Distantly-Supervised Long-Tailed Relation Extraction Using Constraint Graphs

Tianming Liang, Yang Liu, Xiaoyan Liu, Gaurav Sharma, *Fellow, IEEE* and Maozu Guo

Abstract—Label noise and long-tailed distributions are two major challenges in distantly supervised relation extraction. Recent studies have shown great progress on denoising, but pay little attention to the problem of long-tailed relations. In this paper, we introduce constraint graphs to model the dependencies between relation labels. On top of that, we further propose a novel constraint graph-based relation extraction framework (CGRE) to handle the two challenges simultaneously. CGRE employs graph convolution networks (GCNs) to propagate information from data-rich relation nodes to data-poor relation nodes, and thus boosts the representation learning of long-tailed relations. To further improve the noise immunity, a constraint-aware attention module is designed in CGRE to integrate the constraint information. Experimental results on a widely-used benchmark dataset indicate that our approach achieves significant improvements over the previous methods for both denoising and long-tailed relation extraction. Our dataset and codes are available at [https://github.com/tmliang/CGRE](https://github.com/tmliang/CGRE).

Index Terms—Neural Relation Extraction, Distantly Supervision, Long-tailed Distributions, Multi-instance Learning.

1 INTRODUCTION

Relation extraction (RE), which aims to extract the semantic relations between two entities from unstructured text, is crucial for many natural language processing applications, such as knowledge graph completion [1], [2], search engine [3], [4] and question answering [5], [6]. Although conventional supervised approaches have been extensively researched, they are still limited by the scarcity of manually annotated data. Distantly supervised relation extraction (DSRE) [7] is one of the most promising techniques to address this problem, because it can automatically generate large scale labeled data by aligning the entity pairs between text and knowledge bases (KBs). However, distant supervision suffers from two major challenges when used for RE.

The first challenge in DSRE is label noise, which is caused by the distant supervision assumption: if one entity pair has a relationship in existing KBs, then all sentences mentioning the entity pair express this relation. For example, due to the relational triple ("Bill Gates, *Founded*, Microsoft"), distant supervision will generate a noisy label "Bill Gates speaks at a conference held by Microsoft", although this sentence does not mention this relation at all.

In recent years, many efforts have been devoted to improving the robustness of RE models against label noise. The combination of multi-instance learning and attention mechanism is one of the most popular strategies to reduce the influence of label noise [8], [9], [10]. This strategy extracts relations of entity pairs from sentence bags, with the purpose of alleviating the sentence-level label noise. In addition, some novel strategies, such as reinforcement learning [11], [12], adversarial training [13], [14], [15], [16] and deep clustering [17], [18] also show great potential for DSRE. However, these approaches are driven totally by the noisy labeling data, which may misguide the optimization of parameters and further hurt the reliability of models.

To address this problem, some researchers attempt to enrich the background knowledge of models by integrating external information. In general, the external information, e.g., entity descriptions [19], [20], entity types [21], [22], [23] and knowledge graphs [20], [24], will be encoded as vector form, and then integrated to DSRE models by simple concatenation or attention mechanism. As compared with the above implicit knowledge, constraint rules are explicit and direct information that can effectively enhance the discernment of models in noisy instances. However, directly filtering the noisy instances from dataset with the constraints will lose a large amount of useful information. Hence, we explore a soft way to integrate the constraint information by attention mechanism in this paper.

The second challenge in DSRE is long-tailed relation extraction, however, which tends to be neglected as compared with the noisy labeling problem. In fact, real-world datasets of distant supervision always have a skewed distribution with a long tail, i.e., a small proportion of relations (a.k.a head relation) occupy most of the data, while most relations (a.k.a long-tailed relation) merely have a few training instances. As shown in Figure 1, more than 60% relations are long-tailed with fewer than 100 instances in the widely-used New York Times (NYT-10) dataset [25]. Long-tailed relation extraction is important for knowledge graph construction and completion. Unfortunately, even the state-of-the-art DSRE models are not able to handle long-tailed relations well. Hence, how to train a balanced relation...
extractor from unbalanced data becomes a serious problem in relation extracting.

In general, long-tailed classification tasks are addressed by re-sampling or re-weighting, nevertheless, long-tailed relation extraction is special because the relation labels are semantically related instead of independent of each other. For example, if relation /location/country/capital holds, another relation /location/location/contains will holds as well. Therefore, a promising strategy for long-tailed relation extraction is to mine latent relationships between relations by modeling the dependency paths. Once the dependency paths have been constructed, the relation labels are no longer independent of each other, and rich information can be propagated among the relations through these paths, which is crucial for the data-poor long-tailed relations. For that, Han et al. [25] proposed relation hierarchical trees, which connect different relation labels according to hierarchical information in the relation names. For instance, relation /people/person/nationality and relation /people/person/religion have the same parent node /people/person in relation hierarchical trees. Due to the effectiveness, most of the existing long-tailed relation extraction models [26], [27], [28], [29], [30] rely on the relation hierarchical tree. However, relation hierarchical trees suffer from several limitations:

(1) the construction of the relation hierarchical trees requires the relation names in hierarchical format, which conflicts with many existing RE datasets, e.g., SemEval-2010 Task8 [31], TACRED [32], and FewRel [33], [34];

(2) the sparsity of the hierarchy tree hinders the representation learning of some extremely long-tailed relations;

(3) the optimization of parameters is purely driven by the noisy training data, lacking enough effective supervision signals. Although knowledge graph embeddings were incorporated by Zhang et al. [27], they were simply used as initial embeddings of the relation labels.

To overcome the limitations of relation hierarchies, we explore the feasibility of utilizing another structure, constraint graphs, to represent the intrinsic connection between relations. As shown in Figure 2, a constraint graph is a bipartite digraph [35], in which each directed edge connects a relation node to a type node or vice versa. As compared with entity-level knowledge graph, constraint graphs provide more basic and general knowledge, more direct rule constraints, and a smaller vector space for knowledge mining and reasoning. Moreover, most knowledge bases (e.g. Freebase) preserve the entity type constraint information [36], which can be directly used for constraint graph construction. Even for datasets without relevant information, constraint graphs can be easily constructed according to the definition of each relation or the co-occurrence frequency of each relation with entity type pairs in the training set.

In our observations, there are at least two kinds of information in constraint graphs that are beneficial to DSRE: (1) constraint information. For example, it is obvious that the types of head and tail entities for relation /people/person/children are both Person. Such constraint provides direct and effective prior information for DSRE models to recognize the noisy instances; (2) interactive information. As showed in Figure 2, relation nodes are connected indirectly through entity type nodes. Similar to the relation hierarchy-based methods, we can utilize message passing between nodes to transfer rich knowledge from head relations to long-tailed relations.

Based on the aforementioned motivations, we propose a novel constraint graph-based relation extraction framework (CGRE). Our framework consists of three main components: a sentence encoder used for encoding the corpus information, a graph encoder used for encoding the constraint graph information, and an attention module used for integrating different information from the two separate encoders. Specifically, we adopt GCNs [37] as the graph encoder to extract interactive information from the constraint graph. Intuitively, the neighborhood integration mechanism of GCNs can efficiently improve the representation learning of long-tailed relations by propagating rich information from popular nodes to rare nodes. In addition, different from the plain selective attention [8], which is mainly dependent on the semantic similarity between sentences and relation labels, our constraint-aware attention combines both the semantic information and constraint information. In our mechanism,
the attention score of each instance depends on not only its semantic similarity with the relation representations, but also its compatibility with the entity type constraints.

Our main contributions are as follows:

- We explore a novel knowledge structure, constraint graphs, to model the intrinsic connections between relation labels. Compared with the popular relation hierarchical trees, our constraint graphs have better universality, directness and effectiveness.
- We propose to apply GCNs on constraint graphs to facilitate message passing from data-rich head relations to data-poor long-tailed relations.
- We design a novel attention mechanism to integrate both context information and constraint information.
- The experimental results on a widely-used benchmark dataset show the effectiveness of our approach for both denoising and long-tailed relation extraction.

2 Framework

Starting with notations and definitions, we will introduce the construction process of a raw constraint graph, and then detail each component of our framework. As illustrated in Figure 3, our framework consists of three key modules:

- **Sentence Encoder.** Given a sentence with two mentioned entities, the sentence encoder is adopted to derive a sentence representation.
- **Graph Encoder.** Given a raw constraint graph $G$, we first transform it into an embedding matrix and then apply the graph encoder to extract the representations of relations and entity types.
- **Constraint-Aware Attention.** By combining outputs from the two separate encoders, this module allocates a attention score for each instance in a bag, and then compute the bag representation.

### 2.1 Notations and Definitions

We define a constraint graph as a triple $G = \{T, R, C\}$, where $T$, $R$, $C$ indicate the sets of entity types, relations, and constraints, respectively. Each constraint $(t^{e_1}_i, r, t^{e_2}_i) \in C$ indicates that for relation $r$, the type of head entity can be $t^{e_1}_i \in T$ and the type of tail entity can be $t^{e_2}_i \in T$. Given a bag of sentences $B = \{s_1, \ldots, s_n\}$ and a corresponding entity pair $(e_1, e_2)$, the purpose of distantly supervised relation extraction is to predict the relation $r_i$ for the entity pair $(e_1, e_2)$.

### 2.2 Constraint Graph Construction

Most knowledge bases provide the entity type constraint information. For example, in Freebase, these constraints are located in `rdf-schema#domain` and `rdf-schema#range` fields. However, the original constraints always involve thousands of entity types. To avoid over-parameterization, we merely use 18 coarse entity types defined in OntoNotes 5.0 \[38\], and then remove the constraints containing unrelated types. Finally, we can obtain a raw constraint graph $G$ that consists of a relation set $R$, a type set $T$, and a constraint set $C$. Note that we use a special type `Others` for the entities that do not belong to the 18 types, thus the size of $T$ is 19.

### 2.3 Sentence Encoder

To encode the sentence information, we first adopt entity-aware word embeddings \[39\] to represent each word in a sentence, and then apply PCNN \[40\] to derive the sentence representation.

#### 2.3.1 Input Layer

The input layer aims to maps words into a distributed embedding space to capture their semantic and syntactic information. Given a sentence $s = \{w_1, \ldots, w_l\}$, we transform each word $w_i$ into a $d_w$-dimensional vector $v_i$ by a pre-trained embedding matrix. Then following \[39\], we...
represent the target entities $e_1$ and $e_2$ by their word vectors $v^{e_1}$ and $v^{e_2}$. To incorporate the position information, we use two $d_p$-dimensional vectors $p^{e_1}_i$ and $p^{e_2}_i$ to embed the relative distances between $v_i$ and the target entities, as used in [40]. By concatenating, two types of word embeddings can be obtained as follows:

$$
x^{e}_i = [v_i; p^{e_1}_i; p^{e_2}_i] \in \mathbb{R}^{d_v + 2d_p},
$$

Finally, we apply the entity-aware word embedding to represent each word $w_i$ as follows:

$$
A^e = \text{sigmoid} (\lambda \cdot (W_1 X^e + b_1)),
\hat{X}^p = \text{tanh} (W_2 X^p + g_2),
X = A^e \odot X^e + (1 - A^e) \odot \hat{X}^p,
$$

where $X^p = \{x^p_1, \ldots, x^p_n\}$, $X^e = \{x^e_1, \ldots, x^e_n\}$, $\odot$ denotes element-wise product, $W_1$ and $W_2$ are weight matrices, $b_1$ and $b_2$ are bias vectors, and $\lambda$ is a hyper-parameter denoting smoothing coefficient.

2.3.2 Encoding Layer

The encoding layer aims to extract a high-dimensional representation from the input sequence. In consideration of simplicity and effectiveness, we employ PCNN [40] as our feature extractor. Given an input sequence $X = \{x_1, \ldots, x_l\}$, PCNN slides the conventional kernels $W_k$ over $X$ to capture the hidden representations as follows:

$$
h_i = W_k x_{i-w+1:i} \in \mathbb{R}^d \quad 1 \leq i \leq m,
$$

where $x_{i:j}$ denotes the concatenating of $x_i$ to $x_j$, and $m$ is the number of kernels. Then, PCNN performs piecewise max-pooling over the hidden representations as follows:

$$
q^{(1)}_i = \max_{1 \leq j \leq l_1} (h_{ij}),
q^{(2)}_i = \max_{l_1+1 \leq j \leq l_2} (h_{ij}),
q^{(3)}_i = \max_{l_1+1 \leq j \leq l} (h_{ij}),
$$

where $l_1$ and $l_2$ are positions of the two target entities respectively. Then we can obtain the pooling result $q_i = \{q^{(1)}_i; q^{(2)}_i; q^{(3)}_i\}$ of the $i$-th conventional kernel. Finally, we concatenate all the pooling results $q_{1:m}$ and then apply a non-linear function to produce the sentence representation $s$ as follows:

$$
s = \rho (q_{1:m}) \in \mathbb{R}^{3m}.
$$

2.4 Graph Encoder

To encode the information of the constraint graph, we first transform the raw graph into vector representations via the input layer, and then run GCNs over the input vectors to extract the interactive features of the nodes. Finally, the representations of entity types and relations can be obtained by dividing the node representations.

2.5 Constraint-Aware Attention Module

Given a bag of sentences $S = \{s_1, \ldots, s_n\}$ and a raw constraint graph $G$, we achieved the sentence representations $S = \{s_1, \ldots, s_n\}$, the relation representations $R = \{r_1, \ldots, r_n\}$, and the type representations $T = \{t_1, \ldots, t_n\}$ by the two aforementioned encoders, where $n_s$, $n_r$, and $n_t$ are the numbers of sentences, relations, and types, respectively. To aggregate the information of the instances and the constraints, we first construct the instance representations and the constraint representations by concatenation operations, and then apply the selective attention over them to compute the final bag output.
can be obtained by looking up in the type representation matrix $T$. Finally, the instance representation is achieved by concatenating the the representations of the sentence and its entity type representations as follows:

$$g_i = [s_i; t_{per, i}^c; t_{org, i}^c] \in \mathbb{R}^{3d_h}, \quad 1 \leq i \leq n_s. \quad (8)$$

For example, given a sentence "Bill Gates was 19 when he and Paul Allen started Microsoft", we firstly use NER tools to recognize the types of the head entity Bill Gates and the tail entity Microsoft as Person and Organization respectively. Then the instance representation is achieved as $g = [s; t_{per}; t_{org}]$, where $s$ is the sentence representation, $t_{per}$ is the representation of Person, and $t_{org}$ is the representation of Organization.

### 2.5.2 Constraint Representation

Assume $t_{r_i}^c$ and $t_{r_i}^g$ are respectively the immediate predecessor and the immediate successor of relation $r_i$ in the constraint graph. Similarly, we can obtain the type representations $t_{r_i}^c$ and $t_{r_i}^g$ of $r_i$ by looking up in $T$. Note that some relations may have multiple immediate predecessors or successors. For example, the entity type representation of $/business/person/company$ can be achieved as $g_i = [s_i; t_{per, i}^c; t_{org, i}^c]$, where $s$ is the sentence representation, $t_{per}$ is the representation of $/business/person/company$, $t_{org}$ is the representation of Organization.

### 2.5.3 Attention Layer

Different from the previous selective attention mechanism that mainly depends on the semantic similarity between sentences and relations [8], [43], our attention mechanism combines semantic information and constraint information to calculate the bag output. Given a bag of instances, the attention weight $\alpha_i$ of $i$-th instance for the corresponding relation $r$ can be computed as follows:

$$e_i = g_i c_r,$$

$$\alpha_i = \frac{\exp(e_i)}{\sum_{j=1}^{n_r} \exp(e_j)}, \quad (10)$$

where $c_r$ is the constraint representation of $r$. Then the bag representation is derived as the weighted sum of the sentence representations:

$$z_r = \sum_{i=1}^{n_s} \alpha_i g_i. \quad (11)$$

Finally, we feed the bag representation $z_r$ into a softmax classifier to calculate the probability distribution over relation labels as follows:

$$P(r \mid B; \theta) = \text{softmax}(Wz_r + b), \quad (12)$$

where $\theta$ is the set of model parameters, $W$ is the weight of the classifier and $b$ is the bias.

### 2.6 Optimization

We define the objective function using cross-entropy at the bag level as follows:

$$J(\theta) = -\frac{1}{n} \sum_{i=1}^{n} \log P(r_i \mid B_i; G; \theta), \quad (13)$$

where $n$ is the number of instance bags and $r_i$ is the label of $B_i$.

Note that at the test stage, the ground-truth label $r$ is unknown, thus all constraint representations are applied to calculate the posterior probabilities for the corresponding relation, and the relation with the highest probability is the prediction result [8].

### 3 Experiments

#### 3.1 Datasets

We evaluate our framework on the NYT-10 dataset, which is developed by Riedel et al. [25] and has been widely used in previous works [8], [18], [22], [39], [44], [45], [46]. The dataset is generated by aligning Freebase facts with New York Times corpus, where sentences from 2005-2006 are used for the training set and from 2007 for the test set. We use the preprocessed version released by Lin et al. [8]. NYT-10 contains 53 relations including a negative relation NA that indicates no relations between the two entities. There are 30 relations with fewer than 100 training instances, and 32 with fewer than 200. Table 1 shows the overall statistics for NYT-10.

#### 3.2 Hyper-parameters Settings

For a fair comparison, most of the hyper-parameters are set the same as in [8], and we mainly tune the hyper-parameters of the graph encoder and the classifier. The word embeddings are initialized by the pre-trained word2vec released by OpenNRE2. All weight matrixes and position embeddings are initialized by Xavier initialization [47], and the bias vectors are all initialized to 0. To prevent overfitting, we apply dropout [48] before the classifier layer. Table 2 shows all the hyper-parameters used in our experiments.

2. https://github.com/thunlp/OpenNRE
### 3.3 Denoising Evaluation

To demonstrate the denoising performance of CGRE, we compare against the following competitive baselines:

**traditional feature-based models**

- **MINTZ** \[7\]: a multi-class logistic regression model;
- **MULTIR** \[44\]: a probabilistic graphical model based on multi-instance learning;
- **MIML** \[45\]: a probabilistic graphical model based on multi-instance multi-label learning;

**neural selective-attention based models**

- **PCNN+ATT** \[8\]: a PCNN-based model with selective attention;
- **RESIDE** \[22\]: a relation extraction model integrating the external information including relation alias and entity type;
- **PCNN+HATT** \[26\]: a PCNN-based model with hierarchical attention;
- **PCNN+BATT** \[10\]: a PCNN-based model with intra-bag and inter-bag attention;

The results of the traditional models MINTZ, MULTIR, MIML are provided by Vashishth et al.\(^3\). We evaluate **PCNN+ATT**\(^2\), **RESIDE**\(^3\), **PCNN+HATT**\(^4\), **PCNN+BATT**\(^5\), with the source codes provided by authors.

To further verify the effectiveness of adopting the entity-aware word embedding \[39\], we build **PCNN+ATT+ENT** as another baseline model by simply replacing the word embedding layer of PCNN+ATT with the entity-aware word embedding layer.

#### 3.3.1 Overall Performance

Following the previous works \[7\], \[8\], \[10\], we adopt precision-recall (PR) curves in Figure 4 to measure the overall performance of DSRE models in noise environment. For a ready comparison, we report the precisions at different recalls and the area under curve (AUC) values of the PR curves for the neural models in Table 3.

From the PR curves results, it can be observed that:

1. all models have reasonable precision when recall is lower than 0.05. Compared with the neural models, the performance of the feature-based models drops sharply with the rise of recall. At the recall of 0.15, the precisions of all the feature-based models are lower than 0.5, while the precisions of the neural models are still higher than 0.65. This demonstrates that human-designed features have limited ability to express the semantic content of sentences, especially under noisy environments;

2. **PCNN+ATT+ENT** achieves 8.6% improvement over **PCNN+ATT** in AUC values, demonstrating the effectiveness of the entity-aware word embedding for improving the overall performance in noise environment;

3. compared with **RESIDE** which uses 38 entity types, **CGRE** merely uses 18 types but attains 10.4% improvement in AUC;

4. the precision of the baselines drops sharply with the rise of recall (especially when recall > 0.15), but the performance of **CGRE** can remains at a higher level. At the recall of 0.4, the precisions of all the baselines are lower than 0.6, while the precision of **CGRE** is still higher than 0.65. The above observations show that **CGRE** significantly outperforms the compared baselines, confirming the superior capability of **CGRE** against label noise.

#### 3.3.2 Performance of Selective Attention

To further compare the performance of different selective attention mechanisms, we conduct top-N evaluations on bags containing different number of sentences. Following the previous works \[8\], \[10\], \[22\], \[26\], we randomly select one / two / all sentences for each test entity pair with more than two sentences to construct three new test sets,
on which we calculate the top-N precision (P@N) values for these methods.

Results summarized in Table 4 show superior performances of CGRE in all test modes over the other selective attention-based models, demonstrating the efficacy of our constraint-aware attention mechanism.

### 3.4 Long Tail Evaluation

To fully demonstrate the effectiveness of CGRE on long-tailed relation extraction, we compare CGRE with several state-of-the-art long-tailed relation extraction models, including two vanilla DSRE models PCNN+ATT [8] and PCNN+ATT+ENT that ignore the long-tailed relations, and five relation hierarchy-based models:

- **PCNN+HATT [26]**: the first model to apply relation hierarchies for long-tailed relation extraction;
- **PCNN+KATT [27]**: a model that utilizes GCNs to encode relation hierarchies and applies knowledge graph embeddings for initialization;
- **PCNN+HRS [28]**: a model that utilizes regards the relation extraction as a path planning task on the relation hierarchical tree;
- **PA-TRP [29]**: a model that learns relation prototypes from unlabeled texts for embedding relation hierarchies;
- **CoRA [30]**: a model that uses sentence embeddings to generate the representations for each node in relation hierarchies.

Following the previous studies [26, 27, 28, 29, 30], we adopt Hit@K metric to evaluate the performance on long-tailed relations. We extract the relations that have few than 100/200 training instances from the test set. Then Hits@K metric, which measures the probability that the true label falls in the top-K recommendations of the model, is applied over these long-tailed relations. The results in Table 5 show that:

1. The vanilla denoising models PCNN+ATT and PCNN+ATT+ENT obtain the worst results on long-tailed relations. Although the utilization of entity-aware embedding provides remarkable improvement for denoising, it brings few benefits for long-tailed relation extraction;
2. As compared with the vanilla denoising models, the relation hierarchy-based models and our constraint graph-based model are both better at handling long-tailed relations significantly, demonstrating the necessity and effectiveness of our proposed constraint graphs.

From these observations, we can draw conclusions that:
1. Long-tailed relation extraction is so intractable that even the state-of-art DSRE models are powerless. A feasible solution is modeling intrinsic dependencies between the relations to transfer information from data-rich relations to data-poor relations, and the design of relation-dependent structure is one of the key for modeling. The relation hierarchy has been proved useful and is widely used for long-tailed relations, however, it is not the only option. The proposed constraint graph is also an effective structure that can express the latent dependencies between relations, and we believe that there are still more promising relation connection structures that deserve extensive exploration.

### 3.5 Effect of GCNs

To investigate the effect of different layers of GCNs on knowledge transfer between relations, we evaluate the performance of GCNs with different layer numbers and different output options. BASE denotes that GCN is removed and the input embeddings \( V^{(0)} \) are directly as outputs. **k-Layer** denotes that a \( k \)-layer GCN is used as the graph encoder. For a 2-layer GCN, we design 3 different output options: (1) \( CAT-1 \) directly takes the output of layer 2 as the final output, i.e. \( V^{(2)} \); (2) \( CAT-2 \) concatenates the
outputs of layer 1 and 2 for the final output, i.e. $[V^{(1)}; V^{(2)}]$; 
(3) CAT-3 concatenates the outputs of 2 layers and the input embeddings for the final output, i.e. $[V^{(0)}; V^{(1)}; V^{(2)}]$. To ensure dimensional matching, the concatenated vectors are transformed by a linear layer before output.

From the results shown in Figure 5, it can be observed that:

(1) the GCN-based models consistently outperform BASE, indicating that the utilization of GCNs effectively improves the performance on long-tailed relations; 

(2) due to the over-smoothing problem, the increase of layer number of GCNs may decrease the performance. In our experiments, the 2-layer GCN achieve the best performance; 

(3) CAT-1 obtains better performance than CAT-2 and CAT-3 which concatenate the outputs from different layers. It may because the concatenating with the low-layer representations impedes the knowledge transfer among relations.

3.6 Effect of External Information

To explore the effects of integrating different external information, we adopt P@N metric to compare the following models: (1) BASE: we do not use type representations, i.e. no external information is used; (2) BASE+Type: we merely concatenate the sentence representations and the corresponding type representations, i.e., only the type information is utilized; (3) BASE+Hard: a hard-constraining strategy which directly filters the instances that do not satisfy constraint rules. In this case, the instances unsatisfied constraints are dropped during training and predicted as NA during testing; (4) BASE+Soft: a soft-constraining strategy which incorporates the constraint information by the constraint-aware attention module. Note that BASE+Soft is equivalent to CGRE.

We present the precision scores when the recall is 0.1 / 0.2 / 0.3 and their mean in Table 6 from which we observe that:

(1) BASE+Type, BASE+Hard and BASE+Soft outperform BASE by 1.1%, 3.4% and 6.7% respectively in mean precisions, demonstrating that the utilization of external information leads to significant improvements; 

(2) BASE+Hard and BASE+Soft outperform BASE+Type by 2.3% and 5.6% respectively in mean precisions, indicating that compared with pure entity type information, constraint rules provide more direct and effective information for DSRE models against label noise; 

(3) BASE+Soft achieves 3.3% improvement than BASE+Hard in mean precision. Intuitively, hard-constraining strategies lose a large amount of useful information contained in the filtered instances. In contrast, attention mechanism provides an effective soft-incorporating way to utilize constraint information without losing any informative instances.

3.7 Selection of Smoothing Coefficient

Denoising experimental results in section 3.3 demonstrate the effectiveness of the entity-aware word embedding. The smoothing coefficient $\lambda$ balances the contribution of entity information and word information, playing a decisive role in the entity-aware word embedding. Hence, we experiment with $\lambda \in \{0, 10, 20, 30, 40, 50\}$ to explore the effect of this hyper-parameter. We show the AUC results for different values of $\lambda$ in Figure 6 where each point is the average of three runs. It is clear that the selection of $\lambda$ has a significant impact on the denoising result, and the best result is achieved at $\lambda = 20$.

3.8 Case Study

We present some examples to demonstrate how our constraint-aware attention combines the semantic and constraint information. As shown in Table 7, the incorrect sentences with constraint violation ($s_3$ and $s_6$) or semantic inconsistency ($s_2$ and $s_5$) are assigned lower scores, while the correct sentences ($s_1$ and $s_4$) score higher. With the constraint-aware attention mechanism, CGRE can effectively recognize the valid instances from noisy data.

4 Related Work

To automatically obtain large scale labeled training data, Mintz et al. [7] proposed distant supervision. However, the relation labels collected through distant supervision are not only noisy but also extremely unbalanced. Therefore, denoising and long-tailed relation extraction become two major challenges in DSRE.

4.1 Denoising in DSRE.

Multi-instance learning (MIL), aiming to extract relations of an entity pair from a sentence bag instead of a single sentence, is a popular approach to alleviate the noisy labeling problem [25], [44], [45]. Under the MIL framework, various denoising methods are proposed, including selective attention mechanism [8], [10], external information integration [19], [22] and robust context encoders [40], [43]. Different from the bag-level prediction of MIL, some studies [11], [49] attempt to predict relations at sentence level by selecting trustable instances from training data.

In this work, we mainly focus on the bag-level prediction. There are two main differences between CGRE and the above MIL methods: (1) rather than treat each relation label separately, CGRE attempts to mine the latent connections between relations; (2) the attention mechanism of CGRE integrates the prior constraint information, which is effective for improving the noise immunity of RE models.

4.2 Long-tailed relation extraction in DSRE.

Krause et al. [50] develop an RE system, which can automatically learn the rules for long-tailed relations from Web. To generate fewer but more precise rules, Gui et al. [51] apply explanation-based learning to improve the RE system. However, the above methods merely handle each relation in isolation, regardless of the implicit associations between relations. Therefore, some recent works [26], [27], [30] attempt to mine the semantic connections between relations from the hierarchy tree of relations. Although these works achieve significant improvement for long-tailed relations, they are still far from satisfactory.

Different from relation hierarchies that mainly contain the hierarchical information between labels, the proposed constraint graphs involve not only the implicit connection information between labels, but also the explicit prior information of constraints. By integrating both kinds of infor-
mation, our framework can effectively handle the noisy and long-tailed labels.

4.3 Type constraint information in DSRE.

Type information of entities showed great potential on relation extraction [52], [53]. Some works [21], [22] explored the utilization of fine-grained entity type information to improve the robustness of DSRE models. However, these methods merely focus on the semantic information of types, i.e., they simply use type information as concatenating features to enrich the sentence semantic representation, but neglect the explicit constraint information, which can be effective for recognizing the noisy instances. On the contrary, Lei et al. [55] apply probabilistic soft logic to encode the type constraint information for denoising, but ignore the semantic information of entity types.

As compared with the above methods, CGRE can take full advantage of type information. With the constraint-aware attention mechanism, CGRE can combine the semantic and constraint information of entity types. Moreover, in CGRE, the entity types are used as bridges between the relations, enabling message passing between relation labels.

5 Conclusions

In this paper, we aim to address both the challenges of label noise and long-tailed relations in DSRE. We introduced a novel relation connection structure, constraint graphs, to model the dependencies between relations, and then proposed a novel relation extraction framework, CGRE, to integrate the information of constraint graphs. Experimental results on the widely-used benchmark dataset have shown that: (1) constraint graphs can effectively express the latent semantic connections between relation labels; (2) our framework can take full advantage of the information in constraint graphs, significantly and consistently outperforming the competitive baselines in terms of denoising and long-tailed relation extraction.
