

On-Chain Auctions with Deposits

JAN CHRISTOPH SCHLEGEL, City, University of London, United Kingdom

AKAKI MAMAGEISHVILI, ETH Zurich, Switzerland

Second-price auctions with deposits are frequently used in blockchain environments. An auction takes place on-chain: bidders deposit an amount that fully covers their bid (but possibly exceeds it) in a smart contract. The deposit is used as insurance against bidders not honoring their bid if they win. The deposit, but not the bid, is publicly observed during the bidding phase of the auction.

The visibility of deposits can fundamentally change the strategic structure of the auction if bidding happens sequentially: Bidding is costly since deposit are costly to make. Thus, deposits can be used as a costly signal for a high valuation. This is the source of multiple inefficiencies: To engage in costly signalling, a bidder who bids first and has a high valuation will generally over-deposit in equilibrium, i.e. deposit more than he will bid. If high valuations are likely there can, moreover, be entry deterrence through high deposits: a bidder who bids first can deter subsequent bidders from entering the auction. Pooling can happen in equilibrium, where bidders of different valuations deposit the same amount. The auction fails to allocate the item to the bidder with the highest valuation.

1 INTRODUCTION

On-chain implementations of auctions often take the following form: bidders deposit an amount that fully covers their bid in a smart contract. The deposit is used as insurance against bidders not honoring their bid if they win. The deposit, but not the bid, is publicly observed during the bidding phase of the auction. In the case of a second-price (VCG) auctions, [12], the procedure is the following. After bidding is closed the winner is determined by evaluating the non-public bids. The highest bid wins and the winner pays the second highest bid. Leftover deposits are repaid.

Often it is claimed that this auction format is equivalent to a standard second-price auction without depositing. While this is indeed a good approximation if the value of the auctioned item is relatively small for all bidders, the auction has fundamentally different properties if the value of the item is substantial for many bidders. In particular, we claim that this auction format can be vulnerable to entry-deterrence strategies. To illustrate this point consider the instance of the top-level domain (TLD) auction on "namebase.io" for the TLD ".scholar" as reproduced in Figure 1: namebase.io is an example of a popular marketplace that uses the auction format that we analyze in this paper. Bidders can bid on a TLD such as ".scholar" in the example in Figure 1. Bidders submit a bid and a blind to the auction. The sum of the two numbers (the "lockup amount"), but not the bid itself, is visible to other bidders during the bidding phase of the auction. At the end of the bidding phase, bids are evaluated according to a second price auction and left-over lockup amounts are repaid. As can be observed in the bid history reproduced in Figure 1, the sixth bid in the auction involves a substantial lockup amount. Subsequently, no further bid is made. Note that the sixth bid involves substantial over-depositing, i.e. the blind part is much larger than the actual bid. The bidder seems to have successfully engaged in entry deterrence: the large lockup amount likely discouraged further potential bidders to enter the auction and place a bid. In this paper, we want to give a theoretical explanation of this kind of bidding behavior.

Fig. 1. Bid history and auction details for the top level domain ".scholar" on namebase.io.

The logic of our analysis is as follows: Bidding is costly since depositing is costly. If the deposit has to be staked for a substantial amount of time¹ and can not be used or sold meanwhile, the bidder is, for example, exposed to the volatility of the underlying token price. Other costs of depositing can come from transaction costs when buying the native token that is used to make the deposit, from borrowing costs or from transactions cost for processing the bid on-chain. Even if this cost is relatively small, it can have substantial strategic implications if valuations for an item are expected to be high². A bidder can deter entry into the auction by depositing a large amount. This is a costly signal to other bidders that the bidder likely has a high valuation. Another bidder wondering whether to enter the auction infers that this makes it unlikely that he wins the auction, and that he is likely to pay a high price if he wins the auction. Since bidding is costly and the cost of bidding increases in the size of the deposit, he possibly refrains from bidding at all. Since bids are not public, this could be even in the case when he would have had a higher valuation than the first bidder, but the first bidder successfully deters him through over-depositing. Efficiency is lost: with positive probability the item does not go to the bidder with the highest willingness to pay. Moreover, revenue is severely decreased since bidders are deterred from entering the auction. Finally, wasteful over-depositing will take place, bidder 1 will deposit a large amount exceeding his true valuation amount to send a costly signal of his high valuation.

Interestingly the strategy outlined here goes in the opposite direction of other strategies usually observed in online auctions: bidders can have an advantage if they move early because they can scare away other bidders by over-depositing, whereas in other environments bidders want to get late into the auction in order to "snipe" [10].

¹For namebase's auction deposits are kept for 10 days after the end of the bidding phase.

²Bids can be substantial in these kinds of auctions. For the domain auctions organized by namebase.io, domains have been sold for close to 100000 \$: <https://newsoso.com/2021/02/03/this-nft-web-domain-just-sold-for-record-breaking-84000/>. Such auctions can also suffer from speculation, since they allow instant resale, [6].

We flesh out this logic in a stylized model. The paper is organised as follows: As a benchmark, we first consider the case of simultaneous depositing or equivalently the case where privacy-preserving depositing is available so that no information is revealed to other bidders. In this case, bidding in equilibrium is approximately truthful. Bids are only shaded by a small amount to incorporate depositing costs. Social welfare is approximately maximised since the item is allocated to the bidder with the highest valuation, and the only loss in welfare is due to depositing cost.

Next, we study the case of sequential bidding with two bidders. If bidder 1 bids before bidder 2, bidder 1's deposit is visible to bidder 2. This drastically changes the strategic interaction and the equilibrium bidding behavior. Generically, the first bidder will over-deposit if he has a high valuation. This over-depositing is wasteful since it is costly to the bidder and only satisfies the purpose of signalling a high valuation. In addition to the efficiency loss due to over-depositing, there can be additional allocative inefficiencies due to entry deterrence which can come in two forms:

- (1) Unless there is a very high likelihood of low valuations for the second bidder, the first bidder will refrain from entering the auction if he has a low valuation since he wants to save on the depositing cost when facing a low likelihood of winning the auction.
- (2) More severely, if high valuations are likely, equilibria exists in which high types of the first bidder are pooled. In the most extreme case, there can exist equilibria with just two deposit levels. The first bidder will choose either not to bid at all or to over-deposit. If the second bidder observes a large deposit he can be deterred from entering the auction since he assigns a substantial likelihood to the first bidder having a high valuation. Thus, he will not bid at all unless his valuation is very high. The equilibrium can be very wasteful. The first bidder can win the auction even though he could have a substantially lower valuation for the item than the second bidder.

We illustrate these effects with three different distributions with support on the unit interval that capture the scenario of high likelihood for low valuations, equal likelihood of high and low valuations, resp. high likelihood of high valuations:

If valuations are distributed according to the square root $F(x) = \sqrt{x}$, low valuations are more likely. While over-depositing for high types takes place, the other sources of inefficiency are not present. Low valuation bidders are not deterred from entering the auction and the equilibrium is fully separating. Thus the item is always allocated to the bidder with the higher valuation.

If valuations are distributed uniformly $F(x) = x$, all valuations are equally likely. Over-depositing for high types takes place and is very wasteful. Moreover, low valuation bidders that move first are deterred from entering the auction. However, we have separation conditional on entry: if bidder 1 enters the auction his type can be inferred from his deposit. Thus, unless both bidders have very low valuation the item is allocated to the bidder with the higher valuation.

If valuations are distributed according to quadratic distribution $F(x) = x^2$, high valuations are more likely. In this case, very inefficient equilibria exist in which the first bidder will choose either not to bid at all or to over-deposit. Besides wasteful over-depositing allocative efficiency is severely harmed. Bidder 2 can be deterred from entering the auction even though ex-post he would have a higher valuation.

1.1 Other Literature

Exploiting auctions through "front running" in the blockchain environment is studied in [4] and [7]. While the entry-deterrence strategies analyzed in our paper can be interpreted as a form of front-running, they are qualitatively very different. Whereas conventional front-running is used to exploit informational advantages, in our setting bidders want to go early to signal information to others. Sequential bidding with constant cost of entry and deterrence is a topic

of [2]. With constant cost of entry instead of a constant marginal cost of entry, bidders can only signal through their entry decision but not through deposits. We use standard terminology from signalling games [11] and related solution concepts [5]. Costly signalling in auctions, although in a different environment, has been considered before, e.g. in [8]. Deposit costs in on-chain exchange mechanisms are the topic of [9].

2 PRELIMINARIES

We consider two bidders with independently and identically distributed valuations $v_1, v_2 \in (0, 1)$.

Bidders submit a bid $b(v_i)$ and a deposit $d(v_i)$ such that $0 \leq b(v_i) \leq d(v_i)$. Note that both are functions of the real valuation v_i . The constant marginal cost of depositing is $c > 0$. The winner of the item is determined through a second price auction. That is, if i makes the winning bid, equivalent to $b_i > b_j$, then his profit is

$$v_i - b(v_j) - cd(v_i),$$

whereas j loses

$$-cd(v_j).$$

Since we have a second price auction, it will generally be the case that in equilibrium a bidder either bids his valuation or his full deposit,

$$b(v_i) = \min\{v_i, d(v_i)\}.$$

In Section 3 we consider simultaneous bidding with the standard *Bayes-Nash equilibrium* solution concept. In Section 4, we consider sequential bidding with *Perfect Bayesian Equilibrium* as solution concept (see that section for the formal definition in our context). Sequential bidding turns our model into a signalling game.

3 SIMULTANEOUS DEPOSITING

We first consider the benchmark case of simultaneous bidding (and depositing). The following analysis works for any tie-breaking rule to determine the winner in case of equal bids. Since bids are simultaneous it is optimal not to over-deposit, that is $b(v_i) = d(v_i)$ (if $b(v_i) < d(v_i)$, then the bidder could deposit $b(v_i)$ instead, without changing his bid and become strictly better off by saving depositing cost).

Thus the equilibrium bidding function is fully determined by the equilibrium deposit function. We consider symmetric equilibria. Let $d : [0, 1] \rightarrow \mathbb{R}$ be the equilibrium deposit function for both bidders. The expected profit for bidder i when he deposits and bids an amount $d(w)$ corresponding to type w is given by

$$F(w)(v_i - E[d(v_j)|v_j \leq w]) - cd(w),$$

Taking first order conditions and assuming that d is differentiable, and using the fact that $d(0) = 0$:

$$f(w)(v_i - E[d(v_j)|v_j \leq w]) - F(w)f_{(0,w)}(w)d(w) - cd'(w) = 0$$

where $f_{(0,w)}$ is the density conditional on the valuation being smaller w . By the revelation principle the expression is optimized if he deposits and bids the amount $d(v_i)$ corresponding to his true valuation, i.e. when $w = v_i$, and therefore:

$$f(v_i)(v_i - E[d(v_j)|v_j \leq v_i]) - F(v_i)f_{(0,v_i)}(v_i)d(v_i) - cd'(v_i) = 0.$$

Uniform Distribution. If valuations are uniformly distributed on $(0, 1)$ the previous first order condition becomes:

$$v_i - d(v_i) - cd'(v_i) = 0.$$

Fig. 2. Bidding function for simultaneous depositing with quadratic distribution.

We can use the boundary condition $d(0) = 0$ and obtain the solution to the differential equation:

$$d(v_i) = v_i - c(1 - e^{-v_i/c}).$$

Quadratic Distribution. If valuations are distributed according to $F(x) = x^2$, the expected conditional equality becomes:

$$E[d(v_j)|v_j \leq w] = \int_0^w d(z)2z/w^2 dz,$$

and, therefore, expected profit when bidding $d(w)$ becomes:

$$v_i w^2 - \int_0^w d(z)2z dz - cd(w).$$

The first order condition is:

$$2v_i^2 - 2d(v_i)v_i - cd'(v_i) = 0.$$

We can use the boundary condition $d(0) = 0$ to solve the equation. See Figure 2 for a graph of the bidding function for $c = 0.15$.

Square root distribution. Following the same logic as before, we obtain a differential equation that characterizes the bidding function

$$\frac{\sqrt{v_i}}{2} - \frac{d(v_i)}{2\sqrt{v_i}} - cd'(v_i) = 0.$$

Equation can be solved with the boundary condition $d(0) = 0$.

With simultaneous bidding and depositing, we achieve allocative efficiency in equilibrium for all three distributions; the bidder with the higher valuation wins the item. Bids are shaded in equilibrium but only to the extent that depositing costs are incorporated. Moreover, unless a bidder has zero valuation for the item it is optimal to enter the auction. The auction is approximately efficient.

4 SEQUENTIAL DEPOSITING

Next, we modify the model by assuming that bidder 1 moves first and bidder 2 moves second so that bidder 1's deposit (but not his bid) is known to bidder 2 before he chooses his bid. We now use the tie-breaking rule that the second bidder wins in case of equal bids. As observed before, bidder 1 bids either his deposit or his valuation so that the strategy of

bidder 1 is characterized by a deposit function $d_1 : [0, 1] \rightarrow [0, \bar{d}]$ where $\bar{d} \geq 1$ is the maximal deposit a bidder can make.³ It is always optimal for Bidder 1 to bid $\min\{v_1, d_1(v_1)\}$.

For bidder 2, it is no loss of generality to assume that he does not over-deposit. Otherwise, if $b_2 < d_2$, then the bidder could deposit b_2 instead without changing his bid and become strictly better off by saving on depositing cost. So bidder 2's strategy is characterized by his deposit function $d_2 : [0, 1] \times [0, \bar{d}] \rightarrow [0, 1]$ where $d_2(v_2, d_1)$ is his choice of deposit under valuation v_2 if he observes bidder 1 depositing d_1 . It is always optimal for Bidder 2 to bid $b_2 = d_2(v_2, d_1)$.

Given that bidders' strategies are fully determined by their depositing functions, we understand a *Perfect Bayesian Equilibrium* to be a triple (d_1, d_2, μ_2) of deposit functions for the two bidders and beliefs $\mu_2 : [0, 1] \times [0, \bar{d}] \rightarrow [0, 1]$ for bidder 2⁴ where $\mu_2(\cdot, d_1)$ is the cdf for v_1 conditional on observing a deposit d_1 such that

1. each player's strategy specifies optimal actions, given his beliefs and the strategies of the other player, i.e. $d_1(v_1)$ is a solution to

$$\max_{d_1} Pr_{v_2 \sim F}[b_1 > b_2](v_1 - E_{v_2 \sim F}[b_2 | b_1 > b_2]) - cd_1,$$

$$\text{where } b_1 = \min\{v_1, d_1\}, \quad b_2 = \min\{v_2, d_2(v_2, d_1)\},$$

and $d_2(v_2, d_1)$ is a solution to

$$\max_{d_2} Pr_{v_1 \sim \mu_2(d_1)}[b_2 \geq b_1](v_2 - E_{v_1 \sim \mu_2(d_1)}[b_1 | b_2 \geq b_1]) - cd_2,$$

$$\text{where } b_1 = \min\{v_1, d_1\}, \quad b_2 = \min\{v_2, d_2\}.$$

2. Beliefs are updated according to Bayes' rule whenever applicable, for $0 \leq d_1 \leq \bar{d}$ such that there is a type v_1 with $d_1(v_1) = d_1$ we have

$$\mu_2(v, d_1) = F(v | d_1(v_1) = d_1).$$

All subsequently constructed Perfect Bayesian equilibria will also satisfy standard refinement properties for signalling games like the Cho-Kreps intuitive criterion [3]. Following standard terminology of the signalling literature, we call an equilibrium *separating*, if different types send different messages. In our setting, the type of bidder 1 is the valuation v_1 , while a message is the deposit $d_1(v_1)$. Therefore, in a separating equilibrium, the second bidder can exactly determine the valuation of the first bidder from the deposit. We call an equilibrium *separating conditional on entry* if conditional on the first bidder depositing a positive amount, the second bidder can exactly determine the valuation of the first bidder from the deposit. We call an equilibrium *pooling equilibrium* with n deposit levels if bidder 1 uses the same deposit under different valuations and n different deposit levels are observed in equilibrium.

4.1 Separating equilibria

Suppose there is a separating equilibrium, $d_1(v_1) \neq d_1(v'_1)$ for $v_1 \neq v'_1$. In that case, bidder 2 knows bidder 1's valuation when bidding. The equilibrium depositing function will be increasing, $v_1 > v'_1 \Rightarrow d_1(v_1) > d_1(v'_1)$. Let $d := d_1(1)$. Let $v(d_1)$ be the inverse of the depositing function. For $0 \leq d_1 \leq d$ bidder 2 will bid:

$$d_2(v_2, d_1) = \begin{cases} \min\{d_1, v_1(d_1)\}, & \text{for } v_2 \geq (1+c) \min\{d_1, v(d_1)\} \\ 0, & \text{otherwise.} \end{cases} \quad (1)$$

³Typically, we think of \bar{d} as a large quantity. It could for example be the number of tokens in the protocol in total.

⁴We do not need to specify bidder 1's beliefs about bidder 2's valuation as they will coincide with the prior F .

Given the bidding function for bidder 2, the expected utility of bidder 1 when depositing d_1 is

$$v_1 F((1+c) \min\{d_1, v(d_1)\}) - cd_1.$$

In general, the depositing function d_1 as a function of valuation should satisfy the first order condition:

$$(1+c)v_1 f((1+c)d_1) = c, \quad \text{for } d_1(v_1) \leq v_1, \quad (2)$$

$$(1+c)v_1 f((1+c)v_1) = cd'_1(v_1) \text{ for } d_1(v_1) > v_1. \quad (3)$$

Separation and over-depositing for the square root distribution. The existence of a separating equilibrium where bidder 1 always enters the auction requires that the density function f is strictly decreasing in the beginning, i.e. the cumulative distribution function is concave for low types and hence low valuations are more likely. This is the case for the square root distribution $F(x) = \sqrt{x}$.

We have $f(x) = \frac{1}{2\sqrt{x}}$ which for the case that bidder 1 under-deposits, implies by (2):

$$d_1 = \frac{(1+c)v_1^2}{4c^2}.$$

To guarantee $d_1(v_1) \leq v_1$ for the previous expression, we need

$$\frac{(1+c)v_1^2}{4c^2} \leq v_1 \Rightarrow v_1 \leq \frac{4c^2}{1+c}.$$

Thus, for $v_1 > \frac{4c^2}{1+c}$ the bidder will over-deposit. The first order condition (3) transforms into:

$$cd'_1(v_1) = \frac{(1+c)v_1}{2\sqrt{(1+c)v_1}} = \frac{\sqrt{(1+c)v_1}}{2}.$$

Together with the boundary conditions $d_1(v_1) \geq v_1$ and $d(\frac{4c^2}{1+c}) = \frac{4c^2}{1+c}$, we get

$$d_1(v_1) = \frac{((1+c)v)^{3/2} + 5c^2}{3c(1+c)}.$$

We obtain the following equilibrium: Bidder 1 deposits

$$d_1(v_1) = \begin{cases} \frac{1+5c^2}{3c(1+c)}, & v_1 \geq \frac{1}{1+c}, \\ \frac{((1+c)v_1)^{3/2} + 5c^2}{3c(1+c)}, & \frac{1}{1+c} > v_1 \geq \frac{4c^2}{1+c}, \\ \frac{(1+c)v_1^2}{4c^2}, & v_1 < \frac{4c^2}{1+c}. \end{cases}$$

and bids

$$b_1(v_1) = \begin{cases} v_1 & v_1 \geq \frac{4c^2}{1+c}, \\ d_1(v_1), & v_1 < \frac{4c^2}{1+c}. \end{cases}$$

Note that unless cost is very high ($\frac{4c^2}{1+c} > 1$) bidder 1 will over-deposit if his type is high.

If bidder 2 observes a high deposit $d_1 > \frac{4c^2}{1+c}$ he deposits

$$d_2(v_2, d_1) = \begin{cases} \frac{1}{1+c} (3c(1+c)d_1 - 5c^2)^{3/2}, & v_2 \geq t(c), \\ 0, & v_2 < t(c), \end{cases}$$

where $t(c) := (3c(1+c)d_1 - 5c^2)^{3/2}$, and if he observes a low deposit $0 \leq d_1 \leq \frac{4c^2}{1+c}$ he deposits

$$d_2(v_2, d_1) = \begin{cases} d_1, & v_2 \geq (1+c)d_1, \\ 0, & v_2 < (1+c)d_1. \end{cases}$$

In either case he bids his deposit $b_2(v_2, d_1) = d_2(v_2, d_1)$. His belief if he observes $0 \leq d_1 \leq \frac{1+5c^2}{3c(1+c)}$ is

$$\mu_2(v, d_1) = \begin{cases} 1, & \text{for } v \geq v(d_1), \\ 0, & \text{for } v < v(d_1), \end{cases}$$

where $v(d_1)$ is the inverse of the depositing function for bidder 1, and his belief when observing $d_1 > \frac{1+5c^2}{3c(1+c)}$ is

$$\mu_2(\cdot, d_1) = F(\cdot | v_1 \geq \frac{1}{1+c}).$$

In conclusion, we find an essentially (except for the very highest types with valuation above $\frac{1}{1+c}$) fully separating equilibrium for the case of the square root distribution in which bidder 1 will under-deposit for low valuations and over-deposit for high valuations.

Separation conditional on entry for the Uniform Distribution. Next we consider the uniform distribution for which high and low valuations are equally likely. First, we show that for the uniform distribution, there is no separating equilibrium in which bidder 1 always enters the auction. In case of under-depositing the profit is

$$(1+c)v_1d_1 - cd_1,$$

which is positive only if $v_1 > \frac{c}{1+c}$. Thus, types $0 \leq v_1 \leq \frac{c}{1+c}$ over-deposit or do not enter the auction at all. In case of over-deposits, we get the first order condition:

$$(1+c)v_1 = cd_1'(v_1).$$

Together with the boundary condition $d(0) = 0$, we get

$$d_1(v_1) = \frac{1+c}{2c}v_1^2.$$

However, to guarantee over-deposition, we need

$$v_1 \leq d_1(v_1) = \frac{1+c}{2c}v_1^2 \Rightarrow v_1 \geq \frac{2c}{1+c},$$

contradicting that we have over-depositing for $v_1 \leq \frac{c}{1+c}$. Thus, bidder 1 with $v_1 \leq \frac{c}{1+c}$ never enters the auction.

However, we can construct an equilibrium with separation conditional on entry for all but the highest types. More precisely, in the equilibrium there is separation for all types $\frac{c}{1+c} < v_1 < \frac{1}{1+c}$, types below $\frac{c}{1+c}$ will not enter the auction, and types above $\frac{1}{1+c}$ will pool since it is not individually rational for bidder 2 to enter the auction against these high types.

Let u be the smallest type of bidder 1 that deposits a positive amount. Suppose all types of bidder 1 above u over-deposit, $d_1(v_1) \geq v_1$ for $v_1 \geq u$. By the same reasoning as before, we have the first order condition

$$(1+c)v_1 = cd_1'(v_1),$$

and the boundary conditions $d(v_1) \geq v_1$ for $v_1 \geq u$ and

$$(1+c)u^2 - cd_1(u) = 0.$$

One solution is

$$u = \frac{c}{1+c} \quad \text{and} \quad d_1(v_1) = \frac{1+c}{2c}(v_1^2 - u^2) + u = \frac{1+c}{2c}v_1^2 + \frac{c}{2(1+c)}.$$

The equilibrium is as follows (see Figure 3 for a graph of the bidding and depositing functions for bidder 1). Bidder 1 deposits

$$d_1(v_1) = \begin{cases} \frac{1+c^2}{2c(1+c)}, & v_1 \geq \frac{1}{1+c}, \\ \frac{1+c}{2c}v_1^2 + \frac{c}{2(1+c)}, & \frac{1}{1+c} > v_1 \geq \frac{c}{1+c}, \\ 0, & v_1 < \frac{c}{1+c}. \end{cases}$$

and bids

$$b_1(v_1) = \begin{cases} v_1, & v_1 \geq \frac{c}{1+c}, \\ 0, & v_1 < \frac{c}{1+c}. \end{cases}$$

If bidder 2 observes a high deposit $d_1 > \frac{c}{1+c}$ he deposits

$$d_2(v_2, d_1) = \begin{cases} \sqrt{\frac{2c}{1+c}d_1 - \frac{c^2}{(1+c)^2}}, & v_2 \geq \sqrt{2c(1+c)d_1 - c^2}, \\ 0, & v_2 < \sqrt{2c(1+c)d_1 - c^2}, \end{cases}$$

and if he observes a low deposit $0 \leq d_1 \leq \frac{c}{1+c}$ he deposits

$$d_2(v_2, d_1) = \begin{cases} d_1, & v_2 \geq (1+c)d_1, \\ 0, & v_2 < (1+c)d_1. \end{cases}$$

In either case he bids his deposit $b_2(v_2, d_1) = d_2(v_2, d_1)$.

We also need to specify beliefs off-equilibrium when bidder 2 observes a deposit between 0 and $\frac{c}{1+c}$. One possibility is to assume that bidder 2 believes that bidder 1 has type $\frac{c}{1+c}$. Thus his beliefs when observing $0 \leq d_1 \leq \frac{c}{1+c}$ is

$$\mu_2(v, d_1) = \begin{cases} 1, & \text{for } v \geq \frac{c}{1+c}, \\ 0, & \text{for } v < \frac{c}{1+c}, \end{cases}$$

his belief when observing $\frac{1}{1+c} \leq d_1 \leq \frac{1+c^2}{2c(1+c)}$ is

$$\mu_2(v, d_1) = \begin{cases} 1, & \text{for } v \geq v(d_1), \\ 0, & \text{for } v < v(d_1), \end{cases}$$

where $v(d_1)$ is the inverse of the depositing function for bidder 1, and his belief when observing $d_1 \geq \frac{1+c^2}{2c(1+c)}$ is given by

$$\mu_2(\cdot, d_1) = F(\cdot | v_1 \geq \frac{1}{1+c}).$$

In conclusion, for the uniform distribution there is no separating equilibrium. However, there is an equilibrium that is essentially (except for the very highest types with valuation above $\frac{1}{1+c}$) separating conditional on entry.

Fig. 3. Bidding (yellow) and deposit (blue) function for bidder 1 for sequential depositing, a uniform value distribution and cost $c = 0.15$.

4.2 Pooling equilibrium with two deposit levels

If high valuations are more likely than low valuations we can construct pooling equilibria. We consider the case of only two deposit levels in equilibrium, bidder 1 either deposits 0 or the maximal valuation 1, and show that such an equilibrium can be constructed for the quadratic distribution.

To construct the equilibrium, consider a marginal type of bidder 1, $0 < u < 1$, such that he deposits 0 if his valuation is below u and 1 if his valuation is above u . In that case, if bidder 2 observes a deposit of 0, he will bid 0 himself and win the object for free. If bidder 2 observes a deposit of 1, he knows that the valuation of bidder 1 is between u and 1. We also need to specify what bidder 2 believes off-equilibrium if $d_1 \neq 0, 1$. We assume that in that case bidder 2 thinks that bidder 1's type is distributed by:

$$\mu(\cdot, d_1) = \begin{cases} F(\cdot | d_1 \leq v_1 \leq u), & \text{for } 0 \leq d_1 \leq u, \\ F(\cdot | u \leq v_1 \leq \min\{1, d_1\}), & \text{for } u < d_1 \leq \bar{d}. \end{cases} \quad (4)$$

Bidder 2 thinks that bidder 1 will bid d_1 for $d_1 \leq u$. Therefore, bidder 2, when observing $d_1 \leq u$, will bid d_1 in case if this makes him positive profit, $v_2 \geq d_1 + cd_1$, and will not bid in the auction otherwise. Thus, the profit for bidder 1 when depositing and bidding $d_1 \leq u$ is as in the previous section:

$$F((1+c)d_1)v_1 - cd_1.$$

This quantity should be non-positive for the marginal type:

$$F(u(1+c)) \leq c. \quad (5)$$

The expected profit for bidder 2 of bidding $d_1 \geq d_2 \geq u$, if he observes $d_1 > u$ is:

$$\Pi(v_2, d_1, d_2) := Pr[v_1 \leq d_2 | u \leq v_1 \leq d_1] (v_2 - E[v_1 | u \leq v_1 \leq d_2]) - cd_2.$$

Let $v(d_1)$ be the smallest valuation of bidder 2 for which he enters the auction if he observes a deposit of $d_1 > u$, i.e.

$$v(d_1) := \min\{0 \leq v_2 \leq 1 : \max_{u \leq d_2 \leq d_1} \Pi(v_2, d_1, d_2) \geq 0\},$$

respectively $v(d_1) := 1$ if the min does not exist. We let $v := v(1)$.

At the marginal type $v_1 = u$, bidder 1 must be indifferent between depositing 0 and depositing 1 and bidding his type. Note, moreover, that the marginal type when depositing 1 and bidding his type either gets the object for free or does not get the object (since bidder 2 will either not bid at all in that case, $b_2 = 0$, or bid $b_2 \geq u$, since he believes that bidder 1 has a valuation of u or higher). Thus, his payoff of depositing 1 and bidding his type is

$$F(v)u - c.$$

The marginal type is indifferent between depositing 0 and depositing 1 if

$$F(v)u = c. \tag{6}$$

Quadratic Distribution. For the quadratic distribution

$$(u(1+c))^2 \leq c, \tag{7}$$

and

$$uv^2 = c. \tag{8}$$

First, we determine the bidding function for bidder 2, if he observes $d_1 > u$ conditional on entering the auction. For $u < d_2 \leq d_1$, we have

$$\Pi(v_2, d_1, d_2) = \frac{d_2^2 - u^2}{d_1^2 - u^2} \left(v_2 - \int_u^{d_2} v_1 \frac{2v_1}{d_2^2 - u^2} dv_1 \right) - cd_2 = \frac{2v_2 d_2^2 - u^2 d_1^2 - u^2 v_2}{3(d_1^2 - u^2)} - cd_2.$$

Taking first order conditions:

$$\frac{\partial \Pi}{\partial d_2} = \frac{2d_2 v_2}{d_1^2 - u^2} - \frac{2d_2^2}{d_1^2 - u^2} - c = 0.$$

There are two critical points of which the larger one corresponds to a local maximum:

$$d_2 = \frac{1}{2} \left(v_2 + \sqrt{v_2^2 - 2c(d_1^2 - u^2)} \right). \tag{9}$$

To determine the marginal types u and v we need to check whether there are

$$0 < u < v \leq 1$$

such that equations (8) and (9) with $d_1 = 1$ and $v_2 = v$, inequality (7) are satisfied and

$$(d_2^2 - u^2)v - \frac{2}{3}(d_2^3 - u^3) = cd_2(1 - u^2) \tag{10}$$

holds (i.e., the profit for the marginal type of bidder 2 is equal to 0). Similarly, to determine $v(d_1)$, we need to find a $v(d_1)$ that satisfies Equation (9) with $v_2 = v(d_1)$ and

$$(d_2^2 - u^2)v(d_1) - \frac{2}{3}(d_2^3 - u^3) = cd_2(d_1^2 - u^2). \quad (11)$$

The equilibrium is as follows. Bidder 1 deposits

$$d_1(v_1) = \begin{cases} 1, & v_1 \geq u, \\ 0, & v_1 < u, \end{cases}$$

and bids

$$b_1(v_1) = \begin{cases} v_1, & v_1 \geq u, \\ 0, & v_1 < u, \end{cases}$$

If bidder 2 observes a deposit $d_1 > u$ above the threshold he deposits

$$d_2(v_2, d_1) = \begin{cases} \min \left\{ d_1, \frac{1}{2} \left(v_2 + \sqrt{v_2^2 - 2c(d_1^2 - u^2)} \right) \right\}, & v_2 \geq v(d_1), \\ 0, & v_2 < v(d_1), \end{cases}$$

and if he observes a deposit $d_1 \leq u$ below the threshold he deposits

$$d_2(v_2, d_1) = \begin{cases} d_1, & v_2 \geq d_1, \\ 0, & v_2 < d_1. \end{cases}$$

In either case he bids his deposit, $b_2(v_2, d_1) = d_2(v_2, d_1)$. His beliefs are given by Equation 4.

Quadratic distribution for $c = 0.22$. Next we verify that the deposit functions derived above with the beliefs specified above form a Perfect Bayesian Equilibrium if valuations are quadratically distributed for the case that the marginal cost is $c = 0.22$. In this case the marginal type is $u = 0.382981$ and bidder 2 will enter the auction only if his valuation is above $v = 0.757919$. Note that incentive compatibility for the marginal type of bidder 1 holds as

$$u^2(1+c)^2 = 0.382981^2 \cdot 1.22^2 \approx 0.21831 < c = 0.22.$$

It remains to show that the highest type of bidder 1 and the marginal type of bidder 1 cannot profit by depositing $u < d_1 < 1$ (it is not profitable to deposit more than 1 since depositing becomes more costly but the bidding behaviour of bidder 2 does not change). It is straightforward then to see that also the types $u < v_1 < 1$ cannot profit by depositing $u < v_1 < 1$. The expected profit of bidder 1 when depositing $d_1 < 1$ is

$$Pr[d_1 \geq d_2(d_1, v_2)] - Pr[d_1 \geq d_2(d_1, v_2)]E[d_2(d_1, v_2)|d_1 \geq d_2(d_1, v_2)] - cd_1.$$

Denote by $\bar{v}(d_1)$ the type of bidder 2 with $d_1 = d_2(d_1, \bar{v}(d_1))$. We have:

$$d_1 = \frac{1}{2}(\bar{v}(d_1) + \sqrt{\bar{v}(d_1)^2 - 2c(d_1^2 - u^2)}) \Rightarrow \bar{v}(d_1) = d_1 - \frac{2c(d_1^2 - u^2)}{4d_1},$$

(a) Bidding (yellow) and deposit (blue) function for bidder 1 for sequential depositing.

(b) The bidding and depositing function for bidder 2 for sequential depositing.

and the profit of bidder 1 when depositing d_1 is

$$\begin{aligned} \bar{v}(d_1)^2 - \int_{v(d_1)}^{\bar{v}(d_1)} 2v_1 d_2(d_1, v_2) dv_1 - cd_1 &\leq \bar{v}(d_1)^2 - \\ \int_v^{\bar{v}(d_1)} 2v_1 d_2(d_1, v_2) dv_1 - cd_1 &= \bar{v}(d_1)^2 - \frac{1}{3} \\ &\left(\bar{v}(d_1)^3 - v^3 + (\bar{v}(d_1)^2 - 2c(d_1^2 - u^2))^{3/2} - (v^2 - 2c(d_1^2 - u^2))^{3/2} \right) - cd_1, \end{aligned}$$

where the inequality follows as the marginal type $v(d_1)$ of bidder 2 that enters the auction is decreasing in the deposit. For $c = 0.22$, $u = 0.382981$ and $v = 0.757919$ this is an increasing function in d_1 for $d_1 \geq u$. Thus, it is optimal for bidder 1 to deposit the maximal amount \bar{d} if his type is $v_1 = 1$.

Next, we consider the marginal type $v_1 = u$. Differentiating Equation (11) with respect to d_1 gives:

$$(2d_2v(d_1) - 2d_2^2) \frac{\partial d_2}{\partial d_1} + (d_2^2 - u^2) \frac{\partial v(d_1)}{\partial d_1} = 2cd_1d_2 + c(d_1^2 - u^2) \frac{\partial d_2}{\partial d_1}.$$

Therefore,

$$\begin{aligned} \frac{\partial v(d_1)}{\partial d_1} &= \frac{1}{d_2^2 - u^2} \left(2cd_1d_2 - (c(d_1^2 - u^2) - 2d_2(v(d_1) - d_2)) \frac{\partial d_2}{\partial d_1} \right) \\ &= \frac{1}{d_2^2 - u^2} \left(2cd_1d_2 - (c(d_1^2 - u^2) - 2d_2 \frac{1}{2} (v_2 - \sqrt{v_2^2 - 2c(d_1^2 - u^2)})) \frac{\partial d_2}{\partial d_1} \right) \\ &= \frac{1}{d_2^2 - u^2} \left(2cd_1d_2 - (c(d_1^2 - u^2) - \frac{1}{2} (v_2^2 - (v_2^2 - 2c(d_1^2 - u^2)))) \frac{\partial d_2}{\partial d_1} \right) \\ &= \frac{2cd_1d_2}{d_2^2 - u^2} \geq \frac{2cd_1d_2}{d_1d_2 - u^2} \geq \frac{2cd_2}{d_2 - u^2/d_1} \geq \frac{2cv(d_1)}{v(d_1) - u^2/d_1}, \end{aligned}$$

where the first inequality follows as $d_2 \leq d_1$ and the last inequality follows as $d_2 \leq v(d_1)$ and the term $\frac{2cd_2}{d_2 - u^2/d_1}$ is decreasing in d_2 . For the marginal type $v_1 = u$, differentiating the profit as function of $d_1 < \bar{d}$ with respect to d_1 yields

$$\frac{\partial}{\partial d_1}(v(d_1)^2u - cd_1) = 2v(d_1)u \frac{\partial v}{\partial d_1} - c \geq \frac{4cv(d_1)^2u}{v(d_1) - u^2/d_1} - c \geq \frac{4c(2u^2/d_1)^2u}{u^2/d_1} - c = 16cu^3/d_1 - c,$$

which is positive for $d_1 \leq 0.89877$. On the other hand, we have

$$\frac{2cd_1d_2}{d_2^2 - u^2} \geq \frac{2cd_1d_2}{d_2^2} \geq \frac{2cd_1}{d_2} \geq \frac{2cd_1}{v(d_1)},$$

and, therefore

$$2v(d_1)u \frac{\partial v}{\partial d_1} - c \geq 4cd_1u - c = 1.531924cd_1 - c$$

which is positive for $d_1 > 0.89877$. Thus, bidder 1's profit is decreasing in d_1 if $v_1 = u$.

We have established the existence of a pooling equilibrium with just two deposit levels for the quadratic distribution. The equilibrium exhibits the manifold inefficiencies we have highlighted in the introduction. Bidder 2 is deterred from entry unless his valuation is very high, see the Figure on the last page. Bidder 1 may win the auction even if he has a lower valuation. Bidder 1 engages in wasteful over-deposits in equilibrium.

5 DISCUSSION

5.1 Extensions

Our model is rather stylized with only two bidders and a fixed order of moves. While a generalization of the sequential bidding model to more than two bidders soon becomes analytically intractable, we expect that the general logic of our argument should generalize to more bidders, and entry-deterrence also should occur for more bidders. If the order of moves and hence the time of entry is endogenized we expect unraveling with high valuation bidders trying to deposit earlier than other bidders to engage in entry deterrence. A natural extension is to consider the case where the cost of bidding is not only a function of the size of the deposit but also of the waiting time until the end of the auction.

5.2 Potential Remedies

Given the potentially severe inefficiency of the auction design, it is a natural question how to improve it. Several potential remedies, both cryptographic and economic, can be considered: Encryption of deposit levels is a natural idea. There are several blockchain projects with built-in privacy functionality, e.g. [13], that could be used for this purpose. Privacy preservation in on-chain auction specifically has been analyzed in [1]. Lowering the cost of depositing, for example by shortening the staking time, lowering borrowing costs so that it becomes cheaper to make large deposits or decreasing transaction costs can mitigate the problem. A more radical approach would allow for under-collateralizing of bids where the residual sum has to be paid by the winning bidder only after winning. Finally it is a natural question whether other payment rules than the second price rule would allow for more efficient outcomes in the presence of deposits.
