v_{\hat{x}}(c)}^{\bar{v}} f(v)(\hat{x}_c(v)\phi(v) - c) dv + \int_{\bar{v}}^{\infty} f(v)(\hat{x}_c(v)\phi(v) - c) dv \\
&\leq \int_{v_{\hat{x}}(c)}^{\bar{v}} f(v)\hat{x}_c(v)(\phi(v) - c) dv + \int_{\bar{v}}^{\infty} f(v)(\tilde{x}_c(v)\phi(v) - c) dv \\
&= \int_{v_{\hat{x}}(c)}^{\bar{v}} f(v)\hat{x}_c(v)\hat{\phi}(v) dv + \int_{v_{\hat{x}}(c)}^{\bar{v}} f(v)(\hat{x}_c(v)(\phi(v) - c - \hat{\phi}(v))) dv + \int_{\bar{v}}^{\infty} f(v)(\tilde{x}_c(v)\phi(v) - c) dv \\
&= \int_{v_{\hat{x}}(c)}^{\bar{v}} f(v)\hat{x}_c(v)\hat{\phi}(v) dv + \int_{v_{\hat{x}}(c)}^{\bar{v}} f(v)(\tilde{x}_c(v)(\phi(v) - c - \hat{\phi}(v))) dv + \int_{\bar{v}}^{\infty} f(v)(\tilde{x}_c(v)\phi(v) - c) dv \\
&\leq \int_{v_{\hat{x}}(c)}^{\bar{v}} f(v)\tilde{x}_c(v)\hat{\phi}(v) dv + \int_{v_{\hat{x}}(c)}^{\bar{v}} f(v)(\tilde{x}_c(v)(\phi(v) - c - \hat{\phi}(v))) dv + \int_{\bar{v}}^{\infty} f(v)(\tilde{x}_c(v)\phi(v) - c) dv \\
&= R(\tilde{x}; c).
\end{aligned}$$

The first inequality holds because the allocation $\hat{x}_c(v) \in [0, 1]$ for any v and $\hat{x}_c(v) = \tilde{x}_c(v)$ for any $v \geq \bar{v}$. The third equality holds since $\phi(v) - c - \hat{\phi}(v)$ is non-negative, $v_{\tilde{x}}(c) \geq v_{\hat{x}}(c)$, and $\phi(v) - c - \hat{\phi}(v) = 0$ for any value $v \leq v_{\tilde{x}}(c)$. The last statement holds because under allocation \tilde{x} , we have $c' - c = v_{\tilde{x}}(c') - v_{\tilde{x}}(c)$ and hence $\phi(v) - c \leq \phi(\tilde{x}(c)) - c \leq \phi(v_{\tilde{x}}(c')) - c' = 0$ for any value $v \leq \tilde{x}(c)$ since the valuation distribution is MHR. The second inequality holds by applying Inequality (2) since $\hat{\phi}$ can be viewed as the virtual value function for distribution with decreasing marginal revenue, and the allocation rules are converted through the same format. Taking expectation over c , Theorem 4 holds. \square

Note that there is asymmetry between the conditions we require on the item value distribution and the outside option value distribution to establish optimality of posting a price. We have shown that, for any distribution over outside option values, posting a price is optimal as long as the item value satisfies monotone hazard rate or decreasing marginal revenue. However, even if the outside option value distribution is uniform, posting a fixed take-it-or-leave-it price need not be optimal without further assumptions on the item value distribution. The following example illustrates such a scenario.

Example 2. The item value of the buyer is 1 or 2 with probability $\frac{1}{2}$ each. The outside option value is uniformly distributed in $[0, 1]$. The optimal posted price mechanism is to post a price of 1, generating revenue $\frac{1}{2}$. However, the mechanism that offers the menu of two probability-price lotteries $(1, 1), (\frac{2}{3}, \frac{1}{3})$ has revenue $\frac{5}{9}$. The multiplicative gap between the optimal mechanism and optimal pricing is therefore higher than 1.111.

4.2 Perfectly Correlated Outside Options

In this section, we assume the outside option value is perfectly correlated with the item value. That is, there is a publicly known mapping from each item value v to the unique

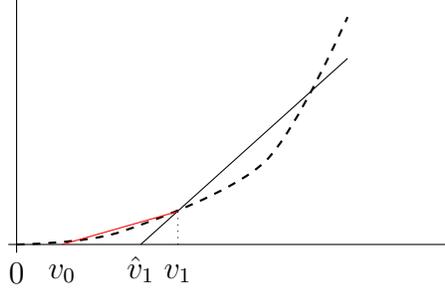

Figure 4: The black solid line is the utility function of the agent given mechanism \mathcal{M} with finite menu and the black dashed curve is the outside option value function c_v . Let v_1 be the minimum value of the agent that participates the auction. The red solid line is the utility function for an agent with value between $[v_0, v_1]$ after adding the additional menu entry $(\hat{x}, \hat{p}) = (\frac{c_{v_1}}{v_1 - v_0}, \frac{v_0 \cdot c_{v_1}}{v_1 - v_0})$ into the mechanism \mathcal{M} . Note that for v_0 that is sufficiently small, part of the red line is strictly above the black dashed curve.

corresponding outside option value c_v , and moreover c_v is monotone increasing in v .¹² Note that even when the outside option value is perfectly correlated with the item value, the optimal mechanism may not be posted pricing. In fact, the menu complexity can be infinite for continuous valuation distributions.

Proposition 1. *For any $H > 0$, if the item value distribution F has continuous and positive density everywhere in the support $[0, H]$, and if the outside option value c_v is a non-negative, increasing, and strictly convex function of v , then the menu complexity of the optimal mechanism is infinite unless the optimal revenue is 0.*

Proof. Suppose by contradiction the optimal mechanism \mathcal{M} has finite menu size. We first show that it is without loss to assume that for any $(x, p) \in \mathcal{M}$, $p > 0$. This holds because if there is some $(x, 0) \in \mathcal{M}$, then removing this entry from mechanism \mathcal{M} weakly increases the expected revenue of the seller.

Let v_1 be the minimum value of any agent that participates in the auction given the outside option value c_{v_1} , and let \hat{v}_1 be the minimum value of any agent that that would have participated in the auction if her outside option value were zero rather than $c_{\hat{v}_1}$. Note that this minimum exists if the optimal revenue is positive, since at least one agent type will participate. Moreover, since any $(x, p) \in \mathcal{M}$ satisfies $p > 0$ and by the finiteness of the menu, we have $v_1 > \hat{v}_1 > 0$. For sufficiently small $v_0 \in (0, \hat{v}_1)$ to be chosen later, let $(\hat{x}, \hat{p}) = (\frac{c_{v_1}}{v_1 - v_0}, \frac{v_0 \cdot c_{v_1}}{v_1 - v_0})$. Note that by the choice of v_0 , $\frac{c_{v_1}}{v_1 - v_0}$ is smaller than the allocation of v_1 , which is at most 1. This can be easily verified from Figure 4. Let $\mathcal{M}' = \mathcal{M} \cup \{(\hat{x}, \hat{p})\}$. The utility functions of mechanisms \mathcal{M} and \mathcal{M}' are illustrated in Figure 4. Note that given mechanism \mathcal{M}' , it is easy to verify that for any value $v \geq v_1$, an agent with value v will make the same choice given mechanisms \mathcal{M} and \mathcal{M}' , and the contribution to the revenue of those agents remains the same. For any agent with value $v < v_1$, given mechanism \mathcal{M} , the agent will not participate in the auction since the utility for participation is strictly below her outside option value. In contrast, given mechanism \mathcal{M}' , since the outside option value

¹²The case in which the outside option value c_v is monotone non-increasing in v is rather trivial since the individual rationality constraint only binds for the lowest type.

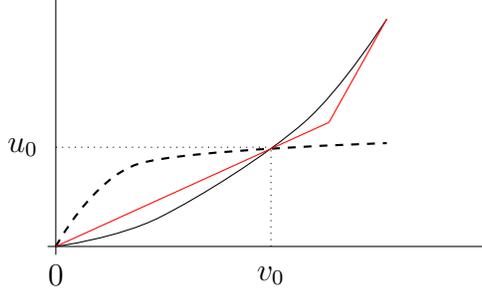

Figure 5: The black (respectively red) solid curve is the utility function of the agent given any mechanism \mathcal{M} (respectively \mathcal{M}'), and the black dashed curve is the outside option value function c_v . All three curves intersect at point (v_0, u_0) .

is strictly convex, for sufficiently small v_0 , there exists $v' \in (v_0, v_1)$ such that for any value $v \in [v', v_1]$, the utility of the agent for menu entry (\hat{x}, \hat{p}) is higher than her outside option value and hence the agent will participate in the auction and pay price $\frac{v_0 \cdot c_{v_1}}{v_1 - v_0}$ to the seller. This is also illustrated in Figure 4. Since the valuation distribution has positive density everywhere in the support, the expected revenue of mechanism \mathcal{M}' is strictly higher than the expected revenue of mechanism \mathcal{M} , a contradiction. \square

In contrast, when the outside option value c_v is concave in v , posted pricing is always revenue maximizing.

Theorem 5. *If the outside option value c_v is a non-negative and concave function of v , then for any item value distribution F , there exists a revenue optimal mechanism that is a posted price mechanism.*

Proof. For any mechanism \mathcal{M} , let v_0 be the minimum value of any agent that participates the auction. Then agents of this type will be indifferent between participating and not participating, and hence have utility $u_0 = c_{v_0}$. Let $x_0 = \frac{u_0}{v_0}$.

Now consider the following alternative revenue maximization problem for a single buyer. This alternative problem will have the same distribution over item values as the original setting, but all outside option values are set equal to 0. Instead of outside option values, we impose three constraints on the class of mechanisms that can be used. First, the seller is constrained to only sell the item to agents with item value above v_0 subject to the incentive constraint. Second, the allocation returned by the mechanism is constrained to be at least x_0 . Third, the utility of an agent with value v_0 is constrained to be exactly u_0 .

What is the revenue-optimal mechanism for this alternative problem? Since there are no outside options, a direct implication of Myerson (1981) is that the revenue optimal mechanism \mathcal{M}' in this alternative setting, subject to the allocation and utility constraints, is a step function. Specifically, since the minimum allocation is at least x_0 , this corresponds to a mechanism with menu size 2, where one of the menu entries is $(x_0, 0)$ and the other is $(1, p)$ with $p \geq v_0 - u_0$. The utility function of mechanism \mathcal{M}' is illustrated in Figure 5 as the red solid line. Note that since mechanism \mathcal{M} is also a feasible mechanism for this alternative revenue maximization problem, we must have $\text{Rev}(\mathcal{M}) \leq \text{Rev}(\mathcal{M}')$ (where revenue is calculated with respect to the new setting).

Now consider any mechanism that is feasible for the new setting. Since the outside option value c_v is concave in v , the utility of an agent participating in the mechanism with item value $v \geq v_0$ is at least $v \cdot x_0 \geq c_v$. Therefore, returning to the original problem formulation with outside options, any agent with item value $v \geq v_0$ (and hence outside option value c_v) will choose to participate in the auction in the original setting. This means that for both \mathcal{M} and \mathcal{M}' (both of which are feasible in the new setting), the revenue remains unchanged when executing the mechanism in the original setting. This implies that in the original setting, $\text{Rev}(\mathcal{M}) \leq \text{Rev}(\mathcal{M}')$. Finally, since the payment for menu entry $(x_0, 0)$ is 0, removing this entry from the mechanism \mathcal{M}' weakly improves the expected revenue. The resulting mechanism is a posted-price mechanism. Hence, if the outside option value c_v is non-negative and concave in v , posted pricing is a revenue optimal mechanism. \square

5 Approximate Optimality of Posted Pricing in the Multi-Buyer Setting

For the multi-buyer setting, as illustrated in Section 2 (and in Appendix A), analyzing the revenue of any mechanism requires characterizing the equilibrium for participating in it, which in general is a hard problem. The following lemma provides a reduction framework for single-item environments that lifts approximation results for posted pricing from a single buyer to multiple buyers, and so avoids the direct analysis of interaction among different buyers.

Lemma 7 (Feng et al., 2020). *For a single-item environment, if there exists $\gamma \geq 1$ such that for each buyer i , for any constraint on the sale probability $q_i \leq 1$, the approximation ratio of (possibly randomized) posted pricing for the single-buyer problem given sale probability constraint q_i is at most γ , then the approximation ratio of sequential posted pricing is at most $\gamma^e/(e-1)$ for the multi-buyer problem.*

Note that when agents have private and exclusive outside options, it is important to specify the timeline for the agents to make participation decisions, as different timeline will affect the equilibrium choice of the agents for participation. In this section, for sequential posted pricing mechanisms, we assume that each agent only needs to make the participation decision after seeing the realized price offered by the seller.

Since Lemma 7 allows us to reduce the analysis to the single-buyer problem with allocation constraints, in the following two Lemmas, we will prove such approximation results for both independent outside option values and perfectly correlated outside option values.

Lemma 8. *In the single-buyer setting with independent and non-negative outside option values, if the item value distribution F has decreasing marginal revenue and bounded support, for any mechanism that sells the item with probability $q \in [0, 1]$, there exists a (possibly randomized) posted price mechanism with weakly higher expected revenue that sells the item with probability at most q .*

Proof. For any mechanism with allocation rule x and sale probability $q \leq 1$, construct the posted price mechanism \hat{x} as in Equation (1). By Theorem 3, the revenue of the mechanism with allocation \hat{x} is weakly higher than x . Next we consider two cases.

If the probability the item is sold given allocation rule \hat{x} is at most q , then \hat{x} is a feasible posted price mechanism with higher revenue, which implies that Lemma 8 holds.

If the probability the item is sold given allocation rule \hat{x} is higher than q , then there exists an allocation rule \tilde{x} that posts (a possibly randomized) price higher than \hat{x} that sells the item with probability q . To prove Lemma 8, it is sufficient to show that the per-unit price (expected payment divided by expected allocation) charged in mechanism with allocation rule \tilde{x} is always higher than x for any type of the buyer, since mechanism with allocation rule \tilde{x} sells the item with probability exactly q , while mechanism with allocation rule x sells the item with probability at most q .

Note that by the definition of allocation rule \tilde{x} , the per-unit price charged under allocation rule \tilde{x} is always higher than \hat{x} , where the latter equals $\int_0^{\bar{v}} (1 - x(z)) dz$. For allocation rule x , if a type with value $v \leq \bar{v}$ participates the auction, the per-unit price for this type is

$$\frac{vx(v) - \int_0^v x(z) dz}{x(v)} \leq v - \int_0^v x(z) dz \leq \int_0^{\bar{v}} (1 - x(z)) dz.$$

Finally, for a type with value $v > \bar{v}$ participating the auction, the per-unit price for this type equals that for a type with value \bar{v} , which is also upper bounded by $\int_0^{\bar{v}} (1 - x(z)) dz$. \square

Lemma 9. *In the single-buyer setting with the outside option value being a non-negative and concave function of v , for any mechanism that sells the item with probability $q \in [0, 1]$, there exists a (possibly randomized) posted price mechanism with at least half of the expected revenue that sells the item with probability at most q .*

Proof. We first show that given any sale probability constraint q , the ex ante optimal mechanism has menu complexity of 3. Similar to the proof of Theorem 5, for any ex ante feasible mechanism \mathcal{M} , let v_0 be the minimum value of the agent that participates the auction with utility u_0 , and let $x_0 = \frac{u_0}{v_0}$. Consider the following revenue maximization problem without concerns for outside options. The seller can only sell the item to agents with value above v_0 subject to the incentive constraint and the sale probability constraint q . In addition, the minimum allocation of the agent is x_0 , and the utility of the agents with value v_0 is u_0 . It is easy to verify that by Alaei et al. (2013), the revenue optimal mechanism \mathcal{M}' in this setting has at most two steps. Since the minimum allocation is at least x_0 , this corresponds to a mechanism with menu size 3. Moreover, one of the menu entries is $(x_0, 0)$. Note that this menu entry does not contribute to the expected revenue. Again similar to the proof of Theorem 5, both \mathcal{M} and \mathcal{M}' have the same revenue across the two settings, and hence in the original setting, $\text{Rev}(\mathcal{M}) \leq \text{Rev}(\mathcal{M}')$.

Now we focus our attention on the original setting. In mechanism \mathcal{M}' , for any menu entry (x, p) with $p > 0$, let q_x be the probability the agent chooses this menu entry in the ex ante optimal mechanism. By definition we have $q_x < q$. Thus by posting price p to the agent, with probability $q_p \geq q_x$, the agent will accept the price and the expected revenue is at least $p \cdot q_p \geq p \cdot q_x$. If $q_p \leq q$, then posting price p is feasible and generates higher revenue than the contribution of the menu entry (x, p) in the ex ante optimal mechanism. If $q_p > q$, there exists a higher price $\hat{p} \geq p$ such that the item is sold with probability exactly q . In this case, the revenue from posting price \hat{p} is $\hat{p}q \geq pq \geq p \cdot q_x$. Therefore, by posting the optimal price such that the item is sold with probability at most q , the revenue is a 2-approximation to the ex ante optimal. \square

Combining Lemma 7 with Lemmas 8 and 9, we have the following approximation result.

Theorem 6. *In the multi-buyer setting, if for each buyer both the outside option value is non-negative and either of the following holds:*

- *the outside option value is independent of the item value, and the item value distribution F has decreasing marginal revenue and bounded support; or*
- *the outside option value is a concave function of the item value;*

then there is a sequential posted pricing mechanism that generates at least a $\frac{1}{2}(1-1/e)$ fraction of the optimal revenue. If the former condition holds for each buyer, then the guaranteed fraction of the optimal revenue is $1 - 1/e$.

6 Conclusions and Open Questions

In this paper we characterize the optimal mechanisms when buyers have private outside options, and provide sufficient conditions on the item value distributions or the outside option value distributions such that posted pricing is optimal or approximately optimal. Following our work, there are a lot of interesting questions that remain open even in the single-buyer setting, including:

1. For the single-item setting with independent item values and non-negative outside option values, is posted pricing a constant approximation to the optimal revenue without additional assumptions?
2. For the single-item setting, can the optimal mechanism be computed in time polynomial in the size of the support?
3. For multi-item settings (e.g., unit-demand valuations) with non-negative outside option values, do there exist simple mechanisms (e.g., item pricing) that generate a constant fraction of the optimal revenue, under assumption such as DMR or MHR on the item value distributions?

A A Generalized Revelation Principle

For the private outside option setting, let W be the general message space and let $\mathcal{M} : W \rightarrow \mathbb{R}^{2n}$ be any mechanism that maps the messages to the profile of allocation and payments. Let $\hat{\mathbb{R}} \equiv \mathbb{R}^2 \cup \{\emptyset\}$ be the augmented outcome space, where \emptyset represents not participating the auction and choosing the outside option. Hence the utility of buyer i for outcome \emptyset is c_i . Similar to the argument in Myerson (1981), any mechanism $\mathcal{M} : W \rightarrow \mathbb{R}^{2n}$ can be transformed into the revelation mechanism $\widehat{\mathcal{M}} : \mathbb{R}^{2n} \rightarrow \hat{\mathbb{R}}^n$ where all buyers participate the auction. Moreover, for any buyer i and any (v_i, c_i) , if there exists (v_{-i}, c_{-i}) such that $\widehat{\mathcal{M}}((v_i, v_{-i}), (c_i, c_{-i})) = \emptyset$, then $\widehat{\mathcal{M}}((v_i, v'_{-i}), (c_i, c'_{-i})) = \emptyset$ for all (v'_{-i}, c'_{-i}) . Note that since the buyers' utility conditional on participation is invariant of the outside option, for any buyer i with value v_i , for any pair of outside option (c_i, c'_i) such that $\widehat{\mathcal{M}}((v_i, v_{-i}), (c_i, c_{-i})) \neq \emptyset$ and

$\widehat{\mathcal{M}}((v_i, v_{-i}), (c'_i, c_{-i})) \neq \emptyset$ for some (v_{-i}, c_{-i}) , we have $\mathbf{E}_{v_{-i}, c_{-i}} \left[u_i(\widehat{\mathcal{M}}((v_i, v_{-i}), (c_i, c_{-i}))) \right] = \mathbf{E}_{v_{-i}, c_{-i}} \left[u_i(\widehat{\mathcal{M}}((v_i, v_{-i}), (c'_i, c_{-i}))) \right]$.

Finally, it is sufficient to show that this mechanism can be implemented as an opt-out-or-revelation mechanism in our setting. For all buyer i , let \bar{F}'_i be the distribution over (v_i, c_i) conditional on $\widehat{\mathcal{M}}((v_i, v_{-i}), (c_i, c_{-i})) = \emptyset$ for some (equivalently all) (v_{-i}, c_{-i}) . Moreover, let $G_i(v_i)$ be the distribution over outside options c_i conditional on value v_i and $\widehat{\mathcal{M}}((v_i, v_{-i}), (c_i, c_{-i})) \neq \emptyset$ for some (equivalently all) (v_{-i}, c_{-i}) . Recall that $\bar{\mathbb{R}} \equiv \mathbb{R} \cup \{\psi\}$ is the augmented report space where ψ represents not participating the auction. Let $\widehat{\mathcal{M}}' : \bar{\mathbb{R}}^n \rightarrow \mathbb{R}^{2n}$ be the opt-out-or-revelation mechanism that maps the reported valuations to the profile of allocations and payments constructed as follows. For any buyer i not participating the auction, or equivalently reporting ψ , the allocation and payment for buyer i is zero. Moreover, when buyer i reports ψ , mechanism $\widehat{\mathcal{M}}'$ resamples (v_i, c_i) according to distribution \bar{F}'_i , and when buyer i reports v_i , mechanism $\widehat{\mathcal{M}}'$ resamples c_i according to distribution $G_i(v_i)$. Then mechanism $\widehat{\mathcal{M}}'$ runs $\widehat{\mathcal{M}}$ on the generated type profile of all n buyers. It is easy to verify that for the mechanism $\widehat{\mathcal{M}}'$, there exists an equilibrium where each buyer participates (i.e., does not play ψ) in $\widehat{\mathcal{M}}'$ and reports truthfully on her valuation if and only if her outcome is not \emptyset in $\widehat{\mathcal{M}}$. Moreover, under mechanism $\widehat{\mathcal{M}}'$, this equilibrium generates the same distribution over outcomes for all buyers as the truthful equilibrium of $\widehat{\mathcal{M}}$, and therefore in the revenue-maximizing equilibrium in \mathcal{M} .

B Missing Proof for Menu Complexity and Sample Complexity

Theorem 1. *For selling a single item to a single buyer with private outside option, when the size of the support for the outside option value distribution is d , the menu size required for the optimal mechanism is at most $2d + 1$.*

Proof. Suppose the support of the outside option value distribution is $\{c_1, \dots, c_d\}$ where $c_j < c_{j+1}$ for any $1 \leq j \leq d-1$. By Lemma 2, it is without loss to consider a single allocation rule and a corresponding incentive compatible payment rule and let the buyer decide whether to participate or not and, contingent on participation, choose her desired allocation and price. Suppose x^* is the optimal allocation function and $p^*(v) = vx^*(v) - \int_0^v x^*(z) dz + p_0^*$ is the corresponding payment. Recall that $v_{x^*}(c)$ is the threshold value at which a buyer with outside option value c will participate in the mechanism with allocation rule x^* . Define $c_0 \equiv -p_0^*$ and $v_{x^*}(c_0) \equiv 0$. Note that for any allocation x satisfying

$$\int_{v_{x^*}(c_j)}^{v_{x^*}(c_{j+1})} x(z) dz = \int_{v_{x^*}(c_j)}^{v_{x^*}(c_{j+1})} x^*(z) dz \quad (3)$$

for all $j \in \{0, \dots, d-1\}$, the cutoff value for the buyer to participate the auction $v_{x^*}(c_j)$ is not affected for any $j \in \{1, \dots, d\}$. Thus it is sufficient to consider the optimization problem between $v_{x^*}(c_j)$ and $v_{x^*}(c_{j+1})$ respectively for any $j \in \{0, \dots, d-1\}$. Note that the allocation x must be non-decreasing between $v_{x^*}(c_j)$ and $v_{x^*}(c_{j+1})$, and satisfy the integration

constraint in Equation (3). Thus the revenue maximization problem is reduced to maximizing the expected virtual value $x_c(v)\phi_c(v)$ for values between $v_{x^*}(c_j)$ and $v_{x^*}(c_{j+1})$, subject to the integration constraint for the allocation rule. This is equivalent to solving a revenue maximization problem subject to a public budget constraint, which only requires at most a menu size of 2 for the optimal mechanism (Devanur and Weinberg, 2017). Thus we need at most $2d$ menu entries for optimizing the allocation below the cutoff $v_{x^*}(c_d)$. Note that for optimizing the allocation above the cutoff $v_{x^*}(c_d)$, the integration constraint is not required, and a single menu entry is sufficient for the revenue maximization problem for linear buyers. Thus in total the menu size required is at most $2d + 1$. \square

Before the proof for the sample complexity result, first we show that the optimal revenue is robust to small perturbation in the type space or the probability space.

Lemma 10. *Let (Ω, \mathcal{F}, P) be any probability measure, and let $t_1, t_2 : \Omega \rightarrow \mathbb{R}^2$ be two 2-dimensional random variables. If $\sup_{\omega \in \Omega} \|t_1(\omega) - t_2(\omega)\|_\infty \leq \epsilon$, then $|\text{OPT}(t_1) - \text{OPT}(t_2)| \leq 3\epsilon$, where $\text{OPT}(t_k)$ is the optimal expected revenue when the valuation and outside option follow the same distribution as the random variable t_k .*

Proof. Due to the symmetry between t_1 and t_2 , it is sufficient to show that $\text{OPT}(t_1) - \text{OPT}(t_2) \leq 3\epsilon$. For simplicity, we write $t_k(\omega)$ for the pair $(v_k(\omega), c_k(\omega))$. Note that by Lemma 2, it is sufficient to assume $x(v), p(v)$ are the optimal allocation and payment function with parameter p_0 . Let $\hat{x}(v) = x(v + \epsilon)$ and $\hat{p}(v) = v\hat{x}(v) - \int_0^v \hat{x}(z) dz - 2\epsilon + p_0$. Next we show that $\text{Rev}(t_2; \hat{x}, \hat{p}) \geq \text{OPT}(t_1) - 3\epsilon$. Since \hat{x} is non-decreasing, \hat{x} and \hat{p} are incentive compatible for the buyer without outside option, and the buyer will truthfully reveal her valuation to the mechanism if the utility for participation is at least her outside option. Note that

$$\begin{aligned} \hat{p}(v) &= v\hat{x}(v) - \int_0^v \hat{x}(z) dz - 2\epsilon + p_0 = vx(v + \epsilon) - \int_0^v x(z + \epsilon) dz - 2\epsilon + p_0 \\ &= vx(v + \epsilon) - \int_\epsilon^{v+\epsilon} x(z) dz - 2\epsilon + p_0 \geq vx(v + \epsilon) - \int_0^{v+\epsilon} x(z) dz - 3\epsilon + p_0 \\ &= p(v + \epsilon) - 3\epsilon. \end{aligned}$$

The above inequality holds since $x(z) \leq 1$ for any z . Moreover, we have

$$\begin{aligned} u(v; \hat{x}, \hat{p}) &= \int_0^v \hat{x}(z) dz + 2\epsilon + p_0 = \int_0^v x(z + \epsilon) dz + 2\epsilon + p_0 \\ &\geq \int_0^{v+\epsilon} x(z) dz + \epsilon + p_0 = u(v + \epsilon; x, p) + \epsilon \end{aligned}$$

where the inequality holds again because $x(z) \leq 1$ for any z . Finally, combining the inequalities, we have

$$\begin{aligned} \text{Rev}(t_2; \hat{x}, \hat{p}) &= \int_\Omega \hat{p}(v_2(\omega)) \cdot \mathbf{1}[u(v_2(\omega); \hat{x}, \hat{p}) \geq c_2(\omega)] dP(\omega) \\ &\geq \int_\Omega (p(v_2(\omega) + \epsilon) - 3\epsilon) \cdot \mathbf{1}[u(v_2(\omega) + \epsilon; x, p) + \epsilon \geq c_2(\omega)] dP(\omega) \\ &\geq \int_\Omega (p(v_1(\omega)) - 3\epsilon) \cdot \mathbf{1}[u(v_1(\omega); x, p) \geq c_1(\omega)] dP(\omega) \geq \text{OPT}(t_1) - 3\epsilon. \end{aligned}$$

The first inequality holds by combining the above inequalities, and the second inequality holds since $\|t_1(\omega) - t_2(\omega)\|_\infty \leq \epsilon$ and both p and u are monotone in v . \square

Lemma 11. *Let $T \subseteq [0, 1] \times [0, 1]$ be a set with finite size, and let \bar{F}_1, \bar{F}_2 be two distributions supported on T . If $\max_{t \in T} \|\bar{F}_1(t) - \bar{F}_2(t)\|_\infty \leq \epsilon$, then $|\text{Rev}(\bar{F}_1; \mathcal{M}) - \text{Rev}(\bar{F}_2; \mathcal{M})| \leq |T| \cdot \epsilon$ for any mechanism \mathcal{M} with non-negative payment.*

Proof. Again it is sufficient to show that $\text{Rev}(\bar{F}_1; \mathcal{M}) - \text{Rev}(\bar{F}_2; \mathcal{M}) \leq |T| \cdot \epsilon$, and the case for $\text{Rev}(\bar{F}_1; \mathcal{M}) - \text{Rev}(\bar{F}_1; \mathcal{M}) \leq |T| \cdot \epsilon$ holds symmetrically. Note that

$$\text{Rev}(\bar{F}_1; \mathcal{M}) - \text{Rev}(\bar{F}_2; \mathcal{M}) = \sum_{t \in T} \text{Rev}(t; \mathcal{M})(\bar{F}_1(t) - \bar{F}_2(t)) \leq |T| \cdot \epsilon$$

since $\text{Rev}(t; \mathcal{M}) \leq 1$ for any $t \in T$. Hence Lemma 11 holds. \square

Theorem 2. *For selling a single item to a single buyer with private outside option, for any constant $\epsilon > 0$, if the joint distribution \bar{F} is supported on $[0, 1] \times [0, 1]$, there exists an mechanism with access to $O(\epsilon^{-6} \log \epsilon^{-1})$ samples that obtains expected revenue at least $\text{OPT}(\bar{F}) - \epsilon$.¹³*

Proof. For any joint distribution \bar{F} , we construct the discrete distribution \bar{F}' supported on the grid with increment $\frac{\epsilon}{6}$ in support $[0, 1] \times [0, 1]$ by rounding down the value and rounding up the outside option to the discretized points. By Lemma 10, we have $\text{OPT}(\bar{F}') \geq \text{OPT}(\bar{F}) - \frac{\epsilon}{2}$.

Note that the size of the support of distribution \bar{F}' is $36\epsilon^{-2}$. We construct the distribution \bar{F}'' by rounding down the value and rounding up the outside option to the multiples of $\frac{\epsilon}{6}$ for any sample $t \sim \bar{F}$. Note that it is easy to verify that \bar{F}'' is the empirical distribution for \bar{F}' . Moreover, for any t in the support of distribution \bar{F}' , by Hoeffding's inequality (Lemma 12), with $O(\epsilon^{-6} \log \epsilon^{-1})$ samples, $|\bar{F}'(t) - \bar{F}''(t)| \leq \frac{\epsilon^3}{288}$ with probability at least $1 - \frac{\epsilon^3}{288}$. By union bounds, with probability at least $1 - \frac{\epsilon}{8}$ we have that $|\bar{F}'(t) - \bar{F}''(t)| \leq \frac{\epsilon^3}{288}$ for all t in the support of distribution \bar{F}' . Let \mathcal{M} be the optimal mechanism for empirical distribution \bar{F}'' and let \mathcal{M}' be the optimal mechanism for distribution \bar{F} . By Lemma 4, both \mathcal{M} and \mathcal{M}' have non-negative payment, and

$$\begin{aligned} \text{Rev}(\bar{F}; \mathcal{M}) &\geq \text{Rev}(\bar{F}'; \mathcal{M}) \geq (1 - \frac{\epsilon}{8})(\text{Rev}(\bar{F}''; \mathcal{M}) - \frac{\epsilon}{8}) \\ &\geq \text{OPT}(\bar{F}'') - \frac{\epsilon}{4} \geq \text{Rev}(\bar{F}''; \mathcal{M}') - \frac{\epsilon}{4} \\ &\geq (1 - \frac{\epsilon}{8})(\text{Rev}(\bar{F}''; \mathcal{M}) - \frac{\epsilon}{8}) - \frac{\epsilon}{4} \geq \text{OPT}(\bar{F}') - \frac{\epsilon}{2} \geq \text{OPT}(\bar{F}) - \epsilon. \end{aligned}$$

The first inequality holds since decreasing the item value and increasing the outside option value weakly decreases the expected revenue of the mechanism. The second and the fifth inequalities hold by applying Lemma 11 and the observation that with probability at least $1 - \frac{\epsilon}{8}$, we have that $|\bar{F}'(t) - \bar{F}''(t)| \leq \frac{\epsilon^3}{288}$ for all t in the support of distribution \bar{F}' . \square

¹³This result is information theoretic as they may not exist polynomial time algorithm for computing the optimal mechanism for discrete distributions.

C Non-exclusive Outside Option

In this paper we have focused on a setting in which a buyer forfeits her right to choose her outside option the moment she participates in the mechanism. In this section we briefly discuss the case in which the buyer can also choose the outside option even if she is not awarded the item by the mechanism, and show that this is equivalent to the setting with fixed outside option value 0. For a buyer with item value v and outside option value c , the utility of the buyer for allocation x and payment p is

$$\begin{aligned} u(x, p) &= x \cdot \max\{v, c\} + (1 - x)c - p \\ &= x \cdot \max\{v - c, 0\} - p + c. \end{aligned}$$

Note that it is easy to verify that a buyer with item value v and outside option value c behaves in a strategically equivalent way to a buyer with item value $\max\{v - c, 0\}$ and outside option value 0. Thus the optimal mechanism for this setting is to run Myerson's mechanism for buyers with a transformed item valuation and fixed public outside option.

Note that for the single-buyer setting, the optimal mechanism is to post a price when the outside option is not exclusive. As illustrated in Example 1, the optimal revenue can be strictly higher when the outside option is exclusive. An implication of this observation is that the seller may strictly prefer excluding the buyer's ability to choose the outside option. Intuitively, in our exclusive model, the seller can better price discriminate the buyers to get higher revenue.

D Negative Outside Option Value

In this section, we show that posted pricing is approximately optimal when the outside option can take negative value with positive probability. Note that in this case, by Lemma 4, the parameter in the payment function satisfies $p_0 \geq 0$.

Proposition 2. *For the single-buyer setting, if the conditional item value distribution \bar{F}_c has identical and bounded support, and has decreasing marginal revenue for any outside option c , there exists a deterministic mechanism with at least half of the optimal revenue.*

Proof. Let $H < \infty$ be the maximum value of the buyer. For any allocation rule x and associated payment rule with parameter $p_0 \geq 0$, let q be the probability the agent participates in the auction given allocation and payment x and p . Let $\bar{v} = \sup_{v \leq H} \{x(v) < 1\}$, $\mu = \int_0^{\bar{v}} (1 - x(z)) dz$, and let

$$\hat{x}(v) = \begin{cases} 1 & v \geq \mu \\ 0 & v < \mu. \end{cases}$$

For any outside option value c , it is easy to verify that

$$\hat{x}_c(v) = \begin{cases} 1 & v \geq \max\{v_c(\hat{x}), \mu\} \\ 0 & v < \max\{v_c(\hat{x}), \mu\}, \end{cases}$$

where $v_c(\hat{x}) = 0$ if $c \leq -p_0$ and $v_c(\hat{x}) = \bar{v} - \mu + c + p_0$ if $c > -p_0$. Moreover, $\int_0^H x(z) dz = \int_0^H \hat{x}(z) dz$ and $\int_0^v x(z) dz \geq \int_0^v \hat{x}(z) dz$ for any $v \geq 0$. By Inequality (2), for any $c \geq 0$, we have $R(x, p_0; c) \leq R(\hat{x}, p_0; c)$. Next we consider the case that $c < 0$. For the case that $-p_0 < c < 0$, the revenue of mechanism with parameter p_0 is

$$\begin{aligned} R(x, p_0; c) &= \int_{v_x(c)}^H \bar{f}_c(v) x_c(v) \phi_c(v) dv - (1 - \bar{F}_c(v_x(c))) \cdot c \\ &\leq \int_{v_{\hat{x}}(c)}^H \bar{f}_c(v) \hat{x}_c(v) \phi_c(v) dv - (1 - \bar{F}_c(v_x(c))) \cdot c \\ &\leq \int_{v_{\hat{x}}(c)}^H \bar{f}_c(v) \hat{x}_c(v) (\phi_c(v) - c) dv - (1 - \bar{F}_c(v_x(c))) \cdot c \\ &= R(\hat{x}, p_0; c) - (1 - \bar{F}_c(v_x(c))) \cdot c. \end{aligned}$$

The first inequality holds by applying Inequality (2), and the second inequality holds since $c < 0$. Finally we consider the case $c \leq -p_0$. Here the buyer will always participate the auction for all item values, $v_x(c) = v_{\hat{x}}(c) = 0$, and

$$\begin{aligned} R(x, p_0; c) &= \int_0^H \bar{f}_c(v) x_c(v) \phi_c(v) dv + p_0 \\ &\leq \int_0^H \bar{f}_c(v) \hat{x}_c(v) \phi_c(v) dv + p_0 = R(\hat{x}, p_0; c), \end{aligned}$$

and the inequality holds again by applying Inequality (2). Combining three cases and taking expectation over c , we have

$$\begin{aligned} R(x, p_0) &= \mathbf{E}_{c \sim G}[R(x, p_0; c)] \\ &\leq \mathbf{E}_{c \sim G}[R(\hat{x}, p_0; c)] - \mathbf{E}_{c \sim G}[(1 - \bar{F}_c(v_x(c))) \cdot c \cdot \mathbf{1}[-p_0 < c < 0]] \\ &\leq R(\hat{x}, p_0) + \mathbf{E}_{c \sim G}[(1 - \bar{F}_c(v_x(c))) \cdot p_0]. \end{aligned}$$

Note that the term of $\mathbf{E}_{c \sim G}[(1 - \bar{F}_c(v_x(c))) \cdot p_0] = p_0 \cdot q$. Moreover, there exists a mechanism that charges price p_0 for the item, and buyer participates in it with probability at least q . The revenue of this posted price mechanism is at least $p_0 \cdot q$. Thus the revenue of allocation x with with parameter $p_0 \geq 0$ is upper bounded by twice of the optimal revenue of posted pricing. \square

E Hoeffding's inequality

Lemma 12 (Hoeffding's inequality). *For any Bernoulli random variable with probability p for value 1, let $H(n)$ be the number of 1 values given n trials. For any $\epsilon > 0$, we have*

$$\Pr \left[\left| \frac{1}{n} H(n) - p \right| \geq \epsilon \right] \leq 2 \exp(-2\epsilon^2 n).$$
