ABSTRACT

We present the clustering analysis of photometric luminous red galaxies (LRGs) at a redshift range of $0.1 \leq z \leq 1.05$ using 615,317 photometric LRGs selected from the Hyper Suprime-Cam Subaru Strategic Program covering ~ 124 deg². Our sample covers a broad range of stellar masses and photometric redshifts and enables a halo occupation distribution analysis to study the redshift and stellar-mass dependence of dark halo properties of LRGs. We find a tight correlation between the characteristic dark halo mass to host central LRGs, M_{\min} , and the number density of LRGs independently of redshifts, indicating that the formation of LRGs is associated with the global environment. The M_{\min} of LRGs depends only weakly on the stellar mass M_{\star} at $M_{\star} \lesssim 10^{10.75} h^{-2} M_{\odot}$ at $0.3 < z < 1.05$, in contrast to the case for all photometrically selected galaxies for which M_{\min} shows significant dependence on M_{\star} even at low M_{\star} . The weak stellar mass dependence is indicative of the dark halo mass being the key parameter for the formation of LRGs rather than the stellar mass. Our result suggests that the halo mass of $\sim 10^{12.5 \pm 0.2} h^{-1} M_{\odot}$ is the critical mass for an efficient halo quenching due to the halo environment. We compare our result with the result of the hydrodynamical simulation to find that low-mass LRGs at $z \sim 1$ will increase their stellar masses by an order magnitude from $z = 1$ to 0 through mergers and satellite accretions, and a large fraction of massive LRGs at $z < 0.9$ consist of LRGs that are recently migrated from massive green valley galaxies or those evolved from less massive LRGs through mergers and satellite accretions.

Keywords: cosmology: observations — dark matter — large-scale structure of universe — galaxies: evolution — formation

1. INTRODUCTION

The formation of the large-scale structure of the Universe, which can be traced by galaxies, is largely governed by cosmology in the early Universe. Small matter density fluctuations in the early Universe evolve into biased objects, known as dark halos, via gravitational instability. Galaxies, which are an important tracer of the large-scale structure, form in dark halos by trapping baryons by their gravitational wells. Dark halos formed

in the early epoch induce cooling and condense processes on the accreted baryonic gasses at the early stage of the Universe. Therefore, highly biased galaxies tend to reside in old, massive dark halos (e.g., [White & Rees 1978](#); [Blumenthal et al. 1984](#)).

Luminous red galaxies (LRGs) are thought to be a passively evolving, long-lived galaxy population hosted by such old dark halos ([Eisenstein et al. 2001](#)). Given the large bias and their brightness, LRGs are a useful tracer of the large-scale structure of the Universe. Many redshift surveys have constructed large samples of LRGs over a broad redshift range, especially after the notable success by the Sloan Digital Sky Survey (SDSS),

from which the clustering of LRGs has been measured as a function of various baryonic properties of the LRGs (e.g., Zheng et al. 2009; Reid et al. 2010; Zehavi et al. 2011; Guo et al. 2013).

Since all galaxies are considered to form within halos in the current paradigm of cosmic structure formation, investigating galaxy clustering provides clues to understand the relationship between galaxies and host dark halos and reveal properties of the underlying dark matter distribution. Furthermore, measuring and interpreting the galaxy clustering signals play an important role in discriminating different physical processes to drive galaxy formation and evolution (e.g., Wechsler & Tinker 2018).

Two-point auto-correlation functions (2PCFs) are commonly used to quantify the clustering of galaxies (Totsuji & Kihara 1969; Peebles 1980). The 2PCF provides various information at different physical scales ranging from the large-scale structure of the Universe to the galaxy formation within dark halos. At large physical scales, the 2PCF is approximately attributed to the matter-matter correlation function in the linear regime enhanced by the halo bias (e.g., Seljak 2000; Ma & Fry 2000). On the other hand, the 2PCF at small scales contains a wealth of information on the non-linear physical processes of galaxy formation and evolution, and the central-satellite interactions within dark halos (e.g., Kravtsov et al. 2004; Tinker et al. 2005).

Observed 2PCFs of galaxies can be interpreted using analytical halo models that are developed based on the galaxy formation model in the context of the Λ -dominated Cold Dark Matter (Λ CDM) cosmological model (Cooray & Sheth 2002, for a review). One of the most successful halo models for analyzing observed clustering signals is the halo occupation distribution (HOD) model (e.g., Berlind & Weinberg 2002; Berlind et al. 2003; van den Bosch et al. 2003). The HOD model characterizes the galaxy bias in terms of the galaxy occupation within dark halos, and predicts 2PCFs via the conditional probability of the number of galaxies N in each halo as a function of the dark halo mass M_h , $P(N|M_h)$. The HOD model has successfully been applied to LRGs selected by several spectroscopic galaxy redshift surveys to reveal a biased relation between LRGs and the underlying dark matter as well as the redshift evolution of the LRG itself (e.g., Zheng et al. 2009; White et al. 2011; Guo et al. 2013; Parejko et al. 2013; Zhai et al. 2017). However, these galaxy redshift surveys focus only on luminous galaxies and hence they can cover only the limited redshift and stellar-mass ranges.

In this paper, we report clustering properties of photometric LRGs selected by the Subaru Telescope Hyper Suprime-Cam Subaru Strategic Program (HSC SSP; Aihara et al. 2018). HSC SSP is a deep and wide optical imaging survey utilizing the capability of the wide-field imaging camera Hyper Suprime-Cam (HSC; Miyazaki et al. 2018) mounted on the Subaru Telescope. Deep and wide-field photometric data of the HSC SSP and the sophisticated LRG-selection algorithm (CAMIRA; Oguri 2014) enable us to construct an LRG sample for a wide range of redshift and stellar mass, where redshifts are estimated using the photometric redshift (photo- z) technique. The main purpose of this paper is to study properties of LRGs as a function of the stellar mass and redshift through the clustering and the subsequent HOD analyses, and compare the result with that for photo- z -selected all galaxy samples containing both red and blue galaxies, where the latter result is also obtained in the same HSC SSP dataset (Ishikawa et al. 2020).

This paper is organized as follows. In Section 2, we present the details of our photometric data and LRG selection method using the CAMIRA algorithm (Oguri 2014; Oguri et al. 2018a). The clustering and HOD analyses of the LRG samples are shown in Section 3. Results obtained by the HOD analyses of the clustering of LRGs and comparison with the all galaxy samples are given in Section 4, discussion based on the HOD analysis is presented in Section 5. We give a conclusion in Section 6.

We employ the Planck 2015 cosmological parameters (Planck Collaboration et al. 2016); i.e., the matter, baryon, and dark energy density parameters are $\Omega_m = 0.309$, $\Omega_b = 0.049$, and $\Omega_\Lambda = 0.691$, respectively, the dimensionless Hubble parameter is $h = 0.677$, the amplitude of the linear power spectrum averaged over $8h^{-1}$ Mpc scale is $\sigma_8 = 0.816$, and the scalar spectrum index of the primordial power spectral is $n_s = 0.967$. Throughout this paper, dark halo masses and stellar masses are denoted as M_h and M_* with their units of $h^{-1}M_\odot$ and $h^{-2}M_\odot$, respectively. All of logarithm in this paper are common logarithm with base 10.

2. DATA AND SAMPLE SELECTION

An LRG catalog used in this study is obtained from the photometric data of the HSC SSP S16A Wide layer, which covers ~ 174 deg² in total (Aihara et al. 2018). LRGs are selected by Oguri et al. (2018a,b) using the CAMIRA algorithm (Oguri 2014). The CAMIRA fits magnitudes and colors of galaxies with a stellar population synthesis (SPS) model of Bruzual & Charlot (2003) with a fixed formation redshift of $z_f = 3$ and a prior on

the metallicity that depends on the stellar mass. The SPS model is designed to reproduce red-sequence in clusters of galaxies, and is also carefully calibrated such that it reproduce colors of spectroscopic LRGs accurately. Oguri et al. (2018b) apply this method to construct a photometric LRG catalog in HSC SSP S16A by selecting galaxies that are fitted well by the SPS model for LRGs. Additionally, in this paper we impose the **bright-star mask** flag to avoid noise signals originated mainly from saturated and crosstalk pixels around luminous stars on clustering signals. Furthermore, we manually mask noisy regions and edge of the survey fields by visual to obtain a reliable LRG catalog for clustering measurements. The final area of our survey field is ~ 124.31 deg² and it contains 615,317 LRGs at $0.1 \leq z \leq 1.05$.

In the CAMIRA LRG catalog, the stellar mass and photo- z of each LRG, which are derived by the CAMIRA algorithm (Oguri 2014), are available. The accuracy of photo- z 's of CAMIRA LRGs is tested in Oguri et al. (2018b) by comparing them with the spectroscopic redshifts that have already been obtained by other surveys. The scatter of photo- z 's, which is defined as a scatter of $(z_{\text{phot}} - z_{\text{spec}})/(1 + z_{\text{spec}})$ after 3σ clipping is found to be $\sim 2\%$, which is comparable to the accuracy of photo- z 's of LRGs selected by the redMaGiC algorithm (Roza et al. 2016). At $0.1 < z_{\text{phot}} < 1.05$, the outlier rate of the whole LRG samples is found to be $\sim 7\%$. Interested readers are referred to Oguri (2014) and Oguri et al. (2018a,b) for more details of the original CAMIRA LRG catalog and its photometric-redshift performance.

The LRG sample is divided into subsamples according to their stellar masses and photo- z 's. The stellar mass versus redshift diagram is shown in Figure 1. We adopt the redshift binning similar to that of Ishikawa et al. (2020) for easier comparisons of physical characteristics of our LRGs with those of photo- z -selected all galaxy samples containing both red and blue galaxies (hereafter photo- z galaxies) defined in Ishikawa et al. (2020) from the same dataset of HSC SSP S16A Wide layer as used in this paper. The redshift distribution of LRGs is shown in the top panel of Figure 2 and details of each subsample are presented in Table 1.

In addition, we also generate a random-point catalog that covers the entire field of the LRG catalog. The surface number density of the random catalog is set to ~ 35 arcmin⁻², which is ~ 100 times larger than that of the LRG catalog, in order to reduce the Poisson noise on clustering signals. The random points around bright stars and near edges of the fields are excluded in the same manner as in the LRG catalog.

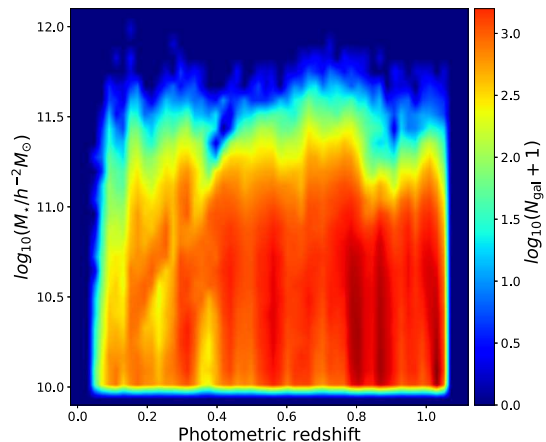

Figure 1. The stellar mass versus redshift diagram of the HSC SSP S16A photometric LRG sample used in this paper. Color indicates the differential abundance of LRGs in logarithmic scale at each cell.

3. CLUSTERING AND HOD ANALYSIS

3.1. Angular Auto-correlation Function

We measure angular auto-correlation functions (ACFs) of the LRG samples. ACFs are calculated using an estimator proposed by Landy & Szalay (1993) as:

$$\omega(\theta) = \frac{\text{DD} - 2\text{DR} + \text{RR}}{\text{RR}}, \quad (1)$$

where DD, DR, and RR denote the numbers of normalized pairs of galaxy–galaxy, galaxy–random, and random–random within the separation angle range of $\theta \pm \delta\theta$, respectively. In this paper, we measure ACFs in the angular scale range of $-3.4 \leq \log_{10}(\theta) \leq 0.0$ with the separation of $\log_{10}(\delta\theta) = 0.1$ in a degree scale.

An observed galaxy correlation function is underestimated at large-angular scales due to the finite survey field, known as the integral constraint (IC) (e.g., Groth, & Peebles 1977). We first calculate this effect by Monte Carlo integration as:

$$\text{IC} = \frac{\sum_i \theta_i^{1-\gamma} \text{RR}(\theta_i)}{\sum_i \text{RR}(\theta_i)}, \quad (2)$$

assuming that the ACF can be modeled by the power-law form $\omega(\theta) \propto \theta^{-\gamma}$ (Roche, & Eales 1999). The unbiased ACFs, ω_{true} , can be evaluated by correcting the observed ACFs, ω_{obs} , as:

$$\omega_{\text{true}}(\theta) = \omega_{\text{obs}}(\theta) \frac{\theta^{1-\gamma}}{\theta^{1-\gamma} - \text{IC}}. \quad (3)$$

We use the jackknife resampling method to evaluate errors of the ACFs (e.g., Norberg et al. 2009). We divide

Table 1. Details of Cumulative Stellar-mass Limited Subsamples

^dLRG number density in units of $10^{-3}h^{-3}\text{Mpc}^3$

our survey field into 123 subfields, each of which covers $\sim 1 \text{ deg}^2$, and calculate the ACFs 123 times, removing each subfield. The covariance matrix can be computed as:

$$C_{ij} = \frac{N-1}{N} \sum_{k=1}^N (\omega_k(\theta_i) - \bar{\omega}(\theta_i)) (\omega_k(\theta_j) - \bar{\omega}(\theta_j)), \quad (4)$$

where $N = 123$, C_{ij} is an (i, j) element of the covariance matrix, $\omega_k(\theta_i)$ is the ACF of the i th angular bin of the k th jackknife realization, and $\bar{\omega}(\theta_i)$ is the ACF with the i th angular bin averaged over the N realizations, $\bar{\omega}(\theta_i) = N^{-1} \sum_{k=1}^N \omega_k(\theta_i)$.

3.2. HOD Analysis

3.2.1. Methodology

We use an HOD formalism for interpreting the observed ACFs and link the LRGs to their host dark halos (e.g., Seljak 2000; Berlind & Weinberg 2002). The HOD model parameterizes the occupation of galaxies as a function of dark halo mass and predicts galaxy correlation functions according to the assumed galaxy distribution within dark halos. In this study, we adopt the standard galaxy occupation function proposed by Zheng et al. (2005) for the distribution of our LRG samples within dark halos. The total number of LRGs within a dark halo with mass M_h , $N_{\text{tot}}(M_h)$, can be decomposed into the central and satellite components, N_c and N_s , respectively, and is described as:

$$N_{\text{tot}}(M_h) = N_c(M_h) [1 + N_s(M_h)]. \quad (5)$$

In the HOD model of Zheng et al. (2005), the occupations of central and satellite galaxies are written as:

$$N_c(M_h) = \frac{1}{2} \left[1 + \text{erf} \left(\frac{\log_{10} M_h - \log_{10} M_{\text{min}}}{\sigma_{\log M}} \right) \right], \quad (6)$$

$$N_s(M_h) = \left(\frac{M_h - M_0}{M_1} \right)^\alpha. \quad (7)$$

There are five free HOD parameters in the above occupation functions; M_{min} is the characteristic mass to host a central galaxy, M_1 is a mass for a halo with a central galaxy to host one satellite, M_0 is the mass scale to truncate satellites, $\sigma_{\log M}$ is the characteristic transition width, and α is the slope of the power law for the satellite HOD. Once a set of these parameters is given, one can uniquely compute the three-dimensional power spectrum, which is then converted to the angular correlation function, $\omega_{\text{HOD}}(\theta)$. Previous studies successfully reproduced galaxy clustering of LRGs (e.g., Zheng et al. 2009; Zhai et al. 2017) and massive red galaxies (e.g., Brown et al. 2008; Matsuoka et al. 2011) at $z < 1$ using the above occupation functions.

The HOD parameters are constrained by comparing the observed ACF with the predicted one from the HOD model using the χ^2 statistic. The χ^2 is computed as:

$$\chi^2 = \sum_{i,j} [\omega_{\text{true}}(\theta_i) - \omega_{\text{HOD}}(\theta_i)] (C_{ij}^{-1}) [\omega_{\text{true}}(\theta_j) - \omega_{\text{HOD}}(\theta_j)] + \frac{(n_g^{\text{obs}} - n_g^{\text{HOD}})^2}{\sigma_{n_g}^2}, \quad (8)$$

where $\omega_{\text{HOD}}(\theta_i)$ is the ACFs of i th angular bin from the HOD model, n_g^{obs} is the observed number density of galaxies (see Table 1), σ_{n_g} is its uncertainty, and n_g^{HOD} is the number density predicted by the HOD model

$$n_g^{\text{HOD}} = \int dM_h \frac{dn}{dM_h} N(M_h), \quad (9)$$

where dn/dM_h is a halo mass function. In calculating the inverse covariance matrix, C_{ij}^{-1} , from equation (4), we apply a correction factor presented by Hartlap et al.

(2007) to avoid underestimating the inverse covariance due to the finite realization effect.

The uncertainty of the observed number density, σ_{n_g} , takes account of the effect of the photo- z errors. While it has been confirmed that the CAMIRA LRG samples are less affected by photo- z uncertainties compared to all photo- z galaxies, we conservatively introduce 10% uncertainties on the galaxy abundance that takes account of photo- z errors and some of unknown systematic biases as is the case with Zhou et al. (2021).

To predict ACFs from the HOD framework, one needs to calculate several quantities analytically. We employ a halo mass function proposed by Sheth, & Tormen (1999), an NFW profile (Navarro et al. 1997) as a density profile of dark halos, the mass and redshift dependence of a concentration parameter presented by Takada, & Jain (2003), and a large-scale halo bias of Tinker et al. (2010) with a halo exclusion effect (Zheng 2004; Tinker et al. 2005). We use the non-linear power spectrum of Smith et al. (2003) with a matter transfer function of Eisenstein, & Hu (1998).

3.2.2. Photo- z error estimation

Although the redshift distributions of LRGs using the best-fitting photo- z 's are already evaluated in the top panel of Figure 2, they are likely different from the true redshift distributions of LRGs due to photo- z uncertainties. Therefore, it is essential to use redshift distributions that take full account of photo- z errors in the HOD-model analysis to fit observed ACFs. To take account of photo- z errors that induce tails of the distribution at each redshift bin boundary in the interpretation of observed clustering, we recalculate redshift distributions of LRGs by considering those uncertainties.

The redshift distribution of the LRGs including photo- z errors is evaluated as follows. First, we focus on LRGs whose spectroscopic redshifts have already been measured by other surveys and calculate the scatter of photometric redshifts σ_z of the residual of both redshifts, i.e., $(z_{\text{phot}} - z_{\text{spec}})/(1 + z_{\text{spec}})$, where z_{phot} and z_{spec} respectively refer to photometric and spectroscopic redshifts of each LRG. It should be noted that the LRGs with spec- z information account for only $\sim 5.3\%$ of the total LRG sample. The photo- z scatter is evaluated by calculating the root mean square of the residual after excluding outliers that satisfy $|z_{\text{phot}} - z_{\text{spec}}|/(1 + z_{\text{spec}}) > 0.15$. The fraction of outlier LRGs among those with spec- z 's is $\sim 2.2\%$. The scatter of photo- z is estimated as a function of both stellar mass and redshift bins with bin sizes of $\delta \log_{10}(M_*/M_\odot) = 0.1$ and $\delta z = 0.1$, respectively. The middle panel of Figure 2 shows the scatter of photo- z 's at various stellar-mass slices as a function

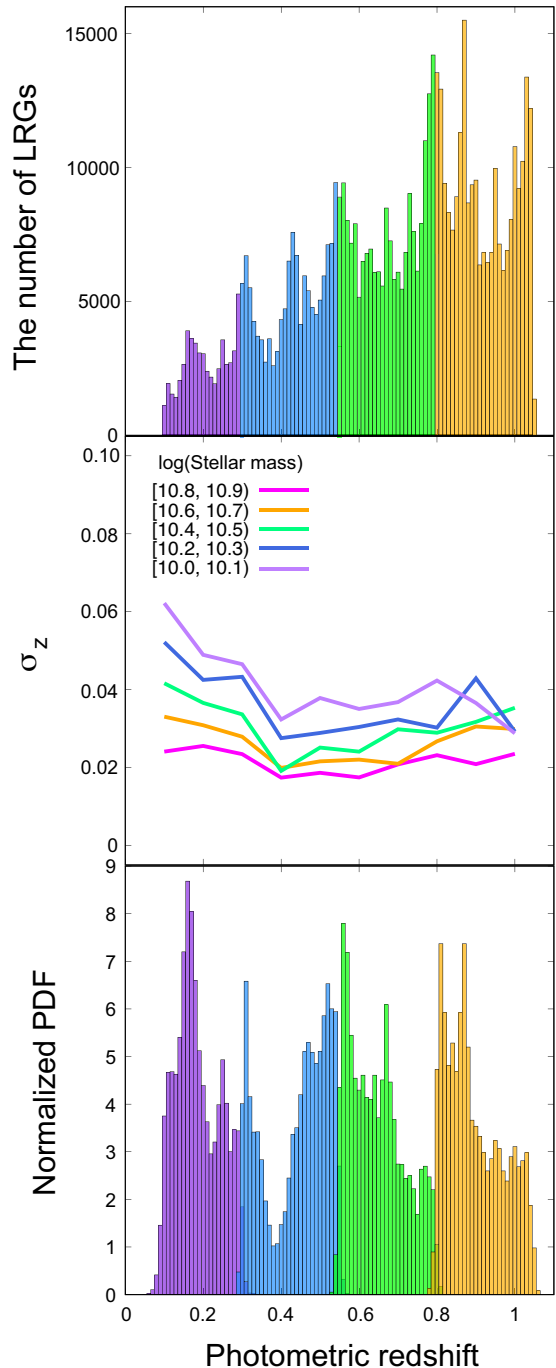

Figure 2. Top: Redshift distribution of the LRG sample. LRGs are divided into four redshift bins: $0.10 \leq z < 0.30$ (purple), $0.30 \leq z < 0.55$ (blue), $0.55 \leq z < 0.80$ (green), and $0.80 \leq z \leq 1.05$ (orange). Middle: Scatter of photo- z 's as a function of photo- z . These scatters are evaluated after excluding outliers (see text for more details). Different colors indicate results for different stellar-mass slices. Bottom: Redshift distribution of total LRGs at each redshift bin that takes account of the photo- z errors. Colors indicate the redshift bins defined in the top panel.

Figure 3. Observed ACFs of LRGs (circles) and their best-fitting ACFs derived by the HOD model (solid lines) at $0.10 \leq z < 0.30$ (top left panel), $0.30 \leq z < 0.55$ (top right panel), $0.55 \leq z < 0.80$ (bottom left panel), and $0.80 \leq z \leq 1.05$ (bottom right panel) redshift bins, respectively. In the HOD fitting procedure, correlations between angular bins are taken into consideration by covariance matrices calculated by the jackknife resampling method. Amplitudes of ACFs are shifted arbitrarily for an illustrative purpose.

of photo- z . As expected, less massive and high- z LRGs tend to have larger photo- z uncertainties.

Using the estimated photo- z scatter, photo- z 's of individual LRGs are randomly reassigned assuming the Gaussian distribution. We repeat this procedure 100 times in order to obtain averaged redshift distributions including the photo- z error of each LRG. The bottom panel of Figure 2 shows the LRG redshift distribution for each redshift bin obtained by the above procedure. These redshift distributions including the photo- z errors are used in the following HOD analysis.

3.2.3. HOD-model fitting

We explore the HOD parameters of each subsample that reproduce the observed ACFs. The HOD param-

eters are constrained using a population Monte Carlo (PMC; Wraith et al. 2009) algorithm. The PMC is an importance sampling method that obtains new samples from a proposal distribution, and the posterior updates the proposal distribution iteratively. We use the COSMOPMC package (Kilbinger et al. 2011) to derive mean values and 1σ confidence intervals of the HOD parameters. The confidence region is evaluated by integrating the normalized posterior of the final iteration from the mean values to the points that reach $\pm 63.27/2\%$.

Results of the HOD-model fitting are shown in Figure 3 and the best-fitting parameters are listed in Table 6. The HOD model successfully reproduces the observed ACFs of LRGs over the whole ranges of the an-

gular scales, the stellar mass, and the redshift explored in this paper. The HOD halo mass parameters M_{\min} and M_1 are tightly constrained thanks to the accurate photo- z 's as well as the large sample size achieved by the large survey volume of the HSC SSP.

4. RESULTS

In this section, we present constraints on physical parameters of LRGs and their host halos based on the HOD modeling. We show constraints on the halo mass parameters, M_{\min} and M_1 , in Figure 4, the satellite fraction of LRGs, f_s , in Figure 5, and the large-scale galaxy bias, b_g , in Figure 6. In each figure, the left panel compares our constraints to those for LRGs in the literature based on different surveys (Ross et al. 2007, 2008; Brown et al. 2008; Zheng et al. 2009; White et al. 2011; Zehavi et al. 2011; Nikoloudakis et al. 2013; Parejko et al. 2013; Zhai et al. 2017) as a function of the galaxy number density. It is noted that the halo occupation function of central LRGs adopted by Zehavi et al. (2011) and Nikoloudakis et al. (2013) are different from that in the other studies. The right panel compares our constraints to those for the photo- z galaxies including both red and blue galaxies from the same HSC survey (Ishikawa et al. 2020) as a function of the stellar mass threshold. We will discuss these results in more detail in the following subsections.

4.1. M_{\min} and M_1

Here we investigate the redshift evolution of the HOD halo mass parameters, M_{\min} and M_1 . By definition, M_{\min} is a halo mass for which the expected number of central galaxy occupation is 50%, whereas M_1 is a typical mass of a halo that is expected to possess one satellite galaxy. We do not discuss the other halo mass parameter in our HOD model, M_0 , since it has large uncertainties ($\sim \pm 2$ dex errors in typical cases).

First, we compare the constraints on M_{\min} and M_1 for CAMIRA LRGs with those for LRGs from previous HOD studies to check the consistency among them. Thanks to the wide survey area and deep imaging data of the HSC SSP Wide layer, we successfully determine the HOD halo mass parameters for wide stellar mass and redshift ranges as shown in the left panel of Figure 4. Our constraints, particularly on M_{\min} , show excellent agreement with those of the previous studies. The constrained values of M_{\min} and M_1 are tightly correlated with the number density of LRGs and approximately follow power-law relations with negative slopes, $M_{\min} \propto n_g^{-0.8}$ and $M_1 \propto n_g^{-1.0}$, which are depicted by the cyan and magenta lines, respectively. The difference of their slopes indicates that the formation efficiency of

massive satellite LRGs is much lower than that of massive central LRGs at each epoch. Interestingly, while the parameter M_{\min} does not depend on redshift, M_1 exhibits a slight redshift evolution such that the LRGs at lower redshift have slightly higher M_1 for a given galaxy number density.

Next, in the right panel of Figure 4 we compare our constraints on the HOD mass parameters for LRGs to those for the different galaxy population, the photo- z galaxies, obtained from the same HSC survey (Ishikawa et al. 2020). The stellar masses and photometric redshifts of the HSC photo- z galaxies are evaluated through a template spectral energy distribution-fitting technique with Bayesian priors on the galaxy physical properties (MIZUKI; Tanaka 2015). The photo- z galaxies are selected using the same HSC SSP S16A Wide layer dataset as the one used in this paper, but without imposing any color cuts. Hence, our LRG sample is a subset of the HSC photo- z galaxy sample that includes both red and blue galaxies. Since the assumed initial mass functions (IMFs) for the stellar-mass estimation are different between the LRGs and photo- z galaxies such that stellar masses of the LRGs are evaluated assuming the Salpeter IMF (Salpeter 1955) and those of photo- z galaxies are estimated assuming the Chabrier IMF (Chabrier 2003), we multiply by a factor of 1.65 to the stellar masses of the photo- z galaxies to account for the offset of stellar masses introduced by the different IMFs.

One of the largest differences between these two populations is that M_{\min} of LRGs increases less rapidly with increasing the stellar-mass threshold for all the redshift bins except for the lowest- z bin, indicating that the dark halo mass is the key parameter for the formation of central LRGs. There are many quenching models that explain the formation of red-sequence galaxies, including the mass quenching (e.g., Peng et al. 2010, 2012; Geha et al. 2012) and the environmental quenching (e.g., Gunn & Gott 1972; van den Bosch et al. 2008; Wetzel et al. 2013), and various physical mechanisms, such as a hot-halo quenching due to the virial-shock heating (e.g., Birnboim & Dekel 2003; Dekel et al. 2009) and the radio-mode AGN feedback (e.g., Kereš et al. 2009; Gabor et al. 2011), have been proposed to quench star formation according to their stellar masses and/or dark halo masses. We will discuss the implication of our results on the quenching models and the formation scenario of LRGs in Section 5.

In addition, values of M_{\min} for LRGs are significantly larger than those for the photo- z galaxies at the low stellar mass end. Since the HSC photo- z galaxies consist of both star-forming and passive galaxies, this result sug-

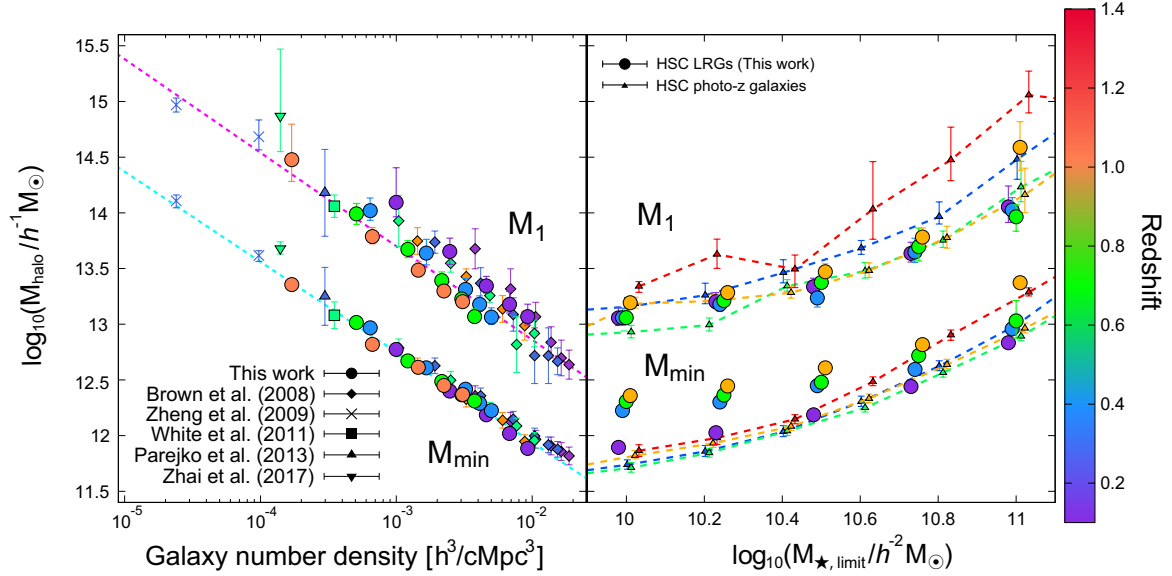

Figure 4. Left: Observed HOD halo mass parameters (M_{min} and M_1 in logarithmic scales) of LRGs as a function of the number density of galaxies. Different colors show the different redshift range as indicated by the color bar on the right side of the figure, both for our results and results in the literature. Dashed cyan and magenta lines are best-fitted power-law slopes for our results of M_{min} and M_1 , respectively. Right: HOD halo mass parameters (M_{min} and M_1 in logarithmic scales) of LRGs (circles) and HSC photo-z galaxies (triangles) as a function of the stellar-mass threshold. Different colors show the different redshift ranges. Symbols are slightly shifted along the horizontal axis for illustrative purpose.

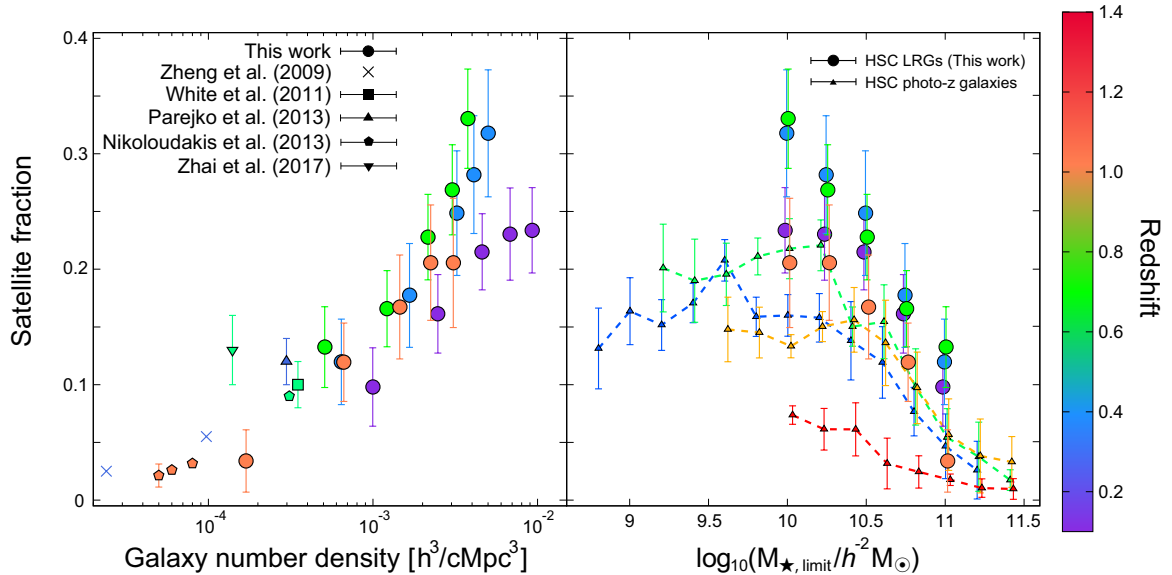

Figure 5. Similar to Figure 4, but for the satellite fraction.

gests that low-mass central LRGs reside in more massive dark halos compared to the photo-z galaxies with similar stellar masses, for which star-forming galaxies dominate the overall photo-z galaxy population.

In contrast to M_{min} , M_1 of LRGs shows the stellar-mass dependence similar to that obtained for the photo-z galaxies. Our results show that M_1 of LRGs evolves little with redshift at a fixed stellar mass, whereas those

of photo-z galaxies appear to have stronger redshift dependence. However, since M_1 contains relatively large uncertainties compared to M_{min} , it is difficult to draw a definitive conclusion from the current observational results.

4.2. Satellite fraction

In this subsection we focus on the fraction of LRGs that are satellites, which can be determined from the

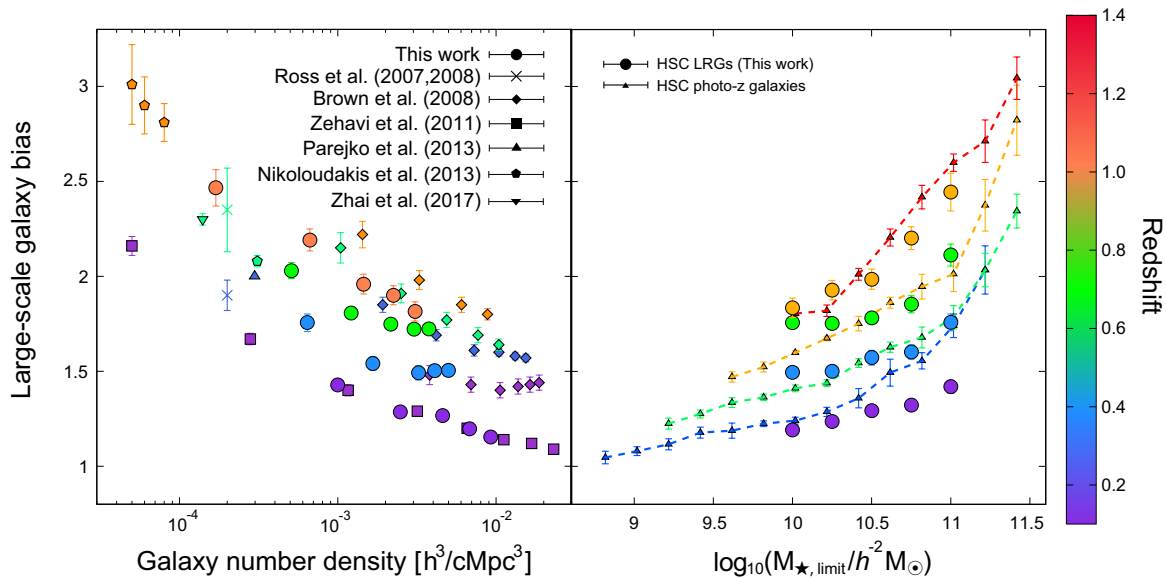

Figure 6. Similar to Figure 4, but for the large-scale galaxy bias.

constrained HOD parameters. Specifically, the satellite fraction f_s can be calculated as:

$$f_s = 1 - f_c = 1 - \frac{1}{n_g^{\text{HOD}}} \int dM_h \frac{dn}{dM_h} N_c(M_h), \quad (10)$$

where f_c represents the fraction of central galaxies. In the left panel of Figure 5, we show the satellite fraction of LRGs as a function of the galaxy number density and compare them with those in the literature. While there are no data from previous studies in the high number density region explored in this paper ($n_g > 10^{-3} (h/\text{cMpc})^3$), satellite fractions obtained by Zheng et al. (2009), White et al. (2011), and Nikoloudakis et al. (2013) appear to be consistent with the extrapolations of our f_s values to the lower galaxy number densities. The satellite fraction of Zhai et al. (2017) is larger than those of the other studies as well as the extrapolation of our result, although the discrepancy is at most $\sim 1.5\sigma$ level and is not significant.

Differences of the satellite fraction between the LRGs and photo- z galaxies are presented in the right panel of Figure 5. We find that, when compared for the same stellar mass limit, satellite fractions of the LRGs are higher than those of the photo- z galaxies irrespective of their stellar-mass and redshift ranges, indicating that systems that consist of a central LRG and satellite LRGs are ubiquitous at least up to $z = 1.05$. Using a SDSS group catalog and cosmological N -body simulations, Wetzel et al. (2013) proposed a “delayed-then-rapid” quenching scenario, in which SFRs of infalled satellites keep evolving for a few Gyr after the infall, and then they quench with a short time scale. In this

scenario, stellar masses of the infalled satellites can grow as much as those of the centrals in the same halo. This scenario can explain our observational results that the satellite fraction of LRGs is higher than that of photo- z galaxies and drastically increases with redshift.

Observational studies have found that physical characteristics of galaxies correlate with nearby galaxies and/or their environments, known as a galactic conformity effect (e.g., Weinmann et al. 2006; Kauffmann et al. 2010). The 1-halo conformity, which is an association of physical properties of central galaxies with those of satellite galaxies within the same dark halos, is well studied at $z < 1$, which indicates that passive satellite galaxies are likely to be hosted by passive central galaxies (Hartley et al. 2015; Berti et al. 2017). The high values of LRG satellite fractions imply that the environmental quenching is effective for the wide stellar-mass range even for LRGs. In addition, LRGs are known as a galaxy population that formed in high-redshift Universe and observed in their old and passively evolving phase (e.g., Eisenstein et al. 2001). Therefore, the high satellite fraction of LRGs may also be explained by merging events experienced in their long evolving history.

4.3. Galaxy bias

In this subsection we discuss the relation of the spatial clustering between galaxies and underlying dark matter. It is quantified by a large-scale galaxy bias, b_g , which can be evaluated through a set of given HOD parameters as:

$$b_g = \frac{1}{n_g^{\text{HOD}}} \int dM_h b_h(M_h) \frac{dn}{dM_h} N(M_h), \quad (11)$$

where $b_h(M_h)$ is the large-scale halo bias (Tinker et al. 2010).

The galaxy biases calculated for our LRG sample using the equation (11) and those in the literature are presented in the left panel of Figure 6. Our results are in good agreement with those of Ross et al. (2007, 2008), Zehavi et al. (2011), Parejko et al. (2013), Nikoloudakis et al. (2013), and Zhai et al. (2017). However, galaxy biases measured by Brown et al. (2008) are systematically larger than those in the other studies. A possible reason of this discrepancy is the difference of procedures to select LRGs. Studies using data obtained in the SDSS adopt a color selection described in Eisenstein et al. (2001), which is based on the SDSS *ugriz* optical magnitudes (Fukugita et al. 1996), and the CAMIRA algorithm is also designed to select red-sequence galaxies with colors similar to SDSS LRGs. However, Brown et al. (2008) selected red galaxies from the bimodal galaxy distribution in the rest-frame ($U - V$) color versus V -band absolute magnitude diagram presented by Bell et al. (2004). Therefore, physical characteristics of galaxies of Brown et al. (2008) can be slightly different from those in other LRG studies, which might explain the difference mentioned above. In addition, the difference of the cosmological parameters may partly explains the discrepancy. To check this possibility, we repeat our HOD analysis of the LRG sample at each redshift bin adopting the *WMAP3* cosmologies (Spergel et al. 2007) as adopted in Brown et al. (2008), and find that the resulting galaxy biases increase by a few percents on average compared to our original analysis, and hence reduces the discrepancy between our result and the Brown et al. (2008) result.

We compare the galaxy biases of the LRGs with those of the photo- z galaxies in the right panel of Figure 6. Our results indicate that galaxy biases of low-mass LRGs satisfying $M_* \lesssim 10^{10.5} h^{-2} M_\odot$ depend only weakly on stellar masses and the galaxy biases rapidly increases with increasing stellar masses at the high stellar mass end. While the stellar-mass dependence of the photo- z galaxies shows a trend similar to the LRGs, galaxy biases of the photo- z galaxies at $10^{10.0} \lesssim M_{*,\text{limit}}/h^{-2} M_\odot \lesssim 10^{10.5}$ show stronger dependence on the stellar mass, which is consistent with the trend found for M_{min} . The rapid increase of the galaxy biases of the LRGs indicates that only the most massive LRGs are highly biased objects in low- z , whereas even intermediate-mass LRGs ($M_* \sim 10^{10.5} h^{-2} M_\odot$) are rare at $z \sim 1$.

5. DISCUSSION

5.1. Correlation between the LRG formation and the dark halo mass

As shown in Figure 5, the satellite fraction of LRGs is much higher compared to the all photo- z sample when compared for the same stellar masses, indicating that LRGs tend to reside in more dense regions. Observational studies have found that the galaxy quenching is much more efficient in dense regions (e.g., Peng et al. 2010, 2012), and this environmental quenching effect can be triggered by the galaxy harassment (Moore et al. 1996) and the ram-pressure stripping (Gunn & Gott 1972). Therefore, the environmental quenching that is efficient in high-density environments can play an important role in the formation of LRGs.

Interestingly, we also find that dark halo masses of central LRGs (i.e., M_{min}) is tightly correlated with the number density of LRGs in all the redshift range we examined, $0.1 < z < 1.05$ (Figure 4), which may not be explained well by the environmental quenching that is caused by the interactions with surrounding galaxies. This may imply that the global environment as well as the local environment can have an impact on the galaxy quenching.

In addition, Figure 4 shows that halo masses of central LRGs are almost constant at $M_* \lesssim 10^{10.75} h^{-2} M_\odot$ at $z > 0.3$, which supports the idea that the halo mass is the key parameter for the galaxy quenching mechanism and the formation of LRGs. The halo quenching is also the galaxy quenching model caused by the disturbance of star-forming activities due to e.g., the virial shock heating (e.g., Birnboim & Dekel 2003; Dekel & Birnboim 2006). Our results suggests that $M_h \sim 10^{12.5 \pm 0.2} h^{-1} M_\odot$ is the threshold dark halo mass such that galaxies hosted by those dark halos are efficiently transformed into the LRGs irrespective of the baryonic properties, which is consistent with the conclusion of Woo et al. (2013).

In short, the formation of LRGs is largely connected to the environment of host dark halos of LRGs, but the internal effect, such as the AGN feedback, can also contribute to the suppression of star formation to some extent. Our results suggest that $M_h \sim 10^{12.5 \pm 0.2} h^{-1} M_\odot$ is the critical halo mass for the formation of LRGs, at least for LRGs with stellar masses of $M_* \lesssim 10^{10.75} h^{-2} M_\odot$ at $z > 0.3$. We leave the exploration of the different behavior of the stellar mass dependence of halo masses at $z < 0.3$ to future work.

5.2. Mass assembly history and evolution of LRGs

The evolution of the dark halo mass also provides a clue to the evolution of galaxies. In this subsection, we trace the evolution of median dark halo masses of central

LRGs, i.e., M_{\min} , from $z \sim 1$ to $z = 0$ for connecting our LRGs at the highest- z bin with those at lower- z bins using the IllustrisTNG simulation (Springel et al. 2018).

We use the TNG100 simulation, which well reproduces observational stellar-mass functions even at $z \sim 1$ (Pillepich et al. 2018). The definition of the stellar mass is the total mass of stellar particles within twice the stellar half mass radius obtained by the SUBFIND algorithm (Springel et al. 2001), while that of the halo mass is the total mass of dark matter particles that consists of dark halos identified by the friend-of-friend algorithm. Red-sequence galaxies from the TNG100 simulation (hereafter TNG LRGs) are selected according to their stellar masses and star-formation rates, which is in the same manner as in Moustakas et al. (2013), and we select them only at $z = 0.92$ that corresponds to the effective redshift of our z_4 redshift bin. Three stellar-mass limited samples satisfying $\log_{10}(M_{\star, \text{limit}}/h^{-2}M_{\odot}) \geq 10.0$, 10.5, and 11.0 are prepared. For each sample, we trace the halo mass of each TNG LRGs from $z = 0.92$ to 0 and derive the evolutionary history of the median halo mass of each stellar-mass limited sample.

Figure 7 shows the evolution of the median halo masses and the root mean square of masses of the TNG LRGs. Again, we emphasize that in the TNG LRGs are selected only at $z = 0.92$ satisfying the stellar-mass limits of $\log_{10}(M_{\star, \text{limit}}/h^{-2}M_{\odot}) \geq 10.0$ (blue), 10.5 (green), and 11.0 (red), and evolutionary tracks of halo masses indicate the assembly history of halo masses those LRGs from $z = 0.92$ to today.

First, we check the consistency of the median halo masses at $z = 0.92$. We find that the median halo masses of our observed LRGs show excellent agreement with those from the simulation, which indicates the consistency between the observation and the simulation. Then we investigate the relation between HSC LRGs at $z = 0.92$ and $z < 0.92$ by comparing the observed halo masses with the evolutionary history of the median halo masses from $z = 0.92$ to 0. By matching halo masses at each redshift bin, we find that the low-mass LRGs at z_4 ($z \sim 0.92$) evolve into the intermediate-mass LRGs at z_3 ($z \sim 0.65$) and z_2 ($z \sim 0.45$) bins and finally evolve into the high-mass LRGs at z_1 ($z \sim 0.2$). While LRGs are thought to be passively evolving galaxies, the halo mass accretion history indicates that low-mass LRGs at $z = 0.92$ increase their stellar masses by an order of magnitude from $z = 0.92$ to 0. Next, we check the evolution of high-mass LRGs at $z = 0.92$. The halo mass of high-mass central LRGs at z_4 is expected to reach $\sim 10^{14}h^{-1}M_{\odot}$ at $z = 0$, which corresponds to the halo masses of galaxy clusters. Therefore, progenitors

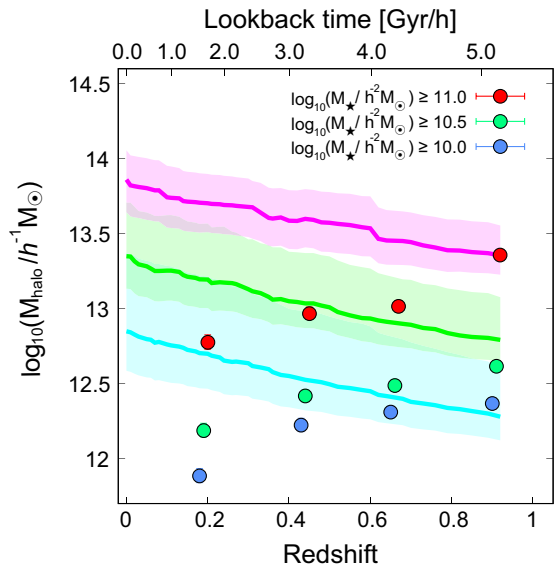

Figure 7. Evolution of median dark halo masses as a function of redshift. Circles show M_{\min} of the HSC LRGs with different stellar-mass thresholds. Lines indicate median halo mass accretion histories traced by the IllustrisTNG simulation and shade regions show the root mean squares of the halo masses in the simulation at each redshift. Specifically, LRG-like galaxies in the IllustrisTNG are selected by imposing the same stellar-mass threshold of circles with corresponding colors at $z = 0.92$, and the evolution of halo masses of host halos of these LRGs are traced from $z = 0.92$ to 0. Our result implies that a halo which hosts LRGs with the stellar mass of $M_{\star} \geq 10^{10}h^{-2}M_{\odot}$ at $z = 0.9$ tends to host those with $M_{\star} \geq 10^{11}h^{-2}M_{\odot}$ at $z = 0$.

of BCGs of local clusters can be the massive LRGs at $z \sim 1$.

However, previous studies have shown that LRGs increase their stellar masses at most $\sim 30 - 50\%$ through mergers since $z \sim 1$ (Cool et al. 2008; Skelton et al. 2012; López-Sanjuan et al. 2012). In addition, Banerji et al. (2010) found that massive LRGs with stellar masses of $M_{\star} > 10^{11}M_{\odot}$ complete their stellar mass assembly by $z \sim 0.8$. These observational results appear to be inconsistent with the evolutionary scenario of the low-mass LRGs that we speculated above via the halo mass evolution. This discrepancy can be explained by a large contribution of LRGs from other galaxy populations. Put another way, our result implies that most of massive ($\log_{10}(M_{\star, \text{limit}}/h^{-2}M_{\odot}) \geq 11$) LRGs at $z \sim 0.2$ are not descendants of LRGs with similar stellar masses at $z \sim 1$, but they are recently migrated from other galaxy populations. The large difference of their number densities shown in Table 1 supports this interpretation. One possible scenario is the contribution from green valley galaxies (or star-forming galaxies), which are not in-

cluded in our LRG sample but can turn into LRGs by an efficient quenching.

As mentioned above, the majority of the low-mass LRGs is not expected to experience significant stellar mass growth from $z \sim 1$ to 0. However it is still possible that some minor fraction of massive LRGs evolved from less massive LRGs through mergers and satellite. The redshift dependence of the satellite fraction (the right panel of Figure 5) shows an increasing trend from $z \sim 1$ to $z \sim 0.3$ and then decreases to $z \sim 0.1$ at a fixed stellar-mass threshold. Therefore possible scenario that partly explains our results is that low-mass LRGs accrete onto more massive halos to become satellite galaxies and also grow their stellar masses by mergers at $0.3 < z < 0.9$, and then those satellite LRGs merge into central LRGs at $z < 0.3$.

6. SUMMARY

We have presented the clustering analysis of LRGs selected in the HSC SSP S16A Wide layer covering $\sim 124 \text{ deg}^2$ (Aihara et al. 2018). We have used 615,317 LRGs selected by the CAMIRA algorithm (Oguri 2014) with photometric redshift and stellar mass measurements to investigate the dependence of clustering and physical properties of LRGs on their redshifts and the stellar masses. We have derived, for the first time, the relation between LRGs and their host dark halos as a function of their stellar masses using the HOD formalism and compared them with those obtained in the literature to check the consistency. Our results have also been compared with those of the photo- z galaxies including both red and blue galaxies selected from the same HSC SSP S16A Wide layer (Ishikawa et al. 2020) to highlight the difference between LRGs and normal galaxies.

The major findings of this study through the HOD analysis are summarized as follows:

1. The characteristic dark halo masses of central galaxies M_{min} is tightly correlated with the number densities of the LRGs irrespective of redshifts, which is consistent with previous studies. The mass of a halo to host one LRG satellite galaxy, M_1 , also follows a power-law relation as a function of the number density as in the case of M_{min} , although the relation is not as tight as for M_{min} and shows some redshift evolution.
2. The characteristic dark halo mass M_{min} depends only weakly on the stellar mass at $M_\star \lesssim 10^{10.75} h^{-2} M_\odot$, which indicates that the dark halo mass is the key parameter for the formation of the LRGs rather than the stellar mass. We have found that $M_h \sim 10^{12.5 \pm 0.2} h^{-1} M_\odot$ is the critical

dark halo mass for the LRG formation, at least for LRGs with stellar masses $M_\star \lesssim 10^{10.75} h^{-2} M_\odot$ at $0.3 < z < 1.05$. This threshold halo mass is expected to be originated from the halo quenching mechanism due to the halo environment.

3. The satellite fractions of the LRGs are much higher compared to those of the photo- z galaxy sample all the redshift and stellar mass ranges examined in this paper, which indicates that the LRGs tend to reside in high density environments even at $z \sim 1$. Moreover, the high satellite fractions of LRGs are indicative of the 1-halo galactic conformity up to $z \sim 1$.
4. We have found that the large-scale galaxy bias of LRGs monotonically increases with increasing stellar mass and redshift. At a fixed redshift, the increasing trend drastically changes at the massive end such that only the most massive LRGs are highly biased objects in low- z and even the intermediate-mass LRGs ($M_\star \sim 10^{10.5} h^{-2} M_\odot$) are rare at $z \sim 1$.
5. We compare the observed median halo masses of central HSC LRGs (M_{min}) with those derived from the IllustrisTNG simulation. The median halo masses of our HSC LRGs at $0.8 \leq z \leq 1.05$ calculated by the HOD analysis show excellent agreement with those in the simulation at $z = 0.92$. By comparing our results with the evolution of halo masses from $z = 0.92$ to 0 in the simulation, we argue that low-mass LRGs at $z \sim 1$ can evolve into intermediate-mass LRGs at $0.3 \lesssim z \lesssim 0.8$ and high-mass LRGs at $z \sim 0.2$. Such stellar mass growth may be realized by galaxy mergers and satellite accretions. On the other hand, the comparison suggests that massive LRGs at low redshifts are mainly formed from green valley galaxies or evolved from less massive LRGs through mergers and satellite accretions.

This paper has presented the first clustering analysis of the HSC LRGs and demonstrated its power for studying the large-scale structure. One possible application of the HSC LRGs may be the detection of baryon acoustic oscillations (BAO; Eisenstein et al. 2005; Okumura et al. 2008) to constrain cosmological parameters. While the sample used in this paper is not large enough for this purpose, the latest LRG catalog (Oguri et al. in prep.) covers a survey volume large enough for the detection of BAO. For such cosmological analysis, three-dimensional clustering in redshift space

rather than the angular clustering analyzed in this paper will be more suited, as done for a similar sample by Chiu et al. (2020). Analyzing the BAO encoded in the LRGs in the HSC survey will enable us to constrain the acoustic scale up to high redshifts, $z \lesssim 1.4$.

In addition, correlation functions in redshift space also enable us to test the theory of the structure formation based on the general relativity via redshift-space distortions (e.g., Davis & Peebles 1983; Guzzo et al. 2008; Okumura et al. 2016). Large and deep samples of the HSC LRG can constrain the growth rate of the Universe up to $z \sim 1.4$ with high precision by analyzing the redshift-space distortion. Moreover, combining the two-point correlation function derived in this paper with weak-lensing signals can constrain cosmological parameters since the degeneracy between cosmological parameters and the galaxy bias can be resolved (e.g., Cacciato et al. 2009; Abbott et al. 2018). This paper presents a first step toward testing the structure formation theory as well as the Λ CDM cosmological model using the two-point (and higher order) statistics of unique HSC photometric LRG samples.
