

Selling Data to an Agent with Endogenous Information*

Yingkai Li[†]

Abstract

We consider the model of the data broker selling information to a single agent to maximize his revenue. The agent has private valuation for the additional information, and upon receiving the signal from the data broker, the agent can conduct her own experiment to refine her posterior belief on the states with additional costs. In this paper, we show that in the optimal mechanism, there is no distortion at the top and the agent has no incentive to acquire any additional costly information under equilibrium. Still, the ability to acquire additional information distorts the incentives of the agent, and reduces the optimal revenue of the data broker. Finally, we show that posting a deterministic price on fully revealing the states is optimal when the prior distribution is sufficiently informative.

1 Introduction

Information can help the decision makers refine their knowledge and make better decisions when there are uncertainty over the environments. The desire for additional information creates opportunities for the data broker to collect payments from the decision makers. There is a large market for selling information such as selling consumer data (e.g., Acxiom and Datalogix), user profiles (e.g., Facebook), credit reports (e.g., Experian, TransUnion), or cookies for web usage (c.f., Bergemann and Bonatti, 2015). Those data brokers extract huge revenue from providing valuable information to the decision makers.

In this paper, we consider the problem of maximizing the revenue of the data broker. There is an unknown state and both the data broker and the agent have a common prior over the set of possible states. The data broker can offer a menu of information structures for revealing the state with associated prices to the agent, the agent picks the expected utility maximization entry from the menu, and pays the corresponding price to the data broker. The agent has a private valuation for the information and can acquire addition costly information upon receiving the signal from the data broker. For example, in our model, the agent can be a decision maker who chooses an action to maximize her expected utility based on her posterior belief over the states, and the optimal action is not affected by her private type.¹ After receiving the signal from the data broker, the agent can refine her posterior with additional costs before making the action. Another example captured in our model is

¹See Example 1 for a detailed discussion of the example.

where the agent can be a firm that sells products to consumers, and the information the data broker provides is a market segmentation of the consumers. The firm has a private and convex cost for producing different level of qualities of the product, and the firm can conduct his own experiments with additional costs to further segment the market after receiving the information from the data broker.² In addition, we allow the firm to repeat the market research until it is not beneficial to do so, i.e., when the cost of information exceeds the marginal benefits of information. This captures the situation that the firm can decide the date for announcing the product to the market, and before the announcement, the firm sends out surveys to potential consumers each day to learn the segmentation of the markets. At the end of each day, the firm receives an informative signal through the survey, and decides whether to continue the survey in next day, or stop the survey and announce the product with corresponding market prices to the public.

We assume that the valuation of the agent as a function of the posterior distribution is separable, i.e., the value of the agent for any posterior distribution is simply the product of the private type of the agent, and the value of the posterior distribution. In the paragraph above, both the decision maker who chooses an optimal action based on the posterior belief and the firm that sells products to consumers satisfy the separable condition for their valuation function. Essentially, the separable condition assumes that the private type of the agent represents her value for information. It excludes the situation where the private type of the agent represents a private signal for the states (e.g., Bergemann et al., 2018).

We show that with separable valuations, the revenue of any mechanism is determined by the information structure chosen by each type of the agent, and the closed form formula can be derived through the envelope theorem. Then we show that the optimal mechanism has no distortion at the top, i.e., it reveals full information to the agent when the private value of the agent is sufficiently high. Moreover, in the optimal mechanism, when the agent receives the signal from the data broker, she does not have incentive to acquire any additional information with positive cost. Note that this does not imply the equivalence to the setting where the agent cannot acquire additional information. In the latter case, we show that the optimal mechanism is a simple posted pricing mechanism for revealing full information. Moreover, in the optimal mechanisms, the revenue of the data broker weakly decreases and the social welfare weakly increases when the agent has the option to acquire additional information. This implies that the expected utility of the agent weakly increases under equilibrium. Finally, we show that when the prior distribution over the state is sufficiently informative, the optimal mechanism is posted pricing even when the agent can choose endogenous information.

The paper is organized as follows. In Section 2, we formally introduce the model and the assumptions considered in this paper. We provide the characterizations of the optimal mechanisms and discuss the corresponding implications in Section 3. We apply our results to a model of matching utilities in Section 4 and conclude our paper in Section 5.

²Yang (2020) studies a similar model, where the firm cannot conduct his own market research to refine his knowledge. Moreover, the cost function of the firm is linear in Yang (2020), which leads to a qualitatively different result compared to our model. See Section 3.1 for a detailed discussion.

1.1 Related Work

There is a large literature on selling information to agents with uncertainty over the states. Admati and Pfleiderer (1986, 1990) considers selling information to traders competing for a common value asset and they show that the optimal mechanisms provide noisy signals to the agents. Bergemann et al. (2018) study the model of selling information to a single decision maker trying to match the action to the unknown state, and they characterize the optimal mechanisms in the binary states setting. The main difference in their model compared to our setting is that the private information of the agent is her private signal of the states. In contrast, we assume the agent has private valuation for the information, and chooses additional information endogenously. Chen et al. (2020) considers selling information to a decision maker who faces a budget constraint, Yang (2020) considers the setting of selling information to a firm that used the information to price discriminate the consumers, and Smolin (2020) characterizes the optimal mechanism for disclosing the information on multi-dimensional attributes to maximize the revenue. In those papers, the private information of the agent is her willingness to pay, and the agent cannot acquire any additional information on the states. Babaioff et al. (2012) considers the model of selling information in through multiple stages of communication. They show that when the buyer does not have any commitment power, revelation principle fails and one stage communication may not be sufficient to guarantee the optimal revenue. In this paper, we assume full commitment power, and we will not go into the details of multiple stages of communication.

The model in this paper contributes to the broader domain of information design and Bayesian persuasion (e.g., Rayo and Segal, 2010; Kamenica and Gentzkow, 2011), particularly the disclosure of information in auctions. Eső and Szentes (2007) and Li and Shi (2017) consider the setting of selling information to the buyer before the auction to maximize the revenue, and Wei and Green (2020) consider the variant where the buyer can walk away without paying the seller after receiving the information. Bergemann and Bonatti (2015) models the problem of a data provider who sells cookies to match the firms with customers, and Bergemann et al. (2015) explores the set of possible outcomes can be implemented by in a monopoly model by providing the segmentations of the customers. Bergemann et al. (2017) and Bobkova (2020) consider the implications of information in given auctions such as the first price auction. See the survey of Bergemann and Bonatti (2019) for a throughout discussion on the information in markets.

Our paper is also relevant to the literature of mechanism design and information design with endogenous valuation and information. Pei (2015), Gentzkow and Kamenica (2017), Bloedel and Segal (2018) and Wei (2020) consider the optimal persuasion problem with endogenously chosen information. Yang (2015) considers the coordination problem where agents may ignore several aspects about the states due to their inattentive behavior. Gershkov et al. (2020) study the revenue maximization problem when the agent can make costly investment to boost their values before the auction starts, and Akbarpour et al. (2020) consider the same model for the objective of approximating the expected welfare. Shi (2012) characterizes the optimal auction when the agents can gather information about the valuation before the auction, and Mensch (2019) considers the model of selling an item to an inattentive agent, where the information acquisition is fully flexible. In the last two papers, the agents have no private information in ex ante, the mechanism offered by the seller affects

the agents' decision to learn the valuation, and the agents make the decision before interacting with the seller. In comparison, in our model the agent has private information in ex ante, and she can acquire additional information after receiving the signal from the seller.

2 Model

There is a single agent making decisions facing uncertainty over the state space Ω . Let D be the prior distribution over the states. The agent has private type $\theta \in \Theta = [\underline{\theta}, \bar{\theta}] \subseteq \mathbb{R}$, and her expected utility given posterior belief $\mu \in \Delta(\Omega)$ is $V(\mu, \theta)$ when her type is θ . The type θ is drawn from a commonly known distribution F with density f . There is a data broker who tries to sell information to the agent to maximize his profit by committing to an information structure to reveal the state. Note that an information structure is a mapping $\sigma : \Omega \rightarrow \Delta(S)$, where S is the signal space. Let Σ be the set of all possible signal structures.

In this paper, upon receiving a signal $s \in S$, the agent can conduct her own experiment to further refine her posterior belief on the state with additional costs. Let $\hat{\Sigma}$ be the set of possible experiments, and any $\hat{\sigma} \in \hat{\Sigma}$ is a mapping $\hat{\sigma} : \Omega \rightarrow \hat{S}$. The cost of experiment $\hat{\sigma}$ given posterior belief μ of the agent is denoted by $C(\hat{\sigma}, \mu) \geq 0$.

A mechanism of the data broker is a menu of information structures and associated prices $\{(\sigma_i, p_i)\}$. The timeline of the model is illustrated as follows.

1. The data broker commits to a mechanism $\mathcal{M} = \{(\sigma_i, p_i)\}$.
2. The agent chooses entry $(\sigma, p) \in \mathcal{M}$, and pays price p to the data broker.
3. State $\omega \in \Omega$ is realized according to prior D and the data broker sends signal $s \sim \sigma(\omega)$ to the agent.
4. Upon receiving the signal s , the agent forms posterior belief μ , chooses an experiment $\hat{\sigma} \in \hat{\Sigma}$, and pays cost $C(\hat{\sigma}, \mu)$.
5. The agent receives a signal $\hat{s} \sim \hat{\sigma}(\omega)$, forms refined posterior belief $\hat{\mu}$, and receives expected reward $V(\hat{\mu}, \theta)$.

By revelation principle, it is without loss to consider the revelation mechanism, that is, the data broker commits to a mapping for information structures $\pi : \Theta \rightarrow \Delta(\Sigma)$ and payment rule $p : \Theta \rightarrow \mathbb{R}$.³ By slightly overloading the notation, denote

$$V(\mu, \hat{\Sigma}, \theta) \triangleq \max_{\hat{\sigma} \in \hat{\Sigma}} \mathbf{E}_{\hat{\mu} \sim \hat{\sigma} | \mu} [V(\hat{\mu}, \theta)] - C(\hat{\sigma}, \mu)$$

as the maximum utility of the agent given posterior belief μ , set of possible experiments $\hat{\Sigma}$, and private type θ .

Definition 1. *The mechanism $\mathcal{M} = (\pi, p)$ is incentive compatible if for any type $\theta, \theta' \in \Theta$, we have*

$$\mathbf{E}_{\mu \sim \pi(\theta)} [V(\mu, \hat{\Sigma}, \theta)] - p(\theta) \geq \mathbf{E}_{\mu \sim \pi(\theta')} [V(\mu, \hat{\Sigma}, \theta)] - p(\theta'),$$

³The agent observes the realized information structure $\sigma \sim \pi(\theta)$.

and the mechanism (π, p) is individual rational if for any type $\theta \in \Theta$, we have

$$\mathbf{E}_{\mu \sim \pi(\theta)} \left[V(\mu, \hat{\Sigma}, \theta) \right] - p(\theta) \geq V(D, \hat{\Sigma}, \theta).$$

In this paper, without loss of generality, we focus on mechanisms (π, p) that are incentive compatible and individual rational. The goal of the data broker is to maximize the expected revenue $\text{Rev}(\mathcal{M}) \triangleq \mathbf{E}_{\theta \sim F}[p(\theta)]$.

For any experiment $\hat{\sigma} \in \hat{\Sigma}$, and for any mapping $\kappa : \hat{S} \rightarrow \hat{\Sigma}$, let $\hat{\sigma} \circ \kappa$ represent the experiment such that the agent first conducts experiment $\hat{\sigma}$, and conditional on receiving signal \hat{s} , the agent continues with experiment $\kappa(\hat{s})$ to further refine the posterior belief. For any belief μ , let $\hat{\mu}_{\hat{\sigma}, \hat{s}, \mu}$ be the posterior belief of the agent when she conducts experiment $\hat{\sigma}$ and receives the signal \hat{s} . Throughout this paper, we make the following assumptions on the set of possible experiments and the cost function.

Assumption 1. *There exists a unique experiment $\hat{\sigma} \in \hat{\Sigma}$ such that $C(\hat{\sigma}, \mu) = 0$. Moreover, the corresponding signal space \hat{S} for experiment $\hat{\sigma}$ is a singleton, i.e., $|\hat{S}| = 1$.*

Assumption 2. *For any experiment $\hat{\sigma} \in \hat{\Sigma}$ and for any mapping $\kappa : \hat{S} \rightarrow \hat{\Sigma}$, we have $\hat{\sigma} \circ \kappa \in \hat{\Sigma}$. Moreover, for any belief μ , we have*

$$C(\hat{\sigma} \circ \kappa, \mu) = C(\hat{\sigma}, \mu) + \int_{\Omega} \int_{\hat{S}} C(\kappa(\hat{s}), \hat{\mu}_{\hat{\sigma}, \hat{s}, \mu}) d\hat{\sigma}(\hat{s}|\omega) d\mu(\omega).$$

Intuitively, Assumption 1 assumes that the agent can always choose to not making any additional experiment and pays no extra cost. Assumption 2 assumes that the set of possible experiments is closed under concatenation, and the cost function is linear under concatenation. This captures the scenario where the agent can repeatedly conduct feasible experiments based on her current posterior belief. Next we illustrate several examples that satisfies the above assumptions.

- $\hat{\Sigma}$ is a singleton. In this case, by Assumption 1, the unique experiment $\hat{\sigma}^\perp \in \hat{\Sigma}$ is the one that always reveals no additional information with zero cost.
- $\hat{\Sigma}$ has two elements, i.e., $\hat{\Sigma} = \{\hat{\sigma}^\perp, \hat{\sigma}^\# \}$. In this case, $\hat{\sigma}^\perp$ is the one that always reveals no additional information with zero cost, and $\hat{\sigma}^\#$ is the one that reveals full information with a positive cost depending on the posterior belief μ .
- $\hat{\Sigma}$ is the set of all possible experiments. The cost function C is the reduction in entropy, i.e., $C(\hat{\sigma}, \mu) = H(\mu) - \mathbf{E}_{\hat{\mu} \sim \hat{\sigma}|\mu}[H(\hat{\mu})]$ where $\hat{\sigma}|\mu$ denotes the distribution over posterior $\hat{\mu}$ induced by experiment $\hat{\sigma}$ when the belief is μ , and $H(\mu) = -\int_{\Omega} \mu(\omega) \log \mu(\omega) d\omega$ is the entropy of the posterior μ . It is easy to verify that the cost function satisfies Assumption 2.
- $\hat{\Sigma}$ is the set of experiments generated by $\hat{\sigma}^\perp$ and $\hat{\sigma}'$ by concatenation, where $\hat{\sigma}^\perp$ is the one that always reveals no additional information with zero cost, and $\hat{\sigma}'$ is an informative experiment that provides a single sample about the state with fixed cost, i.e., there exists constant $c > 0$ such that $C(\hat{\sigma}', \mu) = c$ for all posterior μ . In this case,

the agent can choose experiment $\hat{\sigma}'$ as long as it is beneficial for her given her current belief μ ,⁴ and in total the agent pays the cost c multiplies the number of times the experiment $\hat{\sigma}'$ is conducted.

In this paper, we focus on the setting that the private type of the agent represents her value for the additional information. Particularly, we focus on the case that the valuation of the agent is separable.

Definition 2. *The valuation $V(\mu, \theta)$ is separable for type θ if there exists a function $v(\mu)$ such that $V(\mu, \theta) = v(\mu) \cdot \theta$ for any posterior μ .*

Assumption 3. *The valuation $V(\mu, \theta)$ is separable for all type θ , and the corresponding $v(\mu)$ is convex in μ .*

Note that given separable valuation function V , the assumption that the corresponding $v(\mu)$ is convex in μ is satisfied in most situations. Next we introduce two canonical settings that satisfies the separable assumption on the valuation function.

Example 1. *Consider the model of a decision maker choosing an action facing uncertainty over the states. In our paper, the agent is the decision maker who chooses an action from a finite action space $A = \{a_1, \dots, a_n\}$, and the utility of the agent for choosing action a in state ω is $u(a, \omega; \theta) = \theta \cdot \bar{f}(a, \omega)$, where \bar{f} is any publicly known measurable function and θ is the private type of the agent. In this case, given belief μ , when the agent chooses the action optimally, i.e., chooses any action a_i such that $i \in \arg \max_j \mathbf{E}_{\omega \sim \mu} [\bar{f}(a_j, \omega)]$, the expected utility of the agent is $V(\mu, \theta) = \theta \cdot \max_j \mathbf{E}_{\omega \sim \mu} [\bar{f}(a_j, \omega)]$. Thus, by letting $v(\mu) = \max_j \mathbf{E}_{\omega \sim \mu} [\bar{f}(a_j, \omega)]$, the valuation of the agent is separable and $V(\mu, \theta) = v(\mu) \cdot \theta$ for any posterior μ and type θ .*

Example 2. *Consider the model of monopoly auction in Mussa and Rosen (1978). In this example, the agent is a firm selling a product to a consumer with private value for different quality levels of the product. The state space $\Omega = \mathbb{R}_+$ represents the space of valuations of the consumers. The firm has private cost parameter c , and the cost for producing the product with quality q is $c \cdot q^2$.⁵ Let F_μ and f_μ be the cumulative function and density function given posterior belief μ . Assuming that the distribution μ is regular, i.e., the virtual value function $\phi_\mu(z) = z - \frac{1-F_\mu(z)}{f_\mu(z)}$ is non-decreasing in z ,⁶ the optimal mechanism of the firm with cost c is to provide the product with quality $q(z) = \frac{\max\{0, \phi_\mu(z)\}}{2c}$ to the agent with value z , and the expected profit of the firm is*

$$\int_{\mathbb{R}_+} \frac{\max\{0, \phi(z)\}^2}{4c} d\mu(z).$$

Let $\theta = \frac{1}{c}$ be the private type of the firm, and let $v(\mu) = \frac{1}{4} \int_{\mathbb{R}_+} \max\{0, \phi_\mu(z)\}^2 d\mu(z)$. The valuation function is $V(\mu, \theta) = v(\mu) \cdot \theta$ given any type θ and any belief μ , which satisfies the separable condition.

⁴The agent solves an optimal stopping problem for acquiring additional information.

⁵Yang (2020) considers a similar setting with linear cost function $c \cdot q$.

⁶Note that the assumption on regularity is not essential for this example. For any distribution μ that is not regular, we can apply the ironing technique in Myerson (1981) to show that the valuation of the agent, i.e., the profit of the firm, is still separable by substituting the virtual value with ironed virtual value.

Finally, let $\phi(\theta) = \theta - \frac{1-F(\theta)}{f(\theta)}$ be the virtual value function of the agent. We introduce the following technical assumption on the type distribution to simplify the exposition in the paper. Note that all the qualitative results in this paper hold without this additional assumption.⁷

Assumption 4. *The virtual value function $\phi(\theta)$ is monotone non-decreasing in θ .*

3 Optimal Mechanism

In this section, we characterize the optimal revenue of the data broker using envelope theorem (Milgrom and Segal, 2002). For agent with private type θ , the interim utility given revelation mechanism $\mathcal{M} = (\pi, p)$ is

$$U(\theta) = \mathbf{E}_{\mu \sim \pi(\theta)|D} \left[V(\mu, \hat{\Sigma}, \theta) \right] - p(\theta) = \mathbf{E}_{\mu \sim \pi(\theta)|D} \left[v(\mu, \hat{\Sigma}, \theta) \right] - p(\theta).$$

The derivative of the utility is

$$U'(\theta) = \mathbf{E}_{\mu \sim \pi(\theta)|D} \left[V_3(\mu, \hat{\Sigma}, \theta) \right] = \mathbf{E}_{\mu \sim \pi(\theta)|D} \left[\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{\theta, \mu} | \mu} [v(\hat{\mu})] \right]$$

where $\hat{\sigma}_{\theta, \mu} \in \hat{\Sigma}$ is the optimal experiment for the agent given private type θ and belief μ , and $V_3(\mu, \hat{\Sigma}, \theta)$ is the partial derivative on the third coordinate. Thus, we have

$$U(\theta) = \int_{\underline{\theta}}^{\theta} \mathbf{E}_{\mu \sim \pi(z)|D} \left[\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{z, \mu} | \mu} [v(\hat{\mu})] \right] dz + U(\underline{\theta}).$$

Thus the revenue of the data broker is

$$\begin{aligned} \text{Rev}(\mathcal{M}) &= \mathbf{E}_{\theta \sim F} \left[\mathbf{E}_{\mu \sim \pi(\theta)|D} \left[V(\mu, \hat{\Sigma}, \theta) \right] - \int_{\underline{\theta}}^{\theta} \mathbf{E}_{\mu \sim \pi(z)|D} \left[\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{z, \mu} | \mu} [v(\hat{\mu})] \right] dz - U(\underline{\theta}) \right] \\ &= \mathbf{E}_{\theta \sim F} \left[\mathbf{E}_{\mu \sim \pi(\theta)|D} \left[V(\mu, \hat{\Sigma}, \theta) - \frac{1-F(\theta)}{f(\theta)} \cdot \mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{\theta, \mu} | \mu} [v(\hat{\mu})] \right] \right] - U(\underline{\theta}) \\ &= \mathbf{E}_{\theta \sim F} \left[\mathbf{E}_{\mu \sim \pi(\theta)|D} \left[\phi(\theta) \cdot \mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{\theta, \mu} | \mu} [v(\hat{\mu})] - C(\hat{\sigma}_{\theta, \mu}, \mu) \right] \right] - U(\underline{\theta}), \end{aligned}$$

where the second equality holds by integration by parts. By individual rationality of the mechanism, we have $U(\underline{\theta}) \geq V(D, \hat{\Sigma}, \underline{\theta})$, and the revenue is maximized when the equality holds. Thus in the rest of the paper, we focus on the mechanism that guarantees this equality, and hence

$$\text{Rev}(\mathcal{M}) = \mathbf{E}_{\theta \sim F} \left[\mathbf{E}_{\mu \sim \pi(\theta)|D} \left[\phi(\theta) \cdot \mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{\theta, \mu} | \mu} [v(\hat{\mu})] - C(\hat{\sigma}_{\theta, \mu}, \mu) \right] \right] - V(D, \hat{\Sigma}, \underline{\theta}). \quad (1)$$

Lemma 1. *An allocation rule π can be implemented by an incentive compatible and individual rational mechanism if and only if for any $\theta, \theta' \in \Theta$,⁸*

$$\int_{\theta'}^{\theta} \mathbf{E}_{\mu \sim \pi(z)|D} \left[\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{z, \mu} | \mu} [v(\hat{\mu})] \right] - \mathbf{E}_{\mu \sim \pi(\theta')|D} \left[\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{z, \mu} | \mu} [v(\hat{\mu})] \right] dz \geq 0.$$

⁷See Toikka (2011) for a general discussion of ironing when the virtual value is not monotone.

⁸If $\theta < \theta'$, we use $\int_{\theta'}^{\theta}$ to represent $-\int_{\theta}^{\theta'}$.

The constraint on allocation is similar to the integral monotonicity provided in Yang (2020),⁹ where the author considers selling data to an agent without any ability to further acquire information.¹⁰ The proof of Lemma 1 is standard, which is deferred in Appendix A.

Theorem 1. *Let $\theta^* = \inf_{\theta} \{\phi(\theta) \geq 0\}$. In the optimal mechanism,*

- *for any type $\theta \geq \theta^*$, the data broker reveals full information to the agent;*
- *except for a set with measure 0, for any type $\theta < \theta^*$ and any μ in support of $\pi(\theta)|D$, we have that $C(\hat{\sigma}^*, \mu) = 0$ for any $\hat{\sigma}^* \in \arg \max_{\hat{\sigma} \in \hat{\Sigma}} \mathbf{E}_{\hat{\mu} \sim \hat{\sigma} | \mu} [V(\hat{\mu}, \theta)] - C(\hat{\sigma}, \mu)$.*

The proof of Theorem 1 is provided in Appendix A. Theorem 1 implies that there is no distortion at the top in the optimal mechanism. Intuitively, when the agent has sufficiently high type, i.e., $\phi(\theta) > 0$, by fully revealing the information to the agent, the expected virtual value is maximized since $\mathbf{E}_{\mu \sim \sigma | D} [\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{\theta, \mu} | \mu} [v(\hat{\mu})]]$ is maximized when the signal σ fully reveals the state. Moreover, with fully revealed state, the posterior belief of the agent is a singleton, and hence the cost of the endogenous information is zero since there is no additional information available. By Equation (1), this allocation maximizes the virtual surplus, and hence the expected revenue of the data broker.

Another observation from Theorem 1 is that under equilibrium, the agent never has incentive to acquire additional costly information after receiving the signal from the data broker. This holds because if the agent with type θ acquires additional information by conducting experiment $\hat{\sigma}$ with positive cost, the data broker can directly supply this experiment to the agent in the information structure, and increases the payment of type θ by the additional utility increase of type θ when she conducts the experiment $\hat{\sigma}$ in the original mechanism. The new mechanism increases the expected revenue of the data broker, and eliminates the incentive for agent with type θ to further acquire any additional information. In Appendix A, we will formally show that this new mechanism is also incentive compatible and individual rational.

Finally, note that the optimal revenue maximization mechanism can be reduced to the problem of Bayesian persuasion in with additional constraints. Thus we can apply the concavification technique introduced in Kamenica and Gentzkow (2011) to provide closed form characterizations of the optimal information structure for each type, and verify that the resulting information structures satisfy the integral monotonicity constraint in Lemma 1. We will elaborate on this characterization for applications in Section 4.

⁹Sinander (2019) shows that under some continuity condition, information structures that are monotone in Blackwell order can be implemented by incentive compatible mechanism. However, this continuity condition is violated in our paper and Blackwell monotone information structures may not be implementable. This issue of implementation with the continuity condition has been observed by Yang (2020).

¹⁰Gershkov et al. (2020) considered the setting of single-item auction with endogenous valuation. In their paper, the indirect utility of the agent is convex and supermodular, and hence the incentive constraint simplifies to monotonicity in interim allocation. In our setting, monotonicity in interim allocation is not sufficient since the allocation is not single dimensional and the indirect utility in selling information is not supermodular.

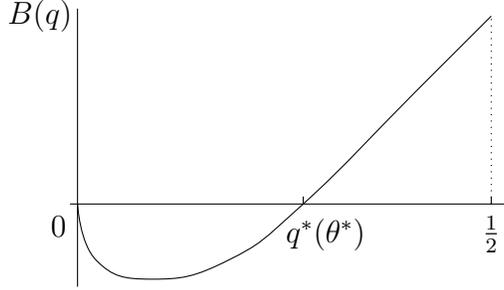

Figure 1: The additional benefit $B(q)$ of choosing the informative experiment when the type is θ^* and the prior D satisfies $D(\omega_1) = q$.

3.1 Posted Pricing Mechanism

In this section, we will provide sufficient conditions such that the optimal mechanism is to post a deterministic price for fully revealing the state.

First note that when $|\hat{\Sigma}| = 1$, by Assumption 1, the agent cannot acquire any additional information, and hence $C(\hat{\sigma}, D) = 0$ for any $\hat{\sigma} \in \hat{\Sigma}$, and $\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{\theta, \mu} | \mu} [v(\hat{\mu})] = v(\mu)$. Thus the revenue of any incentive compatible mechanism \mathcal{M} simplifies to

$$\text{Rev}(\mathcal{M}) = \mathbf{E}_{\theta \sim F} [\phi(\theta) \cdot \mathbf{E}_{\mu \sim \pi(\theta) | D} [v(\mu)]] - V(D, \hat{\Sigma}, \underline{\theta}).$$

Intuitively, in this setting, by viewing $\mathbf{E}_{\mu \sim \pi(\theta) | D} [v(\mu)]$ as a single dimensional quantity, the optimal mechanism is a step function (Myerson, 1981), which in our setting corresponds to fully revealing the state if $\phi(\theta) \geq 0$ and reveals no information if $\phi(\theta) < 0$. We verify that this mechanism satisfies the integral monotonicity of Lemma 1 in Appendix B, and show that this is equivalent to posting a deterministic price for fully revealing the state.

Proposition 1. *If the set of possible experiments is a singleton, i.e., the agent cannot acquire any additional information, the optimal mechanism is to post a deterministic price for fully revealing the state.*

Proposition 1 shows that the optimal mechanism has a simple form when the agent cannot acquire endogenous information. This implies that, for example, when the data broker sells information to a firm that supplies products to consumers with convex cost for qualities (c.f., Example 2), the optimal mechanism is posted pricing. This is in contrast to Yang (2020), where the firm has a linear cost function. The optimal mechanism there is a φ -quasi-perfect mechanism, which is considerably more complicated than posted pricing.

Next we consider the general case that $|\hat{\Sigma}| \geq 2$, and provide sufficient conditions on the prior distribution such that optimal mechanism is posted pricing.

Definition 3. *The prior D is sufficiently informative if there exists an information structure $\hat{\sigma}^* \in \arg \max_{\hat{\sigma} \in \hat{\Sigma}} \mathbf{E}_{\hat{\mu} \sim \hat{\sigma} | D} [V(\hat{\mu}, \theta^*)] - C(\hat{\sigma}, D)$ such that $C(\hat{\sigma}^*, D) = 0$.*

In the following example, we illustrate the intuition for referring to the above definition as sufficiently informative prior.

Example 3. Consider the case the state space $\Omega = \{\omega_1, \omega_2\}$ is binary. The agent is a decision maker who tries to choose an action that matches the state. The action space is $A = \{a_1, a_2\}$. The utility of the agent for choosing action a_i when the state is ω_j is $u(a_i, \omega_j; \theta) = \theta \cdot \mathbf{1}[a_i = \omega_j]$, where $\mathbf{1}[\cdot]$ is the indicator function and θ is the private type of the agent. As illustrated in Example 1, the valuation function of the agent is separable.

Suppose $\hat{\Sigma} = \{\hat{\sigma}^\perp, \hat{\sigma}^\sharp\}$, where $\hat{\sigma}^\perp$ reveals no information and $\hat{\sigma}^\sharp$ reveals full information. In addition, $C(\hat{\sigma}^\perp, \mu) = 0$ for any posterior μ and $C(\hat{\sigma}^\sharp, \mu) = H(\mu)$ for any posterior μ where $H(\mu) = -\sum_i \mu(\omega_i) \log \mu(\omega_i)$ is the entropy function.

Without loss of generality, we will consider the case that $D(\omega_1) \leq \frac{1}{2}$. For type θ^* , given prior D , the additional benefit of choosing experiment $\hat{\sigma}^\sharp$ over experiment $\hat{\sigma}^\perp$ is

$$B(D) = D(\omega_1) \cdot \theta^* - H(D).$$

Thus if $D(\omega_1) \cdot \theta^* - H(D) \leq 0$, then we have $\hat{\sigma}^* = \hat{\sigma}^\perp$ and $C(\hat{\sigma}^*, D) = 0$. Letting $q \triangleq D(\omega_1) \leq \frac{1}{2}$, by representing the additional benefit as a function of q , we have $B(q) = q \cdot \theta^* + q \log q + (1 - q) \log(1 - q)$. Note that B is continuous in q , $B(0) = 0$ and $B'(0) = -\infty$ for any θ^* . Thus there exists $q^*(\theta^*) \in (0, \frac{1}{2}]$ such that for any $q \in [0, q^*(\theta^*)]$, $B(q) \leq 0$. This is illustrated in Figure 1. Note that this exactly corresponds to the case the prior D is more informative.

Intuitively, when the prior is sufficiently informative, the marginal cost for additional information is sufficiently high while the marginal benefit of additional information is bounded. Thus it is not beneficial for the agent to not acquiring any additional information. We formalize the intuition in the following Lemma when the state space Ω is finite, with proof deferred in Appendix B.

Definition 4. The set of possible experiments $\hat{\Sigma}$ is finitely generated if it is generated by $\hat{\sigma}^\perp$ and finite set $\hat{\Sigma}'$ through concatenation, where $\hat{\sigma}^\perp$ is the one that always reveals no additional information with zero cost, and any $\hat{\sigma} \in |\hat{\Sigma}'|$ is an experiment that provides an informative signal about the state with fixed cost $c_{\hat{\sigma}} > 0$.

Lemma 2. Suppose Ω is finite and $\hat{\Sigma}$ is finitely generated. Suppose that there exists $\bar{v} < \infty$ such that $\max_{\omega \in \Omega} v(\omega) \leq \bar{v}$ and $v(\mu) \geq \min_{\omega \in \Omega} \mu(\omega) \cdot v(\omega)$ for any μ . Then there exists $\epsilon > 0$ such that any prior D satisfying $D(\omega) > 1 - \epsilon$ for some $\omega \in \Omega$ is sufficiently informative.

Finally, we have the following proposition when the prior is sufficiently informative.

Proposition 2. When the prior D is sufficiently informative, the optimal mechanism is to post a deterministic price for fully revealing the state.

Remark: Note that when the prior is sufficiently informative, our Theorem 1 and Proposition 2 implies that in the optimal mechanism, the agent never acquires any additional information under equilibrium. However, the sufficiently informative prior condition does not imply that the agent never acquires any additional information under the equilibrium of any incentive compatible mechanism, since the mechanism may send signals such that the posterior of the agent is not sufficiently informative, and the agent strictly benefits from acquiring costly information.

3.2 Comparative Statics

Note that although Theorem 1 shows that the agent never acquire additional information under equilibrium, the ability of acquiring additional information distorts the incentives of the agent, and the optimal mechanism does not coincide with the setting when the agent cannot acquire information. In addition, the ability to potentially acquiring costly information may reduce the revenue of the data broker. In the following proposition, we discuss the implication of endogenous information acquisition on the revenue, the social welfare, and the expected utility of the agent. Recall that $|\hat{\Sigma}| = 1$ is equivalent to the setting where the agent cannot acquire additional information.

Proposition 3. *For any valuation function V , any prior D , and any type distribution F ,*

- *the revenue of the data broker is maximized when $|\hat{\Sigma}| = 1$;*
- *the social welfare is minimized when $|\hat{\Sigma}| = 1$,¹¹*
- *the utility of the agent is minimized when $|\hat{\Sigma}| = 1$.*

The proof of Proposition 3 is provided in Appendix B. Intuitively, when the agent has the ability to acquire additional information, the agent with higher types have higher utilities for the information structure received by lower types, hence limiting the data broker’s revenue from price discrimination. Moreover, for each type of the agent, when the data broker provides more information to the agent, it has two effects on the revenue. It will increase the payment from this particular type while decreasing the payment from higher types. Our result indicates that this difference would be weakly higher if the agent has endogenous information acquisition, and hence the information provided by the data broker would also be weakly higher in the optimal mechanism.

4 Applications

In this section, we provide explicit characterizations of the optimal mechanisms of the data broker for the matching utilities model with binary states.¹² This is a special case of the model illustrated in Example 1.

Suppose that the state space $\Omega = \{\omega_1, \omega_2\}$ is binary. The agent is a decision maker who tries to choose an action that matches the state. The action space is $A = \{a_1, a_2\}$. The utility of the agent for choosing action a_i when the state is ω_j is $u(a_i, \omega_j; \theta) = \theta \cdot \mathbf{1}[a_i = \omega_j]$, where θ is the private type of the agent. In this setting, the valuation of the agent is separable and $V(\mu, \theta) = v(\mu) \cdot \theta$ for any posterior μ and type θ , where $v(\mu) = \max_j \mu(\omega_j)$. Recall that F is the distribution over the type θ and D is the prior over states.

Suppose $\hat{\Sigma}$ contains all possible experiments, and for any $\hat{\sigma} \in \hat{\Sigma}$, the cost is the reduction in entropy, i.e., $C(\hat{\sigma}, \mu) = H(\mu) - \mathbf{E}_{\hat{\mu} \sim \hat{\sigma} | \mu} [H(\hat{\mu})]$ for any posterior μ where $H(\mu) = -\sum_i \mu(\omega_i) \log \mu(\omega_i)$ is the entropy function.

¹¹Our result actually implies that the expected value for each type of the agent is minimized when $|\hat{\Sigma}| = 1$.

¹²This is studied in Bergemann et al. (2018) when the agent has exogenous information and no private valuation.

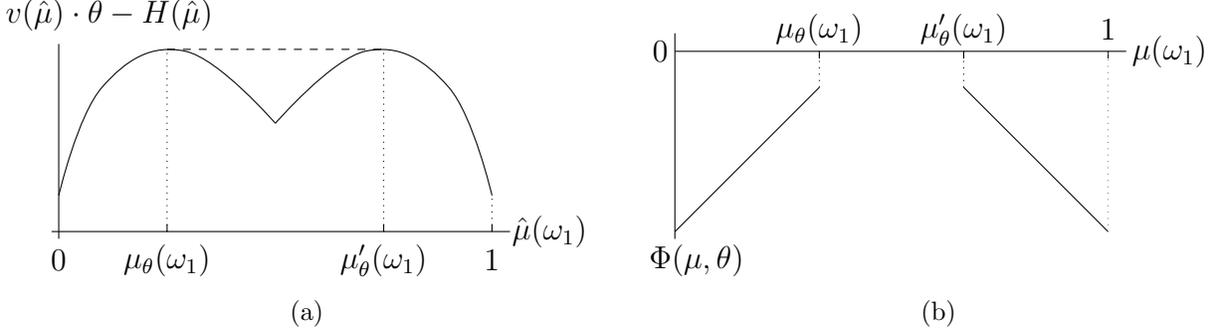

Figure 2: The figure on the left is the value of $v(\hat{\mu}) \cdot \theta - H(\hat{\mu})$ as a function of $\hat{\mu}(\omega_1)$ and the figure on the right is the value of $\Phi(\mu, \theta)$ when $\mu(\omega_1) \in [0, \mu_\theta(\omega_1)] \cup [1 - \mu_\theta(\omega_1), 1]$.

Let σ^\perp be the information structure that reveals no information and σ^\sharp be the information structure that reveals full information. For any type $\theta \geq \theta^*$, by Theorem 1, the optimal mechanism reveals full information to the agent, i.e., $\pi(\theta) = \sigma^\sharp$ for $\theta \geq \theta^*$. For any type $\theta < \theta^*$, given posterior μ , the agent solves the Bayesian persuasion problem of

$$\begin{aligned} \hat{\sigma}_{\theta, \mu} &= \arg \max_{\hat{\sigma} \in \hat{\Sigma}} \mathbf{E}_{\hat{\mu} \sim \hat{\sigma} | \mu} [v(\hat{\mu}) \cdot \theta] - C(\hat{\sigma}, \mu) \\ &= \arg \max_{\hat{\sigma} \in \hat{\Sigma}} \mathbf{E}_{\hat{\mu} \sim \hat{\sigma} | \mu} [v(\hat{\mu}) \cdot \theta - H(\hat{\mu})] + H(\mu). \end{aligned}$$

Note that $v(\hat{\mu}) = \max\{\hat{\mu}(\omega_1), 1 - \hat{\mu}(\omega_1)\}$. The value of the agent with type θ is depicted in Figure 2a. Let

$$\{\mu_\theta, \mu'_\theta\} = \arg \max_{\hat{\mu}} v(\hat{\mu}) \cdot \theta - H(\hat{\mu}).$$

By symmetry it is easy to verify that $\mu_\theta(\omega_1) + \mu'_\theta(\omega_1) = 1$, and $\mu_\theta(\omega_1) \leq \frac{1}{2}$ solves

$$\theta + \ln(\mu_\theta(\omega_1)) - \ln(1 - \mu_\theta(\omega_1)) = 0.$$

Moreover, $C(\hat{\sigma}, \mu) = 0$ if and only if $\mu(\omega_1) \in [0, \mu_\theta(\omega_1)] \cup [1 - \mu_\theta(\omega_1), 1]$. Now recall that the revenue of any mechanism \mathcal{M} is

$$\text{Rev}(\mathcal{M}) = \mathbf{E}_{\theta \sim F} [\mathbf{E}_{\mu \sim \pi(\theta) | D} [\phi(\theta) \cdot \mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{\theta, \mu} | \mu} [v(\hat{\mu})] - C(\hat{\sigma}_{\theta, \mu}, \mu)]] - V(D, \hat{\Sigma}, \underline{\theta}).$$

By Theorem 1, it is without loss to focus on mechanism such that $C(\hat{\sigma}, \mu) = 0$ for any μ in the support of $\pi(\theta)$ for any θ . By defining $\Phi(\mu, \theta) \triangleq \phi(\theta) \cdot \mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{\theta, \mu} | \mu} [v(\hat{\mu})]$, we have

$$\text{Rev}(\mathcal{M}) = \mathbf{E}_{\theta \sim F} [\mathbf{E}_{\mu \sim \pi(\theta) | D} [\Phi(\mu, \theta)]] - V(D, \hat{\Sigma}, \underline{\theta})$$

where $\pi(\theta)$ satisfies that $\mu(\omega_1) \in [0, \mu_\theta(\omega_1)] \cup [1 - \mu_\theta(\omega_1), 1]$ for any μ in the support of $\pi(\theta)$. This implies that $\Phi(\mu, \theta) = \phi(\theta) \cdot \mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{\theta, \mu} | \mu} [v(\hat{\mu})] = \phi(\theta) \cdot v(\mu)$ for any μ in the support of $\pi(\theta)$. This is illustrated in Figure 2b. By maximizing the expected virtual value pointwise for each type, we have the following proposition for maximizing the revenue of the data broker.

Proposition 4. *In the revenue optimal mechanism for matching utilities with binary states, for any type $\theta \geq \theta^*$, the optimal mechanism reveals full information to the agent. For any $\theta < \theta^*$, we have*

- if $D(\omega_1) \in [0, \mu_\theta(\omega_1)] \cup [1 - \mu_\theta(\omega_1), 1]$, the data broker reveals no information to type θ ;
- if $D(\omega_1) \in (\mu_\theta(\omega_1), 1 - \mu_\theta(\omega_1))$, the data broker commit to information structure $\pi(\theta)$ that induce posterior μ_θ with probability $\frac{1 - \mu_\theta(\omega_1) - D(\omega_1)}{1 - 2\mu_\theta(\omega_1)}$ and posterior μ'_θ with probability $\frac{D(\omega_1) - \mu_\theta(\omega_1)}{1 - 2\mu_\theta(\omega_1)}$, where $\mu'_\theta(\omega_1) = 1 - \mu_\theta(\omega_1)$ and $\mu_\theta(\omega_1) \leq \frac{1}{2}$ solves

$$\theta + \ln(\mu_\theta(\omega_1)) - \ln(1 - \mu_\theta(\omega_1)) = 0.$$

To prove Proposition 4, it is sufficient to show that this information structure can be implement by an incentive compatible mechanism. It is easy to verify that the integral monotonicity constraint in Lemma 1 is satisfied, and hence the corresponding mechanism is indeed revenue optimal.

5 Conclusions and Extensions

In this paper, we study the model of selling information to an agent with the ability to acquire costly information upon receiving the signals from the data broker. We show that in the optimal mechanism, there is no distortion at the top, and the agent has no incentive to acquire additional information under equilibrium. Our results apply to a broad class of setting including selling information to a firm providing products to consumers with different level of qualities, and selling information to a decision maker taking an action to maximize her payoff based on her posterior belief on the states. In addition, we show that if the agent cannot acquire additional information, or if the prior distribution is sufficiently informative, then posting a deterministic price is optimal among all possible mechanisms.

Cost of Information. Throughout the paper, we assumed that the data broker has free access to the information. The cost of the data broker can be easily incorporated into our model. If the cost of the data broker is always higher than the cost of the agent for acquiring any information, one can verify that in this case, the data broker cannot make any profit by selling information to the agent. If the cost of the data broker is always smaller, the data broker can make positive profit from selling information, and in the optimal mechanism, the agent still does not have incentive to acquire any additional information under equilibrium.

Limited Information Structures of the Data Broker. In this paper, the data broker can sell any information structure to the agent. In reality the data broker may only collect additional information about the states with certain formats. Specifically, the set Σ is only a subset of possible information structures and the data broker cannot commit to information structure $\sigma \in \Sigma$. In the case that $\hat{\Sigma} \subseteq \Sigma$, i.e., the ability of the data broker is stronger than the agent in learning the states, the optimal mechanism still guarantees that the agent does not have incentive to acquire any additional information under equilibrium. In addition, if

the set Σ contains the information structure that fully reveals the state, then there is no distortion at the top and the optimal mechanism fully reveals the states if the private type of the agent is sufficiently high.

Non-separable Valuation. We have focused on the case when the agent has separable valuation. This assumption can be relaxed by considering the model when there is a commonly known monotone supermodular function \tilde{f} and a convex valuation function $v(\mu)$ such that for any type θ and any posterior μ , the value of the agent is $V(\mu, \theta) = \tilde{f}(v(\mu), \theta)$. Essentially, the crucial assumption in our paper is that θ measures how much the agent values the information, and it should not affect how the agent processes the signals from the data broker or how the agent update her posteriors. Under the relaxed assumption, the qualitative results in our paper extend naturally.

When different types of the agent have heterogeneous information about the states in ex ante (e.g., Bergemann et al., 2018), the agent with different prior information may have heterogeneous preference order over the information structures. Thus results such as no distortion at the top may fail since the top type may be ill defined in this situation. However, we can still show that in the optimal mechanism, the agent does not have incentive to acquire additional information under equilibrium.

A Optimal Mechanism

Lemma 3. *Let $\sigma^\#$ be the information structure that reveals full information, and σ^\perp be the information structure that reveals no information. For any information structure σ , any prior D , and any type θ , we have*

$$\mathbf{E}_{\mu \sim \sigma^\# | D} [\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{\theta, \mu} | \mu} [v(\hat{\mu})]] \geq \mathbf{E}_{\mu \sim \sigma | D} [\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{\theta, \mu} | \mu} [v(\hat{\mu})]] \geq \mathbf{E}_{\mu \sim \sigma^\perp | D} [\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{\theta, \mu} | \mu} [v(\hat{\mu})]]$$

Proof. First for the fully informative signal $\sigma^\#$, for any information structure σ , any prior D , and any type θ , we have

$$\mathbf{E}_{\mu \sim \sigma^\# | D} [\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{\theta, \mu} | \mu} [v(\hat{\mu})]] = \mathbf{E}_{\omega \sim D} [v(\omega)] \geq \mathbf{E}_{\mu \sim \sigma | D} [\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{\theta, \mu} | \mu} [v(\hat{\mu})]],$$

since v is convex in μ and $\sigma^\#$ fully reveals the states. For information structure σ^\perp that reveals no information, for any information structure σ , any prior D , and any type θ , we have

$$\begin{aligned} \mathbf{E}_{\mu \sim \sigma | D} [\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{\theta, \mu} | \mu} [v(\hat{\mu})]] &\geq \mathbf{E}_{\mu \sim \sigma | D} [\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{\theta, D} | \mu} [v(\hat{\mu})]] \\ &\geq \mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{\theta, D} | D} [v(\hat{\mu})] = \mathbf{E}_{\mu \sim \sigma^\perp | D} [\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{\theta, \mu} | \mu} [v(\hat{\mu})]], \end{aligned}$$

where the first inequality holds because under information structure σ , one possible choice for the agent is to choose experiment $\hat{\sigma}_{\theta, D}$ after observing any posterior belief $\mu \sim \sigma | D$. The second inequality hold since v is convex and by Jensen's inequality, more informative signal generates higher expectation for valuation. \square

Proof of Lemma 1. By the envelope theorem, for any incentive compatible mechanism \mathcal{M} , the interim utility $U(\theta)$ is convex in θ and

$$U(\theta) = \int_{\underline{\theta}}^{\theta} \mathbf{E}_{\mu \sim \pi(z) | D} [\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{z, \mu} | \mu} [v(\hat{\mu})]] dz + U(\underline{\theta}).$$

Thus the corresponding payment rule is

$$p(\theta) = \mathbf{E}_{\mu \sim \pi(\theta) | D} \left[V(\mu, \hat{\Sigma}, \theta) - \int_{\underline{\theta}}^{\theta} \mathbf{E}_{\mu \sim \pi(z) | D} [\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{z, \mu} | \mu} [v(\hat{\mu})]] dz \right] - U(\underline{\theta}).$$

It is easy to verify that the mechanism $\mathcal{M} = (\pi, p)$ is individual rational if and only if $U(\underline{\theta}) \geq V(D, \hat{\Sigma}, \underline{\theta})$. Next we verify that this mechanism is incentive if and only if the integral constraint in the statement of Lemma 1 is satisfied. Note that for any $\theta, \theta' \in \Theta$, letting $U(\theta; \theta')$ be the utility of the agent with type θ when she reports θ' in mechanism \mathcal{M} , we have

$$\begin{aligned} U(\theta) - U(\theta; \theta') &= U(\theta) - U(\theta') - \mathbf{E}_{\mu \sim \pi(\theta') | D} [V(\mu, \hat{\Sigma}, \theta)] + \mathbf{E}_{\mu \sim \pi(\theta') | D} [V(\mu, \hat{\Sigma}, \theta')] \\ &= \int_{\theta'}^{\theta} \mathbf{E}_{\mu \sim \pi(z) | D} [\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{z, \mu} | \mu} [v(\hat{\mu})]] dz - \int_{\theta'}^{\theta} \mathbf{E}_{\mu \sim \pi(\theta') | D} [V_3(\mu, \hat{\Sigma}, z)] dz \\ &= \int_{\theta'}^{\theta} \mathbf{E}_{\mu \sim \pi(z) | D} [\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{z, \mu} | \mu} [v(\hat{\mu})]] - \mathbf{E}_{\mu \sim \pi(\theta') | D} [\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{z, \mu} | \mu} [v(\hat{\mu})]] dz. \end{aligned}$$

Thus $U(\theta) - U(\theta; \theta') \geq 0$ if and only if the integral constraint in the statement of Lemma 1 is satisfied. \square

Proof of Theorem 1. Recall that by Equation (1), the optimal revenue is

$$\text{Rev}(\mathcal{M}) = \mathbf{E}_{\theta \sim F} [\mathbf{E}_{\mu \sim \pi(\theta)|D} [\phi(\theta) \cdot \mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{\theta, \mu} | \mu} [v(\hat{\mu})] - C(\hat{\sigma}_{\theta, \mu}, \mu)]] - V(D, \hat{\Sigma}, \underline{\theta}).$$

For any type $\theta \geq \theta^*$, i.e., $\phi(\theta) \geq 0$, the contribution of revenue from type θ is

$$\begin{aligned} \text{Rev}(\mathcal{M}; \theta) &\triangleq \mathbf{E}_{\mu \sim \pi(\theta)|D} [\phi(\theta) \cdot \mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{\theta, \mu} | \mu} [v(\hat{\mu})] - C(\hat{\sigma}_{\theta, \mu}, \mu)] \\ &\leq \phi(\theta) \cdot \mathbf{E}_{\mu \sim \sigma^\#|D} [\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{\theta, \mu} | \mu} [v(\hat{\mu})]] \end{aligned}$$

since $C(\hat{\sigma}_{\theta, \mu}, \mu) \geq 0$ for any posterior μ , and the equality holds when the posterior μ is in the support of $\sigma^\#|D$ since $\sigma^\#$ fully reveals the state. Let $\hat{\pi}$ be the allocation that replaces $\pi(\theta)$ with $\sigma^\#$ for types $\theta \geq \theta^*$. Finally we verify that $\hat{\pi}$ satisfies the integral constraint in Lemma 1. For any type θ, θ' such that both θ, θ' are below or above θ^* , it is easy to verify that the integral constraint is satisfied. When $\theta \geq \theta^* \geq \theta'$, we have

$$\begin{aligned} &\int_{\theta'}^{\theta} \mathbf{E}_{\mu \sim \hat{\pi}(z)|D} [\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{z, \mu} | \mu} [v(\hat{\mu})]] - \mathbf{E}_{\mu \sim \hat{\pi}(\theta')|D} [\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{z, \mu} | \mu} [v(\hat{\mu})]] dz \\ &= \int_{\theta^*}^{\theta} \mathbf{E}_{\mu \sim \sigma^\#|D} [\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{z, \mu} | \mu} [v(\hat{\mu})]] - \mathbf{E}_{\mu \sim \pi(\theta')|D} [\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{z, \mu} | \mu} [v(\hat{\mu})]] dz \\ &\quad + \int_{\theta'}^{\theta^*} \mathbf{E}_{\mu \sim \pi(z)|D} [\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{z, \mu} | \mu} [v(\hat{\mu})]] - \mathbf{E}_{\mu \sim \pi(\theta')|D} [\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{z, \mu} | \mu} [v(\hat{\mu})]] dz \\ &\geq \int_{\theta'}^{\theta} \mathbf{E}_{\mu \sim \pi(z)|D} [\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{z, \mu} | \mu} [v(\hat{\mu})]] - \mathbf{E}_{\mu \sim \pi(\theta')|D} [\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{z, \mu} | \mu} [v(\hat{\mu})]] dz \geq 0 \end{aligned}$$

where the inequality holds by applying Lemma 3. Similarly, when $\theta \leq \theta^* \leq \theta'$, we have

$$\begin{aligned} &\int_{\theta'}^{\theta} \mathbf{E}_{\mu \sim \hat{\pi}(z)|D} [\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{z, \mu} | \mu} [v(\hat{\mu})]] - \mathbf{E}_{\mu \sim \hat{\pi}(\theta')|D} [\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{z, \mu} | \mu} [v(\hat{\mu})]] dz \\ &= \int_{\theta}^{\theta^*} -\mathbf{E}_{\mu \sim \pi(z)|D} [\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{z, \mu} | \mu} [v(\hat{\mu})]] + \mathbf{E}_{\mu \sim \sigma^\#|D} [\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{z, \mu} | \mu} [v(\hat{\mu})]] dz \\ &\quad + \int_{\theta^*}^{\theta'} -\mathbf{E}_{\mu \sim \sigma^\#|D} [\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{z, \mu} | \mu} [v(\hat{\mu})]] + \mathbf{E}_{\mu \sim \sigma^\#|D} [\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{z, \mu} | \mu} [v(\hat{\mu})]] dz \\ &\geq \int_{\theta}^{\theta^*} -\mathbf{E}_{\mu \sim \pi(z)|D} [\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{z, \mu} | \mu} [v(\hat{\mu})]] + \mathbf{E}_{\mu \sim \pi(\theta')|D} [\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{z, \mu} | \mu} [v(\hat{\mu})]] dz \\ &\geq \int_{\theta}^{\theta^*} -\mathbf{E}_{\mu \sim \pi(z)|D} [\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{z, \mu} | \mu} [v(\hat{\mu})]] + \mathbf{E}_{\mu \sim \pi(\theta')|D} [\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{z, \mu} | \mu} [v(\hat{\mu})]] dz \\ &\quad + \int_{\theta^*}^{\theta'} -\mathbf{E}_{\mu \sim \pi(z)|D} [\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{z, \mu} | \mu} [v(\hat{\mu})]] + \mathbf{E}_{\mu \sim \pi(\theta')|D} [\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{z, \mu} | \mu} [v(\hat{\mu})]] dz \geq 0. \end{aligned}$$

The first inequality holds by combining Lemma 3 and the observation that the sum of last two terms is 0. The second inequality holds by applying Lemma 1 to types θ^* and θ' . Thus,

combining the inequalities, $\hat{\pi}$ can be implemented by incentive compatible mechanisms, and it is revenue optimal.

Next we prove the second statement of Theorem 1. Let $\mathcal{M} = (\pi, p)$ be the optimal mechanism. Let κ_θ be the optimal choice of experiments for agent with type θ given mechanism \mathcal{M} . By contradiction, suppose that there exists a type $\tilde{\theta} < \theta^*$ such that the additional cost for experiments given mapping $\kappa_{\tilde{\theta}}$ is positive, i.e.,

$$C(\pi(\tilde{\theta}) \circ \kappa_{\tilde{\theta}}, D) - C(\pi(\tilde{\theta}), D) = \int_{\Omega} \int_{\hat{\mathcal{S}}} C(\kappa_{\tilde{\theta}}(\hat{s}), \hat{\mu}_{\pi(\tilde{\theta}), \hat{s}, D}) d\pi(\tilde{\theta})(\hat{s}|\omega) dD(\omega) > 0,$$

where $\hat{\mu}_{\pi(\tilde{\theta}), \hat{s}, D}$ is the posterior given information structure $\pi(\tilde{\theta})$ and signal \hat{s} , assuming the prior is D . Let $\hat{\pi}$ be the allocation rule such that $\hat{\pi}(\theta') = \pi(\theta')$ for any $\theta' \neq \tilde{\theta}$, and $\hat{\pi}(\tilde{\theta}) = \pi(\tilde{\theta}) \circ \kappa_{\tilde{\theta}}$.¹³ Let \hat{p} be the payment rule such that $\hat{p}(\theta') = p(\theta')$ for any $\theta' \neq \tilde{\theta}$, and

$$\hat{p}(\tilde{\theta}) = p(\tilde{\theta}) + C(\pi(\tilde{\theta}) \circ \kappa_{\tilde{\theta}}, D) - C(\pi(\tilde{\theta}), D).$$

Let $\hat{\mathcal{M}} = (\hat{\pi}, \hat{p})$. It is easy to verify that the revenue of mechanism \mathcal{M} is higher. Moreover, in mechanism $\hat{\mathcal{M}}$, the utility of the agent with type θ has at least the same expected utility compared to mechanism \mathcal{M} by not acquiring any additional information upon receiving the signal s . Thus the mechanism is individual rational. Next we show that mechanism $\hat{\mathcal{M}}$ is incentive compatible. It is easy to verify that agent with type $\tilde{\theta}$ has no incentive to deviate since her utility for reporting truthfully weakly increases, while her utility for misreport remains the same. Moreover, for any types $\theta, \theta' \neq \tilde{\theta}$, agent with type θ has no incentive to deviate to type θ' since the allocation and the payment for both types are the same across both mechanisms. Finally, for any types $\theta \neq \tilde{\theta}$, under mechanism $\hat{\mathcal{M}}$, the utility for deviating the report from type θ to type $\tilde{\theta}$ is

$$\begin{aligned} U(\theta; \tilde{\theta}, \hat{\mathcal{M}}) &= \mathbf{E}_{\mu \sim \hat{\pi}(\tilde{\theta})|D} \left[V(\mu, \hat{\Sigma}, \theta) \right] - \hat{p}(\tilde{\theta}) \\ &= \mathbf{E}_{\mu \sim \hat{\pi}(\tilde{\theta})|D} \left[V(\mu, \hat{\Sigma}, \theta) \right] - p(\tilde{\theta}) - \int_{\Omega} \int_{\hat{\mathcal{S}}} C(\kappa_{\tilde{\theta}}(\hat{s}), \hat{\mu}_{\pi(\tilde{\theta}), \hat{s}, D}) d\pi(\tilde{\theta})(\hat{s}|\omega) dD(\omega) \\ &= \int_{\Omega} \int_{\hat{\mathcal{S}}} \left(\mathbf{E}_{\hat{\mu} \sim \kappa_{\tilde{\theta}}(\hat{s})|\hat{\mu}_{\pi(\tilde{\theta}), \hat{s}, D}} \left[V(\hat{\mu}, \hat{\Sigma}, \theta) \right] - C(\kappa_{\tilde{\theta}}(\hat{s}), \hat{\mu}_{\pi(\tilde{\theta}), \hat{s}, D}) \right) d\pi(\tilde{\theta})(\hat{s}|\omega) dD(\omega) - p(\tilde{\theta}) \\ &\leq \int_{\Omega} \int_{\hat{\mathcal{S}}} V(\hat{\mu}_{\pi(\tilde{\theta}), \hat{s}, D}, \hat{\Sigma}, \theta) d\pi(\tilde{\theta})(\hat{s}|\omega) dD(\omega) - \hat{p}(\tilde{\theta}) \\ &= \mathbf{E}_{\mu \sim \pi(\tilde{\theta})|D} \left[V(\hat{\mu}_{\pi(\tilde{\theta}), \hat{s}, D}, \hat{\Sigma}, \theta) \right] - \hat{p}(\tilde{\theta}) = U(\theta; \tilde{\theta}, \mathcal{M}). \end{aligned}$$

The inequality holds because by Assumption 2, given any posterior $\hat{\mu}_{\pi(\tilde{\theta}), \hat{s}, D}$, a feasible choice for the agent is to choose $\kappa_{\tilde{\theta}}(\hat{s}) \in \hat{\Sigma}$, pay cost $C(\kappa_{\tilde{\theta}}(\hat{s}), \hat{\mu}_{\pi(\tilde{\theta}), \hat{s}, D})$, and then choose additional experiments optimally given the realized signal. The utility of this choice is upper bounded by directly choosing the optimal experiment from $\hat{\Sigma}$, which induces value $V(\hat{\mu}_{\pi(\tilde{\theta}), \hat{s}, D}, \hat{\Sigma}, \theta)$ for the agent. Thus, we have

$$U(\theta; \hat{\mathcal{M}}) - U(\theta; \tilde{\theta}, \hat{\mathcal{M}}) \geq U(\theta; \mathcal{M}) - U(\theta; \tilde{\theta}, \mathcal{M}) \geq 0,$$

¹³Note that under this new information structure $\hat{\pi}(\tilde{\theta})$, both the signal \hat{s} and the signal generated by $\hat{\sigma}^*$ will be revealed to the agent.

and mechanism $\hat{\mathcal{M}}$ is incentive compatible. \square

B Posted Pricing and Comparative Statics

Proof of Proposition 1. Let \mathcal{M} be the mechanism that that fully revealing the state if $\phi(\theta) \geq 0$ and reveals no information if $\phi(\theta) < 0$. When $|\hat{\Sigma}| = 1$, for any type θ and any posterior μ , we have that $\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{\theta, \mu} | \mu} [v(\hat{\mu})] = v(\mu)$, and hence the integral constraint simplifies to

$$\begin{aligned} & \int_{\theta'}^{\theta} \mathbf{E}_{\mu \sim \pi(z) | D} [\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{z, \mu} | \mu} [v(\hat{\mu})]] - \mathbf{E}_{\mu \sim \pi(\theta') | D} [\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{z, \mu} | \mu} [v(\hat{\mu})]] \, dz \\ &= \int_{\theta'}^{\theta} \mathbf{E}_{\mu \sim \pi(z) | D} [v(\mu)] - \mathbf{E}_{\mu \sim \pi(\theta') | D} [v(\mu)] \, dz \geq 0. \end{aligned}$$

Note that this is equivalent to the condition that $\mathbf{E}_{\mu \sim \pi(\theta) | D} [v(\mu)]$ is non-decreasing in θ . It is easy to verify that the mechanism \mathcal{M} satisfies the simplified monotonicity condition, and hence it is incentive compatible and revenue optimal. \square

Proof of Lemma 2. Let $c_m = \min_{\hat{\sigma} \in \hat{\Sigma}'} > 0$. By construction, for any experiment $\hat{\sigma} \in \hat{\Sigma}$, we have $C(\hat{\sigma}, \mu) \geq c_m$ for any μ . Let ω^* be the state such that $D(\omega^*) > 1 - \epsilon$. Given prior D , the utility increase of type θ^* for additional information is at most

$$\theta^* \cdot \left(\sum_{\omega \in \Omega} D(\omega) v(\omega) - v(D) \right) \leq \theta^* \cdot \left(\sum_{\omega \neq \omega^*} D(\omega) v(\omega) \right) < \theta^* \cdot \epsilon \cdot \bar{v}.$$

The first inequality holds since $v(D) \geq D(\omega^*) v(\omega^*)$, and the second inequality holds since $v(\omega) \leq \bar{v}$ and $\sum_{\omega \neq \omega^*} D(\omega) < \epsilon$. Thus, when $\epsilon = \frac{c_m}{\theta^* \cdot \bar{v}}$, the cost of information is always higher than the benefit of information, and the agent with type θ^* will never acquire any additional information given prior D . \square

Proof of Proposition 2. Recall that σ^\sharp is the information structure that reveals full information and σ^\perp is the information structure that reveals no information. Let $\mathcal{M} = (\pi, p)$ be the mechanism that that $\pi(\theta) = \sigma^\sharp$ if $\phi(\theta) \geq 0$ and $\pi(\theta) = \sigma^\perp$ if $\phi(\theta) < 0$. Since the prior is sufficient informative, we have that $C(\hat{\sigma}_{\theta^*, D}, D) = 0$. Next we claim that for any $\theta < \theta^*$, $C(\hat{\sigma}_{\theta, D}, D) = 0$. Suppose by contradiction that there exists $\theta < \theta^*$ such that $C(\hat{\sigma}_{\theta, D}, D) = 0$, i.e.,

$$\mathbf{E}_{\mu \sim \hat{\sigma}_{\theta, D} | D} [v(\mu)] \cdot \theta - C(\hat{\sigma}_{\theta, D}, D) \geq \mathbf{E}_{\mu \sim \sigma^\perp | D} [v(\mu)] \cdot \theta.$$

Since $\theta^* > \theta$, we have that

$$\begin{aligned} & \mathbf{E}_{\mu \sim \hat{\sigma}_{\theta, D} | D} [v(\mu)] \cdot \theta^* - C(\hat{\sigma}_{\theta, D}, D) - \mathbf{E}_{\mu \sim \sigma^\perp | D} [v(\mu)] \cdot \theta^* \\ & > (\mathbf{E}_{\mu \sim \hat{\sigma}_{\theta, D} | D} [v(\mu)] - \mathbf{E}_{\mu \sim \sigma^\perp | D} [v(\mu)]) \cdot \theta - C(\hat{\sigma}_{\theta, D}, D) \geq 0, \end{aligned}$$

contradicting to the assumption that $C(\hat{\sigma}_{\theta^*, D}, D) = 0$. Thus by Lemma 3, the expected revenue of the data broker in Equation (1) is maximized by mechanism \mathcal{M} . Finally, for any

$$\theta \geq \theta^* \geq \theta',$$

$$\begin{aligned} & \int_{\theta'}^{\theta} \mathbf{E}_{\mu \sim \pi(z)|D} [\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{z,\mu}|\mu} [v(\hat{\mu})]] - \mathbf{E}_{\mu \sim \pi(\theta')|D} [\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{z,\mu}|\mu} [v(\hat{\mu})]] \, dz \\ &= \int_{\theta^*}^{\theta} \mathbf{E}_{\mu \sim \sigma^\#|D} [\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{z,\mu}|\mu} [v(\hat{\mu})]] - \mathbf{E}_{\mu \sim \sigma^\perp|D} [\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{z,\mu}|\mu} [v(\hat{\mu})]] \, dz \geq 0 \end{aligned}$$

where the inequality holds by applying Lemma 3. For any $\theta \leq \theta^* \leq \theta'$,

$$\begin{aligned} & \int_{\theta'}^{\theta} \mathbf{E}_{\mu \sim \pi(z)|D} [\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{z,\mu}|\mu} [v(\hat{\mu})]] - \mathbf{E}_{\mu \sim \pi(\theta')|D} [\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{z,\mu}|\mu} [v(\hat{\mu})]] \, dz \\ &= \int_{\theta}^{\theta^*} -\mathbf{E}_{\mu \sim \sigma^\perp|D} [\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{z,\mu}|\mu} [v(\hat{\mu})]] + \mathbf{E}_{\mu \sim \sigma^\#|D} [\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{z,\mu}|\mu} [v(\hat{\mu})]] \, dz \geq 0 \end{aligned}$$

where the inequality holds again by applying Lemma 3. Thus mechanism \mathcal{M} is incentive compatible and revenue optimal. \square

Proof of Proposition 3. Recall that $\sigma^\#$ is the information structure that reveals full information, and σ^\perp is the information structure that reveals no information. Also recall that $\theta^* = \inf_{\theta} \{\phi(\theta) \geq 0\}$. Let $\hat{\Sigma}'$ be the set of experiments such that $|\hat{\Sigma}'| = 1$. Given any set of possible experiments $\hat{\Sigma}$ of the agent, the revenue of the data broker in mechanism \mathcal{M} is

$$\begin{aligned} \text{Rev}(\mathcal{M}) &= \mathbf{E}_{\theta \sim F} [\mathbf{E}_{\mu \sim \pi(\theta)|D} [\phi(\theta) \cdot \mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{\theta,\mu}|\mu} [v(\hat{\mu})] - C(\hat{\sigma}_{\theta,\mu}, \mu)]] - V(D, \hat{\Sigma}, \underline{\theta}) \\ &\leq \mathbf{E}_{\theta \sim F} [\mathbf{E}_{\mu \sim \pi(\theta)|D} [\phi(\theta) \cdot \mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{\theta,\mu}|\mu} [v(\hat{\mu})]]] - V(D, \hat{\Sigma}, \underline{\theta}) \\ &\leq \int_{\underline{\theta}}^{\theta^*} \mathbf{E}_{\mu \sim \pi(\theta)|D} [\phi(\theta) \cdot \mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{\theta,\mu}|\mu} [v(\hat{\mu})]] \, d\theta \\ &\quad + \int_{\theta^*}^{\bar{\theta}} \mathbf{E}_{\mu \sim \sigma^\#|D} [\phi(\theta) \cdot \mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{\theta,\mu}|\mu} [v(\hat{\mu})]] \, d\theta - V(D, \hat{\Sigma}', \underline{\theta}) \\ &\leq \int_{\underline{\theta}}^{\theta^*} \mathbf{E}_{\mu \sim \sigma^\perp|D} [\phi(\theta) \cdot v(\mu)] \, d\theta + \int_{\theta^*}^{\bar{\theta}} \mathbf{E}_{\mu \sim \sigma^\#|D} [\phi(\theta) \cdot v(\mu)] \, d\theta - V(D, \hat{\Sigma}', \underline{\theta}) \end{aligned}$$

where the last line is the optimal revenue when the set of possible experiments is $\hat{\Sigma}'$. Note that the first inequality holds since the cost is always non-negative. The second inequality holds because $V(D, \hat{\Sigma}, \underline{\theta}) \geq V(D, \hat{\Sigma}', \underline{\theta})$, and by Theorem 1, the data broker reveals full information to types above θ^* in the optimal mechanism. The last inequality holds since $\phi(\theta) < 0$ for $\theta < \theta^*$, and $\mathbf{E}_{\mu \sim \pi(\theta)|D} [\mathbf{E}_{\hat{\mu} \sim \hat{\sigma}_{\theta,\mu}|\mu} [v(\hat{\mu})]] \geq \mathbf{E}_{\mu \sim \sigma^\perp|D} [v(\mu)]$ since v is a convex function. Thus the expected revenue of the data broker is maximized when $|\hat{\Sigma}'| = 1$.

Note that for any type $\theta \geq \theta^*$, the agent receives full information in both setting, and for any type $\theta < \theta^*$, by Proposition 1, the agent receives no information when $|\hat{\Sigma}'| = 1$. Thus the social welfare is minimized when $|\hat{\Sigma}'| = 1$. Combining this with the observation on the expected revenue implies that the expected utility of the agent is minimized when $|\hat{\Sigma}'| = 1$. \square
