Over the past two decades, causal decision making (CDM) at scale has become a routine part of business, and increasingly CDM is based on statistical models and machine learning algorithms. For example, businesses target offers, incentives, and recommendations algorithmically with the goal of affecting consumer behavior. Not surprisingly, recently we have seen an acceleration of research related to CDM and to causal effect estimation (CEE) using machine learned models. This article highlights an important perspective: CDM is not the same as CEE, and counterintuitively, accurate CEE is not necessary for accurate CDM. Our experience is that this is not well understood by practitioners nor by most researchers. Technically, the estimand of interest is different, and this has important implications both for modeling and for the use of statistical models for CDM. We draw on recent research to highlight three of these implications. (1) We should consider carefully the objective function of the causal machine learning, and if possible we should optimize for accurate “treatment assignment” rather than for accurate effect-size estimation. (2) Confounding does not have the same effect on CDM as it does on CEE. The upshot here is that for supporting CDM it may be just as good or even better to learn with confounded data as with unconfounded data. Finally, (3) causal statistical modeling may not be necessary at all to support CDM, because there may be (and perhaps often is) a proxy target for statistical modeling that can do as well or better. This observation helps to explain at least one broad common CDM practice that seems “wrong” at first blush—the widespread use of non-causal models for targeting interventions. The last two implications are particularly important in practice, as acquiring (unconfounded) data on both “sides” of the counterfactual for modeling can be quite costly and often impracticable. Our perspective is that these observations open up substantial fertile ground for future research. Whether or not you share our perspective completely, we hope we facilitate future research in this area by pointing to related articles from multiple contributing fields, including two dozen articles published the last three to four years.

Key words: causal inference, treatment effect estimation, treatment assignment policy

1. Introduction

Causal decision making at scale has become a routine part of business. Firms build statistical models, using machine learning algorithms, to support decisions about targeting all manner of

interventions. The most common are offers, advertisements, retention incentives, and recommendations made to customers and prospective customers. The goal of these interventions is to affect consumer behavior, for example to increase purchasing or to keep a customer from churning. When we talk about causal decision making in this article, we are speaking specifically about deciding on whether or not to “treat” a particular individual with a particular intervention (more on treatment assignment presently). Making explicit the causal nature of such decision making has lagged its actual implementation in practice. The more data-savvy firms do now routinely conduct causal *evaluations* of their targeting decisions, for example conducting A/B tests when making offers or targeting advertisements. However, still very very few firms are actually building causal models to support their causal decision making.

The academic community has taken on (conditional) causal estimation, and over the past 3-4 years we have seen an acceleration of research on the topic.¹ Much of this work has focused on machine learning methods for individual causal effect estimation (Dorie et al. 2019). The main motivation behind several of these methods is causal decision making (Athey and Imbens 2017, 2019, McFowland et al. 2021).

This article highlights an important perspective: Causal Decision Making (CDM) is not the same as Causal Effect Estimation (CEE). Moreover, and counterintuitively, accurate CEE is not necessary for accurately assigning treatments to maximize causal effect. Our experience is that this is not well understood by practitioners nor by most data science researchers—even those who routinely build models for estimating causal effects. Very recent research has started to dig in here, but there is a lot of fertile ground for new research due to the limited attention that this perspective has received. We will present three main implications for research and practice, in order to highlight how this perspective can be enlightening and impactful, but there likely are many other—possibly even more important—implications to be revealed by future research.

If we step back briefly, the fundamental problem in many predictive tasks is often one of assessing whether an intervention will have an effect. For example, when attempting to stop customers from leaving, the goal is not just to target the customers most likely to leave, but instead to target the customers that the incentive will cause to stay (in other words, when they otherwise would not have). For many advertising settings, the advertiser’s goal is not simply to target ads to people who will purchase after seeing the ad, but to target people for whom the ad will cause them to purchase. Generally, instead of simply predicting the likelihood of a positive outcome, for tasks such as these we ideally would like to predict whether a particular individual’s outcome can be improved by means of an intervention or treatment (i.e., the ad or the retention incentive in the examples).

¹ We hope that one contribution of this article is the two dozen very recent articles on the topic that we point to.

This type of causal decision making is an instance of the problem of treatment assignment (Manski 2004). Each possible course of action corresponds to a different “treatment” (e.g., “target” vs “not target”), and ideally each individual is assigned to the treatment associated with the most beneficial outcome (e.g., the one with the highest profit). Treatment assignment policies may be estimated from data using statistical modeling, allowing decision makers to map individuals to the best treatment according to their characteristics (e.g., preferences, behaviors, history with the firm). There are many different ways in which one could proceed, and various methods for the estimation of treatment assignment policies from data have been proposed across different fields, including econometrics (Bhattacharya and Dupas 2012), data mining (Radcliffe and Surry 2011), and machine learning in the contextual bandit setting (Li et al. 2010).

One approach for causal decision making that is becoming popular in the research literature is to use machine learned models to estimate causal (treatment) effects at the individual level, and then use the models to make intervention decisions automatically (Olaya et al. 2020). For instance, in cases where there is a limited advertising budget, causal effect models may be used to predict the expected effect of a promotion on each potential customer and subsequently target those individuals with the largest predicted effect.

However, causal decision making (treatment assignment) and causal effect estimation are not the same. Going back to the advertising example, suppose that a firm is willing to send an offer to customers for whom it increases the probability of purchasing by at least 1%. In this case, precisely estimating individual-level causal effects is desirable but not necessary; the only concern is identifying those individuals for whom the effect is greater than 1%. Importantly, overestimating (underestimating) the effect has no bearing on decision making when the focal individuals have an effect greater (smaller) than 1%. This is very similar to the distinction in non-causal predictive modeling between regression or probability estimation and classification, and we will take advantage of that analogy as we proceed.

More formally, the main distinction between causal decision making and causal effect estimation is their estimand of interest. The main object of study in (heterogeneous) causal effect estimation is the understanding of treatment effects in heterogeneous subpopulations. On the other hand, causal effect estimates are important for causal decision making only to the extent that they help to discriminate individuals according to preferred treatments.²

This paper draws on recent research to highlight three of the implications of this distinction.

1. We should consider carefully the objective function of the causal machine learning algorithm, and if possible it should optimize for accurate treatment assignment rather than for accurate effect

² Also compare this with distinctions between explanatory modeling and predictive modeling (Shmueli et al. 2010).

estimation. A CDM practitioner reaching for a “causal” machine learning algorithm that is geared toward accurately estimating conditional causal effects (as most are) may be making a mistake.

2. Confounding does not have the same effect on CDM as it does on CEE. The upshot is that for supporting CDM it may be just as good or even better to learn with confounded data—such as data suffering from uncorrectable selection bias. Acquiring (unconfounded) data on both “sides” of the counterfactual for modeling can be quite costly and often simply impracticable. Furthermore, even when we have invested in unconfounded data—for example, via a controlled experiment—often we have much more confounded data, so there is a causal bias/variance tradeoff to be considered.

3. Causal statistical modeling may not be necessary at all to support CDM, because there may be (and perhaps often is) a proxy target for statistical modeling that can do as well or better. This third implication helps to explain at least one broad common CDM practice that seems “wrong” at first blush—the widespread use of non-causal models for targeting interventions.

Overall, this paper develops the perspective that what might traditionally be considered “good” estimates of causal effects are not necessary to make good causal decisions. The three implications above are quite important in practice, because acquiring data to estimate causal effects accurately is often complicated and expensive, and empirically we see that results can be considerably better when modeling intervention decisions rather than causal effects. On the research side, as mentioned above, taking this perspective reveals substantial room for novel research

2. Distinguishing Between Effect Estimation and Decision Making

We use the potential outcomes framework (Rubin 1974) to define causal effects. The framework defines interventions in terms of **treatment levels**, which may range from two (e.g., to represent absence or presence of a treatment) to many more (e.g., to represent treatment doses). The framework also assumes the existence of one **potential outcome** associated with each treatment level for each individual, which represents the value that the outcome of interest would take if the individual were to be exposed to the associated treatment level. **Causal effects** are defined in terms of the difference between two potential outcomes.

The main difference between causal effect estimation and treatment assignment is the causal estimand of interest. Formally, let $Y(i) \in \mathbb{R}$ be the potential outcome associated with the treatment level i . When there are only two intervention levels (e.g., to represent the presence and absence of an intervention), the estimand of interest in (heterogeneous) **causal effect estimation** is:

$$f(x) = E[Y(1) - Y(0)|X = x], \quad (1)$$

which corresponds to the **conditional average treatment effect (CATE)** given the feature vector X that is used to characterize individuals. Several studies have proposed the use of machine

learning methods for CATE estimation (see Dorie et al. 2019, for a survey). Popular methods include Bayesian additive regression trees (Hill 2011), causal random forests (Wager and Athey 2018), and regularized causal support vector machines (Imai et al. 2013).

The counterpart in **causal decision making** (or treatment assignment) is:

$$a^*(x) = \arg \max_i E[Y(i)|X = x] = \mathbf{1}(f(x) > 0), \quad (2)$$

which corresponds to the treatment level (or action) that maximizes the expected value of the outcome of interest given the feature vector X .

Why are causal effect models so often considered the natural choice for causal decision making? We can see clearly that Equation 2 can be defined in terms of Equation 1: individuals with a positive CATE should be intervened. However, that is based on the true causal effect; models provide estimates, and estimates incorporate errors. It turns out that the sorts of errors incorporated in the estimates are critical. Moreover, as we discuss in detail, precise causal effect estimation is not necessary to make good intervention decisions, and more precise estimates of causal effects do not necessarily lead to better treatment assignments.

Another important distinction between causal effect estimation and causal decision making is that the outcome of interest may differ between the two. For example, in advertising settings, machine learning could be used to predict treatment effects on purchases with the intent of making treatment assignments that maximize profits. Nevertheless, the individuals for whom treatments are most effective (in terms of increasing the likelihood of purchase) are not necessarily the ones for whom the promotions are most profitable (Miller and Hosanagar 2020, Lemmens and Gupta 2020), so making decisions based on CATEs may lead to sub-optimal treatment assignments in these cases. On the other hand, when the outcomes of interest in the two tasks match (e.g., when CATEs are defined in terms of profits rather than purchases), making decisions based on the true CATEs (as defined in Equation 2) leads to optimal treatment assignments. (The problem with estimation errors still stands.) For a nuanced discussion on how CATEs may be used to optimize causal decision making under budget constraints, see McFowland et al. (2021).

3. Why It Matters

Let's consider three important practical implications that result from causal decision making and causal effect estimation having different estimands of interest.

3.1. Choosing the Objective Function for Learning

The first implication is that a machine learning model directly optimizing for treatment assignment can lead to better decisions than a machine learning model optimizing for causal effect estimation (Fernández-Loría et al. 2020). Machine learning procedures that estimate causal effects are

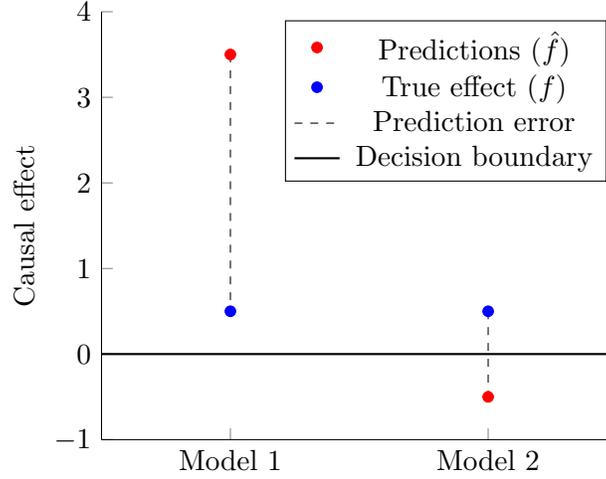

Figure 1 Comparison of the causal effect predictions made by two models

designed to segment individuals according to how their effects vary, but doing so is a more general problem than segmenting individuals according to how they should be treated. By focusing on a specific task (treatment assignment) rather than on a more general task (estimating causal effects), machine learning procedures can better exploit the statistical power available.

Formally, the (sometimes unstated) goal of machine learning methods that estimate causal effects is to optimize the **mean squared error (MSE)** for treatment effects:

$$\text{MSE}(\hat{f}) = E[(Y(1) - Y(0)) - \hat{f}(X)]^2, \quad (3)$$

which is minimized when $\hat{f} = f$ (see Equation 1). The main challenge in causal inference is that only one potential outcome is observed for any given individual, so Equation 3 cannot be directly calculated because $Y(1) - Y(0)$ is not observable. Fortunately, alternative formulations may be used to estimate the treatment effect MSE from data (Schuler et al. 2018), allowing one to compare (and optimize) models on the basis of how good they are at predicting causal effects.

However, optimizing causal effect predictions (by minimizing Equation 3) is not the same as optimizing treatment assignments. We illustrate this in Figure 1, which compares the causal effect predictions made by two different models for a single individual, one with a high prediction error (Model 1) and another with a low prediction error (Model 2). The blue (dark) dots correspond to the “true” CATE for the individual (they are the same for both models), whereas the red dots correspond to the predictions made by the models. A larger distance between the blue and the red dots (represented by dashed lines) implies that the model has a larger MSE and therefore makes worse causal effect predictions.

In this example, the true CATE is greater than 0 (and hence above the decision boundary), which implies that this individual should be treated. Therefore, to the extent that $\hat{f}(x) > 0$, \hat{f} leads

to an optimal treatment assignment. Consider the zero line to be the causal effect of the “don’t treat” decision.³ Figure 1 shows that the model with a larger prediction error makes the optimal treatment assignment because the rank ordering of the treatment alternatives (“treat” and “not treat”) when using the predicted effect is the same as the rank ordering when using the CATE. The second model makes a worse treatment assignment, even though its prediction errors are smaller, because the ordering is inverted. Therefore, choosing the model with the lower (and thus better) MSE leads to a worse treatment assignment.

The above implies that, when evaluating models for treatment assignment, what matters is their ability to minimize the expected difference between the best potential outcome that could possibly be obtained and the potential outcome that would be obtained by using the model. This evaluation measure is also known as **expected regret (or just “regret”)** in decision theory:

$$\text{Regret}(\hat{a}) = E[Y(a^*(X)) - Y(\hat{a}(X))], \quad (4)$$

where \hat{a} corresponds to the evaluated treatment assignment policy, such as $\hat{a} = \mathbf{1}(\hat{f}(x) > 0)$. Regret is minimized when $\hat{a} = a^*$ (see Equation 2). As with causal effect estimation, an important challenge when learning treatment assignment policies from data is that only one potential outcome is observed for each individual. However, alternative formulations of Equation 4 allow the use of historical data to evaluate models for individual treatment assignment on an aggregate basis, based on observed treatment assignments (Li et al. 2010, Schuler et al. 2018).

So, how can machine learning methods optimize for treatment assignment itself, instead of optimizing for accurate effect estimation? One approach to minimizing Equation 4 using machine learning is to reduce treatment assignment to importance weighted classification (Zadrozny 2003, Zhao et al. 2012). As Zadrozny (2003) first noted, treatment assignment can be framed as a weighted classification problem where the optimal treatment assignment is the target variable (as defined in Equation 2) and the outcomes observed under each treatment level serve to weight observations. This allows the use of any supervised classification algorithm to optimize for treatment assignment (Beygelzimer and Langford 2009), but methods specifically designed for solving treatment assignment as a weighted classification problem also exist (Zhao et al. 2012).

Notably, since minimizing regret is equivalent to minimizing the weighted misclassification rate as specified by Zadrozny (2003), a useful analogy in this context is to think about treatment assignment as a classification problem and to think about causal effect estimation as a probability estimation (or regression) problem; the two tasks are related but not exactly the same. Importantly, it is well known in the predictive modeling literature that models that have a good classification

³ This allows what follows to apply when there is more than just one possible treatment.

performance are not necessarily good at estimating class probabilities and vice versa (Friedman 1997). Similarly, the bias and variance components of the estimation error in causal effect predictions may combine to influence treatment assignment in a very different way than with the squared error of the predictions themselves (Fernández-Loría and Provost 2018). So, models that are relatively bad at causal effect prediction may be good at making treatment assignments, and models that are relatively good at causal effect prediction may be bad at making treatment assignments.

Of course, in theory, the gap in performance between models optimized for causal effect estimation and models optimized for treatment assignment should disappear with unlimited data because models that accurately estimate individual-level causal effects should converge to optimal decision making (as shown in Equation 2). However, there is empirical evidence that the gap can persist even with training data consisting of more than half a billion observations (Fernández-Loría et al. 2020).⁴ Modeling optimal treatment assignment (rather than causal effects) can result in better causal decision making even in cases where there is plenty of data to estimate causal effects.

3.2. Choosing the Training Data

The second implication is that data that provides little utility for accurate causal effect estimation, due to confounding, may still be quite useful for causal decision making (Fernández-Loría and Provost 2019). One of the main concerns when estimating causal effects from data is the possibility of bias due to confounding, e.g. due to selection bias (Yahav et al. 2015). Formally, if T represents the treatment assignment, confounding occurs whenever $E[Y(i)|T = i, X] \neq E[Y(i)|X]$, which implies that individuals that were exposed to the treatment level i are systematically different from the individuals in the overall population, and in particular different with respect to the outcome of interest. To estimate causal effects from data, the individuals that received the treatment (the **treated**) and the individuals that did not receive the treatment (the **untreated**) ideally should be comparable in all aspects related to the outcome, with the exception of the assigned treatment. This assumption is known as ignorability (Rosenbaum and Rubin 1983), the back-door criterion (Pearl 2009), and exogeneity (Wooldridge 2015). If, for example, the treated would have a better outcome than the untreated even without the treatment, then the estimation will suffer from an upward “causal” bias⁵; the treatment will be falsely attributed a positive causal effect that should be attributed to another unobserved, systematic difference between treated and untreated.

Bias due to (unobserved) confounding is often regarded as the kiss of death in the causal inference world. Because it cannot be quantified from observational data alone, no additional amount of data

⁴ In this case to build Spotify playlists that will lead to longer listening.

⁵ We explicitly call this “causal” bias to distinguish it from all the other sorts of bias that are involved in statistical estimation. In particular, this bias is different from the statistical bias usually examined in the context of machine learning’s bias/variance tradeoff. There is a separate causal bias/variance tradeoff (Fernández-Loría and Provost 2019).

can help if the goal is to estimate causal effects. In fact, with more data, the estimate will converge to a biased (and so, arguably wrong) estimate of the effect. Nevertheless, confounding bias does not necessarily hurt decision making (Fernández-Loría and Provost 2019). For example, suppose that the large prediction error made by Model 1 in Figure 1 is the result of using confounded training data to estimate the model. In this case, the confounding bias is clearly not hurtful for decision making. In addition, more data can in fact potentially correct the detrimental effect of confounding bias on decision making, and even confer a beneficial effect by lessening potential errors due to variance, as we illustrate below.

This implication is particularly important because modern business information systems often are *designed* to confound the data they produce. For example, advertisers use machine learning models to target likely buyers with ads, and websites often recommend to their users the products that they are more likely to choose. If we were to use the data produced by these systems to estimate the causal effects of ads or recommendations, the estimates will almost certainly be biased because those targeted with interventions are the ones who had been estimated to be likely to have a positive result (even without an intervention). Some recent developments in the estimation of treatment assignment policies from observational data are specifically motivated to deal with confounding bias (Athey and Wager 2021). However, these approaches assume that the selection is observable (i.e., all confounding is captured by the feature vector X) or that treatment effects can be consistently estimated in some alternative way (e.g., by using instrumental variables). Yet evidence from large-scale experiments suggests that confounding bias is likely to persist after controlling for observable variables (Gordon et al. 2019), and as pointed out above, correcting for confounding bias in causal effect estimates may actually lead to worse treatment assignments by increasing errors due to variance.

An important alternative to dealing with confounding is to collect data for model training using randomized experiments. Observational studies that do causal estimation have been downplayed in favor of randomized experiments due to the ability of the latter to control for all confounders; the randomization procedure ensures that, on average, treated and untreated will be comparable in all aspects other than the treatment assignment. Therefore, one could think about experiments as the natural approach to avoid confounding. We should note that by our understanding of current practice (not academic research), most randomized experiments are not implemented to gather data for training models, but rather for the evaluation of specific hypotheses. This may include evaluating different machine learning models, for example to determine if a new model is statistically significantly better than the currently deployed model. The important point here is that the amount of data needed to *evaluate* model performance is usually much smaller than the amount of data needed to *train* accurate models of conditional treatment effects.

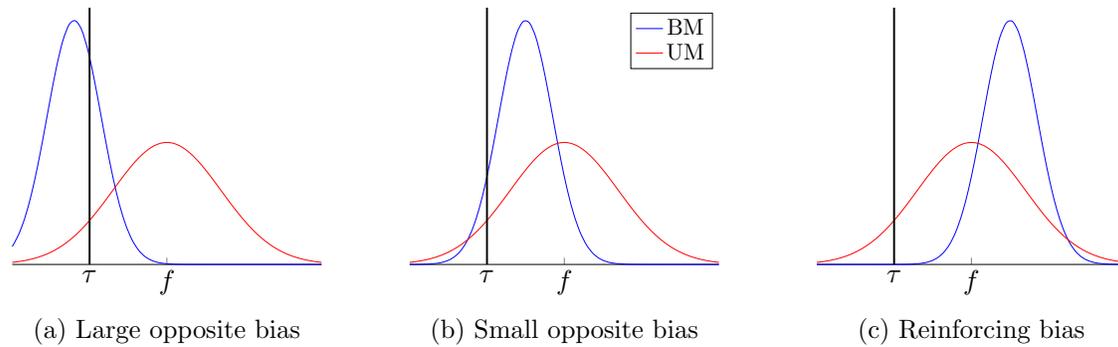

Figure 2 Sampling distributions of the causal effect estimate of a biased model (BM) and an unbiased model (UM). In this example (see details in the text), the correct decision is made when a model’s estimate of f is larger than τ . For decision making, BM can be either worse (a), about the same (b), or even better (c) than UM.

Randomized experiments producing data large enough to train accurate CATE models may be very expensive—in many situations prohibitively expensive—forcing us to proceed using whatever data we may have at hand. They are expensive because the treatments may be costly (especially treating those for whom it would have no beneficial effect) and because of the opportunity costs incurred by withholding treatment from those for whom it would be beneficial. Moreover, randomized experiments are not always possible. For example, one cannot randomly force workers to switch jobs in order to assess the impact of different jobs on future career opportunities. Yet, freelancing platforms like Upwork may be interested in making job recommendations. Business-to-business firms often cannot simply withhold services from their customers, as a consumer-oriented business might.⁶

Let’s illustrate the feasibility of using confounded data for causal decision making with another example, shown in Figure 2. In this example, we need to decide whether to intervene on a particular individual. Figure 2 shows the true causal effect f and the optimal threshold τ for deciding whether to intervene (i.e., τ considers the costs of intervening vs. not intervening). In our example, $f > \tau$, meaning that for this individual the optimal decision is to intervene. Of course, we do not know the true effect f , so we consider two models to estimate it (BM and UM). Each of the panels in Figure 2 shows the sampling distributions of the causal effect estimates provided by the two models under different degrees of causal bias. One model (BM, in blue) is biased due to confounding that varies across panels—this bias can be seen in the figures, as the distributions of BM’s estimate are not centered on f . On the other hand, BM benefits from relatively small variance because there is plenty of naturally occurring (biased) training data available. The second model (UM, in red) is the same across all three panels, and it is unbiased—we can see that its distribution is indeed centered

⁶ Understanding how confounding affects intervention decision making is useful even when experiments are feasible. For example, as we describe next, causal bias may either help or hurt decision making. Careful experimentation may help to determine whether it would be profitable to invest in correcting causal bias.

on f . However, UM suffers from larger variance because it was learned using an unconfounded training data set that is smaller due to experimentation costs.

When using a model for decision making, we obtain an estimate drawn from the model’s sampling distribution, and we intervene if the estimate of the causal effect is greater than (to the right of) τ . Therefore, for each sampling distribution, the area to the left side of τ represents the probability of making the wrong decision. In this example, UM usually leads to the correct decision (i.e., most of the red distribution falls to the right of τ).⁷ In contrast, decision making using BM is strongly affected by the causal bias. Figure 2a shows a case in which more than half of the distribution of BM falls to the left of τ , due to a large “downward” bias that leads BM to systematically underestimate f . Under these circumstances, the bias is so strong that BM makes the wrong decision on average. Thus, here UM is a better alternative, despite having larger variance.

Now consider Figure 2b. Here the causal bias still leads BM to systematically underestimate f , but slightly less. This small change in effect estimation bias has a large effect on decision-making accuracy—for decision-making BM’s smaller variance compensates for its bias. Whereas in Figure 2a UM was clearly a much better choice, in Figure 2b it is no longer clear which model is a better alternative—the two models seem equally likely to make the correct decision, and it is easy to see how BM could be preferable despite its bias if it had even smaller variance. Importantly, both BM and UM would converge to the optimal decision with unlimited data because their distributions are centered in the “correct side” of the threshold, implying that in such cases the detrimental effect of confounding on decision making can be corrected with larger data. So, while BM cannot recover the true causal effect, it can in fact identify the optimal decision.

Finally, Figure 2c shows an example in which causal bias could help. In our example, this would happen when the bias leads to an overestimation of the causal effect,⁸ which lessens errors due to variance. In practice, this could occur when confounding is stronger for individuals with large effects—for example, if confounding bias is stronger for “likely buyers,” but the effect of ads is also stronger for them. In such scenarios, BM would be a better alternative than UM for making intervention decisions, even if its causal effect estimates are highly inaccurate.

The key insight here is that optimizing to make the correct decision generally involves understanding whether a causal effect is above or below a given threshold, which is different from optimizing to reduce the magnitude of the bias in a causal effect estimate. Hence, correcting for confounding bias when learning treatment assignment policies (e.g., as proposed in Athey and Wager (2021)) may actually hurt decision making! Furthermore, models trained with confounded

⁷ If f had been closer to τ , UM would make the wrong decision more often.

⁸ More generally, it happens when the bias pushes the estimation further in the direction of the correct decision.

data may lead to decisions that are just as good (or better) than the decisions made with models trained with costly experimental data (Fernández-Loría and Provost 2019), in particular when larger causal effects are more likely to be overestimated or when the variance reduction benefits of larger and cheaper data outweigh the detrimental effect of confounding.

Although most of our discussion focuses on selection in treatment assignment as a source of confounding bias, this insight is agnostic to the source of the bias and can be generalized to other situations where the data may be problematic for causal effect estimation. For instance, the bias could be the result of violating the Stable Unit Treatment Value Assumption (SUTVA), non-compliance with the treatment assignment, flaws in the experimental design, or differences between the setup in the training data and the setting where the trained model is expected to be used. The main takeaway is that data issues that make it impossible to accurately estimate causal effects do not necessarily imply that the data is useless for making intervention decisions.

3.3. Leveraging Alternative Target Variables

The third implication that arises from drawing the distinction between causal decision making and causal effect estimation is that, for causal decision making, modeling with alternative (potentially non-causal) target variables may work better than predicting the actual causal effects on the outcome of interest (Fernández-Loría and Provost 2018). To elaborate on this implication, consider again the binary treatment setting where we would like to treat those individuals for whom the treatment will have a positive effect. This essentially defines a causal classification problem: classify individuals into treat or do-not-treat.⁹ Viewing CDM as a classification task allows us to draw an analogy with the distinctions between classification versus regression and classification versus probability estimation, that have been studied in depth in non-causal predictive modeling. Specifically, many classification decisions essentially involve comparing an instance’s estimated class membership probability to a threshold, and then taking action based on whether the estimate is above or below the threshold.¹⁰ In such situations, causal effect estimates are relevant for decision making only to the extent that they help to discriminate between the desired actions, for example, those who would benefit from being treated versus those who would not.

What does this have to do with alternative target variables? For traditional classification, we know that often we can build more effective predictive models by using a proxy target variable,

⁹ The binary treatment distinction is purely for ease of illustration. With multiple treatment options we have a multi-class classification problem. As mentioned earlier, causal decision making can be reduced to a classification task where individuals should be classified into the treatment level (class) that produces the most beneficial outcome (Zadrozny 2003, Zhao et al. 2012).

¹⁰ The threshold could be based on a cost/benefit matrix (Provost and Fawcett 2013); it could be based on a budget or workforce constraint (Provost and Fawcett 2001), or it could even be instance-specific (Saar-Tsechansky and Provost 2007).

rather than a target variable that represents the true outcome of interest (Provost and Fawcett 2013). Proxy modeling is often applied when data on the true objective is in short supply (or even completely nonexistent). In online advertising, for example, often little data is available on the ultimate desired conversion (e.g., purchases). This can pose a challenge for accurate campaign optimization (due to low conversion rates, cold start periods, etc.). In this context, Dalessandro et al. (2015) demonstrate the effectiveness of proxy modeling and find that predictive models built based on brand site visits (which are much more common than purchases) do a remarkably good job of predicting which browsers will make a purchase. Causal modeling also often suffers from scant training data; similarly to non-causal predictive modeling, estimating the best action based on a proxy target may work better than directly estimating causal effects on the outcome of interest.

The use of proxy outcomes to build predictive conditional causal models should not be a major paradigm shift for researchers, because proxy or “surrogate” outcomes already are sometimes used to evaluate treatment effects (Prentice 1989, VanderWeele 2013). For example, in clinical trials, the goal is often to study the efficacy of an intervention on outcomes such as the long-term health or survival rate of patients. However, the primary outcome of interest might be very rare or only observed after years of delay (e.g., a 5-year survival rate). In such cases, it is common to use the effect of an intervention on surrogate outcomes as a proxy for its effect on long-term outcomes. Recently, Yang et al. (2020) propose how to use surrogate outcomes to impute the missing long-term outcomes and use the imputed long-term outcomes to optimize a targeting policy; they demonstrate their approach in the context of proactive churn management. The use of short-term proxies to estimate long-term treatment effects is discussed in more detail by Athey et al. (2016).

However, in practice, it is much more common for firms to make targeted intervention decisions without any sort of causal modeling at all! Instead, in large-scale predictive applications such as ad targeting and churn incentive targeting, typically practitioners simply target based on models predicting outcomes (e.g., whether someone will buy after being shown an ad) rather than models predicting treatment effects (Ascarza et al. 2018). For example, in targeted online advertising, although ad campaigns are sometimes evaluated in terms of their causal effect (e.g., through A/B testing), causal effect models are rarely used for actually targeting the ads! Instead, potential customers are usually targeted based on predictions of how likely they are to convert, which are upwardly biased estimates of individual causal effects because they do not account for the counterfactual (e.g., a customer may buy even without the ad). Researchers and savvy practitioners see this as due either to naivety, lack of modeling sophistication, or pragmatics (Ascarza et al. 2018, Provost and Fawcett 2013). However, outcome prediction models are used even when practitioners have looked carefully at the estimation of treatment effects (cf., Stitelman et al. (2011) and Perlich

et al. (2014) for a clear example). We suggest that this use of outcome models rather than causal-effect models can be seen as proxy modeling—and we should not simply criticize the practitioners for lack of modeling sophistication, but rather ask what George Box might have asked: are the proxy models more useful?

Although practitioners should indeed proceed with caution when targeting with outcome prediction models (Ascarza 2018, Radcliffe and Surry 2011), prior research studies do show evidence that targeting based on outcome predictions can be effective. For example, in an advertising campaign of a major food chain, Stitelman et al. (2011) found that displaying ads based on likelihood of conversion increased the volume of prospective new customers by 40% more than displaying ads to the general population. Huang et al. (2015) deployed a churn prediction model in a telecommunications firm that increased the recharge rate of potential churners by more than 50% according to an A/B test. MacKenzie et al. (2013) estimated that 35% of what consumers purchase on Amazon and 75% of what they watch on Netflix come from product recommendations based on predictive models. Importantly, none of these targeting approaches modeled more than one potential outcome, so it would be wrong to interpret the model estimates as causal effects; yet their estimates were useful to identify individuals who would be positively affected by interventions.

In fact, consistent with the proxy-modeling view, using outcome predictions can result in more effective causal decision making than using causal effect predictions. Radcliffe and Surry (2011) provide a list of several conditions under which causal effect predictions may not produce better targeting results than outcome predictions, such as when treatment effects are particularly small and outcomes are informative of effects. Fernández-Loría and Provost (2018) explain why, presenting a theoretical analysis comparing the two approaches and showing that larger sampling variance in treatment effect estimation may lead to more errors than the (biased) outcome prediction approach. Moreover, they show that the often stronger signal-to-noise ratio in outcome prediction may help with intervention decisions when outcomes and treatment effects are correlated. Thus, in some settings, it may be possible to make good targeting decisions without actually having any data on how people behave when targeted!

We illustrate this last point using data made available by Criteo (an advertising platform) based on randomly targeting advertising to a large sample of users. (Diemert et al. 2018).¹¹ We use “conversions” as the outcome of interest. The data include 13,979,592 instances, each representing a user with 11 features, a treatment indicator for the ad, and the label (i.e., whether the user converted or not). The treatment rate is 85%.

¹¹ Check <https://ailab.criteo.com/criteo-uplift-prediction-dataset/> for details and access to the data. We use the version of the dataset that does not have leakage.

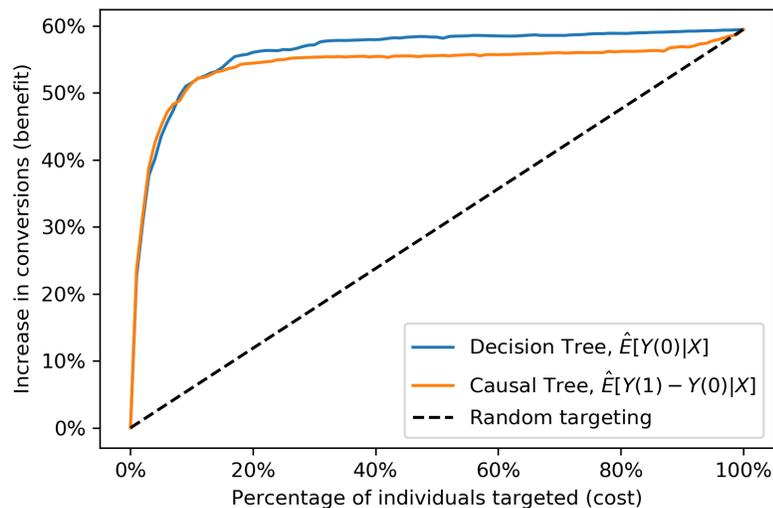

Figure 3 Increase in conversions produced by an outcome model and an uplift model

We consider two different targeting models: a causal tree (Athey and Imbens 2016) that predicts the CATE of the ad on conversions, and a non-causal decision tree that predicts the probability of conversion (without showing the ad). Both models were tuned and evaluated using cross-validation, so the results we report next were obtained using out-of-sample predictions. Figure 3 shows the uplift curves (Radcliffe and Surry 2011) of the two approaches. An uplift curve shows the causal impact (y-axis) as a function of how many individuals are treated with a given treatment policy.

Surprisingly, the (non-causal) decision tree is better than the causal tree at identifying the candidates for whom the ad is most effective! The explanation behind this counterintuitive result is that features that are predictive of conversions are also predictive of treatment effects. However, the signal-to-noise ratio is higher for conversions than for treatment effects. Therefore, it’s easier for machine learning algorithms to discriminate individuals according to outcomes than according to treatment effects. Critically, the training data used to estimate the causal tree is almost 7 times larger than the training data used to estimate the decision tree (recall that the treatment ratio is 85%). Thus, even though (in theory) the causal tree should outperform the decision tree with more data, acquiring enough training data to reach that point may be overly expensive in this case (because the data is collected by randomly targeting and withholding treatments).

4. Conclusions and Future Research

This paper takes the perspective that causal decision making and causal effect estimation are fundamentally different tasks. They are different tasks because their estimands of interest are different. Causal effect estimation assesses the impact of an intervention on an outcome of interest, and often we want or need accurate (and unbiased) estimations. On the other hand, unbiased and

accurate estimation of causal effects is not necessary for causal decision making, where the goal is to decide what treatment is best for each individual—a causal classification problem.

We present implications of making this distinction on (1) choosing the algorithm that is used to learn treatment assignment policies, i.e., causal predictive models, (2) choosing the training data that is used to learn the causal models, and (3) choosing the target variable for training the causal models. Importantly, we highlight that traditionally “good” estimates of causal effects are not necessary to make good causal decisions.

Of course, this does not imply that firms should stop investing in randomized experiments or that causal effect estimation is not relevant for decision making. The argument here is that causal effect estimation is not necessary for *doing* effective treatment assignment. However, causal effect estimation is certainly important for the *evaluation* of causal decisions, particularly if there are concerns about how and why the decisions were made. Therefore, this paper should not be interpreted as a discourse against randomized experiments or methods for causal effect estimation; if anything, we hope this paper will encourage practitioners to run randomized experiments evaluating all sorts of treatment assignment policies, including policies based on non-causal statistical models. Furthermore, randomized experiments can be leveraged to identify the underlying theoretical mechanisms that result in some treatments being more effective for certain subpopulations (Tafti and Shmueli 2020), which may lead to the development of even more effective treatments.

There are multiple major opportunities for future research in causal decision making. First, most studies that distinguish between causal decision making and causal effect estimation do so in the context of decisions that are categorical and independent. This limitation in scope is what has allowed researchers to draw parallels between causal decision making and classification. However, few studies have discussed continuous decisions (Dubé and Misra 2019) or settings where multiple treatments are assigned to the same individuals over time (Chakraborty and Murphy 2014). The results discussed in this paper imply that what matters in causal decision making is the *ranking* of the alternatives available to the decision maker rather than accurately estimating the outcomes or effects associated with each alternative. Therefore, prediction errors that preserve the ranking should not affect continuous or time-dependent decisions either. A unified and general framework explaining how prediction errors may affect causal decision making in more broad settings is thus a natural step for future research.

Another promising direction for future work is the mathematical formalization of the conditions under which optimal treatment assignments can be learned from data. In causal effect estimation, several studies have proposed mathematical assumptions to characterize the conditions under which causal effects can be consistently estimated from data. Well-known examples include SUTVA (Cox 1958), ignorability (Rosenbaum and Rubin 1983), back-door criterion (Pearl 2009), front-door

criterion (Pearl 2009), transportability (Pearl and Bareinboim 2011), and other assumptions for the identification of causal effects using instrumental variables (Angrist et al. 1996). The perspective presented in this paper suggests that such assumptions are not necessary to learn optimal treatment assignments from data. As an example, assuming the unconfoundedness assumption is violated and the selection mechanism producing the confounding is a function of the causal effect—so that the larger the causal effect the stronger the selection—then (intuitively) the ranking of the preferred treatment alternatives should be preserved in the confounded setting, allowing the estimation of optimal treatment assignment policies from data. Mathematically formalizing such settings and linking them to real-world applications is a promising direction for future research.

The results discussed here also suggest that machine learning procedures that combine multiple sources of data (e.g., observational and experimental data) could conceivably lead to better intervention decisions by optimizing the trade-off between confounding bias and supervised learning errors. Hence, another promising area for future research in causal decision making is the development of methods that can combine multiple sources of data. There have been several pioneering efforts to combine observational and experimental data for causal inference (Peysakhovich and Lada 2016, Rosenman et al. 2020, Kallus et al. 2018, Fernández-Loría and Provost 2020, Athey et al. 2020), but most of them with the intention of estimating causal effects (rather than treatment assignment policies). Another interesting direction for the development of new methods is to try “clever” experimentation. For instance, decision makers could focus on running randomized experiments in parts of the feature space where the confounding is particularly hurtful for decision making, resulting in higher returns on their experimentation budget. Recent efforts seeking to maximize the decision making benefits of randomized controlled trials while minimizing experimentation costs (Feit and Berman 2019, Simester et al. 2020, Gangarapu et al. 2020, Miller and Berman 2020) suggest that this is a particularly promising research direction.
