

DISTRIBUTED COLORING AND THE LOCAL STRUCTURE OF UNIT-DISK GRAPHS

LOUIS ESPERET, SÉBASTIEN JULLIOT, AND ARNAUD DE MESMAY

ABSTRACT. Coloring unit-disk graphs efficiently is an important problem in the global and distributed setting, with applications in radio channel assignment problems when the communication relies on omni-directional antennas of the same power. In this context it is important to bound not only the complexity of the coloring algorithms, but also the number of colors used. In this paper, we consider two natural distributed settings. In the location-aware setting (when nodes know their coordinates in the plane), we give a constant time distributed algorithm coloring any unit-disk graph G with at most $(3 + \epsilon)\omega(G) + 6$ colors, for any constant $\epsilon > 0$, where $\omega(G)$ is the clique number of G . This improves upon a classical 3-approximation algorithm for this problem, for all unit-disk graphs whose chromatic number significantly exceeds their clique number. When nodes do not know their coordinates in the plane, we give a distributed algorithm in the LOCAL model that colors every unit-disk graph G with at most $5.68\omega(G)$ colors in $O(\log^3 \log n)$ rounds. Moreover, when $\omega(G) = O(1)$, the algorithm runs in $O(\log^* n)$ rounds. This algorithm is based on a study of the local structure of unit-disk graphs, which is of independent interest. We conjecture that every unit-disk graph G has average degree at most $4\omega(G)$, which would imply the existence of a $O(\log n)$ round algorithm coloring any unit-disk graph G with (approximately) $4\omega(G)$ colors.

1. INTRODUCTION

A *unit-disk graph* is a graph G whose vertex set is a collection of points $V \subseteq \mathbb{R}^2$, and such that two vertices $u, v \in V$ are adjacent in G if and only if $\|u - v\| \leq 1$, where $\|\cdot\|$ denotes the Euclidean norm. Unit-disk graphs are a classical model of wireless communication networks, and are a central object of study in distributed algorithms (see the survey [26] for an extensive bibliography on this topic). A classical way to design distributed communication protocols avoiding interferences is to find a proper coloring of the underlying unit-disk graph: the protocol then lets each vertex of the first color communicate with their neighbors, then each vertex of the second color, etc. Clearly the efficiency of the protocol depends on the number of colors used, so it is important to minimize the total number of colors (in addition to optimizing the complexity of the distributed coloring algorithm).

The *chromatic number* of a graph G , denoted by $\chi(G)$, is the smallest number of colors in a proper coloring of G . The *clique number* of G , denoted by $\omega(G)$, is the largest size of a clique (a set of pairwise adjacent vertices) in G . Note that for any graph G we have $\omega(G) \leq \chi(G)$, but the gap between the parameters can be arbitrarily large in general (see [25] for a recent survey on the relation between ω and χ for various graph classes). However, for unit-disk graphs it is known that $\chi(G) \leq 3\omega(G) - 2$ [20] (see also [12] for a different proof), and improving the multiplicative constant 3 is a longstanding open problem. It should be noted that while computing $\chi(G)$ for a

A preliminary version of this work appeared in the proceedings of the 17th International Symposium on Algorithms and Experiments for Wireless Sensor Networks (ALGOSENSORS 2021).

unit-disk graph G is NP-hard, computing $\omega(G)$ for a unit-disk graph G can be done in polynomial time [5].

In the LOCAL model, introduced by Linial [17], the graph G that we are trying to color models a communication network: its vertices are processors of infinite computational power and its edges are communication links between (some of) these nodes. The vertices exchange messages with their neighbors in a certain number of synchronous rounds of communication (the round complexity), and then (in the case of graph coloring) each vertex outputs its color in a proper coloring of G . When in addition each vertex knows its coordinates in the plane, we call the model the location-aware LOCAL model (more details about these models will be given in Section 2.1).

In the location-aware LOCAL model, the following is a classical result [14, 15, 28, 29] (see also [26] for a survey on *local algorithms*, which are algorithms that run in a constant number of rounds).

Theorem 1.1 ([14, 15, 28, 29]). *A coloring of any unit-disk graph G with at most $3\chi(G)$ colors can be obtained in a constant number of rounds by a deterministic distributed algorithm in the location-aware LOCAL model.*

We prove the following complementary result, which improves the number of colors as soon as $\omega(G)$ is sufficiently large, and $\chi(G)$ itself is significantly larger than $\omega(G)$. This result can be seen as an efficient distributed implementation of the proof of [12] that unit-disk graphs satisfy $\chi \leq 3\omega$.

Theorem 1.2. *For any $\epsilon > 0$, a coloring of any unit-disk graph G with at most $(3+\epsilon)\omega(G)+6$ colors can be computed in $O(1/\epsilon)$ rounds by a deterministic distributed algorithm in the location-aware LOCAL model.*

As mentioned above we have $\chi(G) \geq \omega(G)$ for any graph G , so this result improves upon Theorem 1.1 as soon as $\omega(G)$ is sufficiently large and $\chi(G) \geq (1 + \delta)\omega(G)$, for some fixed $\delta > 0$. It was proved that for different models of random unit-disk graphs the ratio between the chromatic number and the clique number is equal to $\frac{2\sqrt{3}}{\pi} \approx 1.103$ with high probability [18, 19], so this shows that Theorem 1.2 outperforms Theorem 1.1 for almost all unit-disk graphs (with respect to these distributions).

Given two integers $p \geq q \geq 1$, a $(p:q)$ -coloring of a graph G is an assignment of q -element subsets of $[p]$ to the vertices of G , such that the sets assigned to any two adjacent vertices are disjoint. The *fractional chromatic number* $\chi_f(G)$ is defined as the infimum of $\{\frac{p}{q} \mid G \text{ has a } (p:q)\text{-coloring}\}$ [23] (it can be proved that this infimum is indeed a minimum). Observe that a $(p:1)$ -coloring is a (proper) p -coloring, and that for any graph G , $\omega(G) \leq \chi_f(G) \leq \chi(G)$. The fractional chromatic number is often used in scheduling as an alternative to the chromatic number when resources are fractionable, which is the case for communication protocols. It was proved in [8] that for any unit-disk graph G , $\chi_f(G) \leq 2.155\omega(G)$. Here we give an efficient distributed implementation of this result, up to a small additive constant.

Theorem 1.3. *For any sufficiently large integer q , a $(p:q)$ -coloring of any unit-disk graph G with $\frac{p}{q} \leq 2.156\omega(G) + 4.31$ can be computed in $O(1)$ rounds by a deterministic distributed algorithm in the location-aware LOCAL model.*

We now turn to the abstract setting, where vertices do not have access to their coordinates in the plane. For a real number $n > 0$, let $\log^* n$ be the number of times we have to iterate the logarithm, starting with n , to reach a value in $(0, 1]$. Since paths are unit-disk graphs and coloring n -vertex paths with a constant number of colors takes $\Omega(\log^* n)$ rounds in the LOCAL model [17], coloring unit-disk graphs of bounded clique number with a bounded number of colors also takes $\Omega(\log^* n)$ rounds in the LOCAL model. Recalling that for any unit-disk graph G , $\omega(G) \leq \chi(G) \leq 3\omega(G)$, a natural question is the following.

Question 1.4. *What is the minimum real $c > 0$ such that a coloring of any n -vertex unit-disk graph G with $c \cdot \omega(G)$ colors can be obtained in $O(\log^* n)$ rounds in the LOCAL model?*

Using the folklore result that any unit-disk graph G has maximum degree at most $6\omega(G) - 6$ (see [12]), together with the fact that graphs of maximum degree Δ can be colored efficiently with $\Delta + 1$ colors in the LOCAL model [17], we deduce that unit-disk graphs G can be colored efficiently with $6\omega(G)$ colors in the LOCAL model. We obtain the following improved version by studying the local structure of unit-disk graphs, using techniques that might be of independent interest.

Theorem 1.5. *Every unit-disk graph G can be colored with at most $5.68\omega(G)$ colors by a randomized distributed algorithm in the LOCAL model, running in $O(\log^3 \log n)$ rounds w.h.p. Moreover, if $\omega(G) = O(1)$, the coloring can be obtained deterministically in $O(\log^* n)$ rounds.*

In relation to Question 1.4, it is natural to study the power of graph coloring algorithms in unit-disk graphs in a different (less restrictive) range of round complexity.

Question 1.6. *What is the minimum real $c > 0$ such that a coloring of any n -vertex unit-disk graph G with $c \cdot \omega(G)$ colors can be obtained in $O(\log n)$ rounds in the LOCAL model?*

An interesting property of the $O(\log n)$ range of round complexity (compared to the $O(\log^* n)$ range) is that it allows to solve coloring problems for graphs of bounded average degree (rather than bounded maximum degree). The *average degree* of a graph G is the average of its vertex degrees. The *maximum average degree* of a graph G is the maximum average degree of a subgraph H of G . In [1], Barenboim and Elkin gave, for any $\epsilon > 0$, a deterministic distributed algorithm coloring n -vertex graphs of maximum average degree d with at most $(1 + \epsilon)d + 3$ colors in $O(\frac{d}{\epsilon} \log n)$ rounds (the result was proved in terms of arboricity rather than average degree).

While the chromatic number and degeneracy of unit-disk graphs (as a function of the clique number) are well studied topics, it seems that little is known about the average degree of unit-disk graphs. We conjecture the following:

Conjecture 1.7. *Every unit-disk graph G has average degree at most $4\omega(G)$.*

It can be checked that the constant 4 would be best possible by considering uniformly distributed points in the plane. In this case each vertex has degree equal to some density constant $c > 0$ times the area of a disk of radius 1, so the average degree is $c \cdot \pi$. On the other hand any clique is contained in a region of diameter at most 1, and the area of such a region is known to be maximized for a disk of radius $\frac{1}{2}$ [3], i.e., the graph has clique number $c \cdot \pi/4$, giving a ratio of 4 between the average degree and the clique number.

Using the result of Barenboim and Elkin [1] mentioned above, Conjecture 1.7 would imply the existence of a deterministic distributed coloring algorithm using $(4 + \epsilon)\omega(G)$ colors in $O(\frac{\omega(G)}{\epsilon} \log n)$ rounds (for fixed $\epsilon > 0$ and sufficiently large $\omega(G) = \Omega(1/\epsilon)$).

Unfortunately we are quite far from proving Conjecture 1.7 at the moment. Our best result so far is the following.

Theorem 1.8. *Every unit-disk graph G has average degree at most $5.68\omega(G)$.*

Our final result shows that Conjecture 1.7, if true, is more subtle than it might seem. In the example above showing the optimality of Conjecture 1.7, the largest cliques are formed by sets of points that are all contained within some disk of radius $\frac{1}{2}$. We may naturally define the *disk clique number* of a unit-disk graph G , denoted by $\omega_D(G)$, to be the largest size of a clique contained within such a disk. Note that $\omega_D(G)$ depends on the embedding of G in the plane, not just of the underlying graph (contrary to the clique number $\omega(G)$). One may wonder whether Conjecture 1.7 holds for $\omega_D(G)$ instead of $\omega(G)$ – by the same argument as for Conjecture 1.7, the constant 4 would be best possible. It is however not the case and we show the following stronger lower bound:

Theorem 1.9. *There exists a unit-disk graph G of average degree at least $4.0905\omega_D(G)$.*

Here, 4.0905 is roughly $4 \cdot (1 + \frac{J_1(2B)}{2B})$, where J_1 is the Bessel function of the first kind and B its first zero. Theorem 1.9 shows that any approach to prove Conjecture 1.7 needs to account for possible shapes of cliques different than the ones contained in disks of radius $\frac{1}{2}$. As the constant suggests, our proof technique relies on Fourier analysis and special functions and we believe that they could be of independent interest. In particular they also allow us to prove Conjecture 1.7 when the distribution of points is sufficiently close to the uniform distribution (in the sense that the support of its Fourier transform is contained in a small disk around 0).

Organization of the paper. We start with a presentation of the LOCAL model and some basic results on coloring and unit-disk graphs in Section 2. Section 3 is devoted to proving our main results in the location-aware setting, Theorem 1.2 and Theorem 1.3. In Section 4, we study the local structure of unit-disk graphs and deduce our coloring result in the LOCAL model, Theorem 1.5, together with our upper bound on the average degree of unit-disk graphs, Theorem 1.8 above. In Section 5, we introduce Fourier-analytical tools to approach Conjecture 1.7 and prove Theorem 1.9.

2. PRELIMINARIES

2.1. Distributed models of communication. All our results are proved in the LOCAL model, introduced by Linial [17]. The underlying network is modelled as an n -vertex graph G whose vertices have unbounded computational power, and whose edges are communication links between the corresponding vertices. In the case of deterministic algorithms, each vertex of G starts with an arbitrary unique identifier (an integer between 1 and n^α , for some constant $\alpha \geq 1$, such that all integers assigned to the vertices are distinct). For randomized algorithms, each vertex starts instead with a collection of (private) random bits. The vertices then exchange messages (possibly of unbounded size) with their neighbors in synchronous rounds, and after a fixed number of rounds (the *round complexity of the algorithm*), each vertex v outputs its local “part” of a global solution to a combinatorial problem in G , for instance its color $c(v)$ in some proper k -coloring c of G .

It turns out that with the assumption that messages have unbounded size, after t rounds we can assume without loss of generality that each vertex v “knows” its neighborhood $B_t(v)$ at distance t (the set of all vertices at distance at most t from v). More specifically v knows the labelled subgraph of G induced by $B_t(v)$ (where the labels are the identifiers of the vertices), and nothing more, and the output of v is based solely on this information.

The goal is to minimize the round complexity. Since nodes have infinite computational power, the paragraph above shows that any problem can be solved in a number of rounds equal to the diameter of the graph, which is at most n when G is connected. The goal is to obtain algorithms that are significantly more efficient, i.e., of round complexity $O(\log n)$, or even $O(\log^* n)$.

If in addition, the n -vertex graph modelling the communication network is a unit-disk graph embedded in the plane, and every vertex knows its coordinates in the embedding, this stronger communication model is called the *location-aware LOCAL* model.

2.2. Distributed coloring. Consider a graph G with maximum degree Δ , and some $\epsilon > 0$. In the $(\deg + \epsilon\Delta)$ -list coloring problem, each vertex v is given a list $L(v)$ of colors such that $|L(v)| \geq d(v) + \epsilon\Delta$, where $d(v)$ denotes the degree of v in G , and the goal is to color each vertex with a color from its list, so that any two adjacent vertices receive different colors. In the $(\deg + 1)$ -list coloring problem, the setting is the same, except that each vertex v has a list of at least $d(v) + 1$ colors. The union of all the lists in a list coloring problem is called *the color space*, and in some results below it will be convenient to assume that it has bounded size.

The following result can be obtained by combining the approach of [6, 2] with a more recent result of Ghaffari and Kuhn [10] (note that recent breakthrough results on network decompositions [21, 9] can also be used instead, giving a slightly larger round complexity).

Theorem 2.1 ([6, 2, 10]). *For any fixed $\epsilon > 0$, there exists a randomized distributed algorithm in the LOCAL model that solves the $(\deg + \epsilon\Delta)$ -list coloring problem in n -vertex graphs of maximum degree Δ in $O(\log^3 \log n)$ rounds w.h.p.*

Proof. If $\Delta = \Omega(\log^2 n)$, Theorem 4.1 in [6] gives an algorithm running in $O(\log^* \Delta) = O(\log^* n)$ rounds. Assume now that $\Delta = O(\log^2 n)$. The shattering algorithm of Theorem 5.1 in [2] solves the $(\deg + 1)$ -list coloring problem (which is stronger than the $(\deg + \epsilon\Delta)$ -list coloring problem) in $O(\log \Delta) + \text{Det}_d(\Delta^2 \log n)$ rounds, where $\text{Det}_d(n')$ is the deterministic round complexity of the $(\deg + 1)$ -list coloring problem in graphs of n' vertices. Using the recent result from [10] that $\text{Det}_d(n') = O(\log^3 n')$, we obtain that if $\Delta = O(\log^2 n)$, the $(\deg + 1)$ -list coloring problem (and thus the $(\deg + \epsilon\Delta)$ -list coloring problem) can be solved by a randomized algorithm running in $O(\log \Delta + \log^3(\Delta^2 \log n)) = O(\log^3 \log n)$ rounds, as desired. \square

A graph G has *neighborhood independence* less than k if for any vertex $v \in G$ and set S of k neighbors of v , the set S contains two adjacent vertices. It was proved that when each list $L(v)$ contains at least $d(v) + 1$ colors and G has bounded neighborhood independence, the problem can be solved even more efficiently (and deterministically) when Δ is small.

Theorem 2.2 ([16]). *There exists a deterministic distributed algorithm in the LOCAL model that solves the $(\deg + 1)$ -list coloring problem in any n -vertex graph of bounded neighborhood independence and maximum degree Δ , with a color space of size $\text{poly}(\Delta)$, in $2^{O(\sqrt{\log \Delta})} + O(\log^* n)$ rounds.*

It is easy to check that unit-disk graphs have neighborhood independence at most 5, which yields the following immediate corollary.

Corollary 2.3. *There exists a deterministic distributed algorithm in the LOCAL model that solves the $(\deg + 1)$ -list coloring problem in any n -vertex unit-disk graph of maximum degree Δ , with a color space of size $\text{poly}(\Delta)$, in $2^{O(\sqrt{\log \Delta})} + O(\log^* n)$ rounds.*

Note that for the related *Maximal Independent Set* problem in graphs of bounded neighborhood independence, Schneider and Wattenhofer [24] obtained an algorithm running in $O(\log^* n)$ rounds, independent of Δ , but it is not known whether the dependence in Δ can be avoided in Corollary 2.3.

2.3. Unit-disk graphs. For $0 \leq r \leq 1$, and a point v let $D_r(v)$ be the disk of radius r centered in v and let $C_r(v)$ the circle of radius r centered in v . Given a unit-disk graph G embedded in the plane, a vertex v , and a real $0 \leq r \leq 1$, we denote by $d_r(v)$ the number of neighbors of v lying in $D_r(v)$, and by $x_r(v)$ the number of neighbors of v lying on $C_r(v)$. Note that $d_1(v)$ is precisely $d(v)$, the degree of v in G , and for every $0 \leq r \leq 1$, $d_r(v) = \sum_{s \in [0, r]} x_s(v)$ (note that since $s \mapsto x_s(v)$ has finite support, this sum is well defined).

It is well known that a disk of radius 1 can be covered by 6 regions of diameter 1 (see [12]), and thus the neighborhood of each vertex of G can be covered by 6 cliques (and thus $d(v) \leq 6\omega(G)$ for each vertex v of G). A *Reuleaux triangle* is the intersection of 3 disks of radius 1, centered in the three vertices of an equilateral triangle of side length 1 (see the green region in Figure 1). Note that Reuleaux triangles have diameter 1, and 6 Reuleaux triangles are enough to cover a disk of radius 1. Moreover, points close to the center of the disk are covered by more triangles than points on the outer circle. This can be used to prove the following.

FIGURE 1. The intersection (in bold) of a circle C_r of radius r with a Reuleaux triangle R_θ (the green region).

Lemma 2.4. *For each vertex v of a unit-disk graph G embedded in the plane, $\sum_{r \in [0, 1]} (2-r)x_r(v) \leq 6\omega(G)$.*

Proof. Let v be a vertex of G . Note that each neighbor of v lies in $D_1(v)$ (the disk of radius 1 centered in v). For θ chosen uniformly at random in the interval $[0, 2\pi)$, consider the Reuleaux triangle R_θ depicted in Figure 1. Consider also a neighbor u of v lying on $C_r(v)$, the circle of radius r centered in v . Then the probability that u is covered by R_θ is the length of $C_r(v) \cap R_\theta$ (the bold arc of Figure 1) divided by $2\pi r$ (the circumference of $C_r(v)$). This probability is thus

$$\frac{(2 \arccos(r/2) - \pi/3)r}{2\pi r} = \frac{1}{\pi} \arccos(r/2) - 1/6 \geq \frac{1}{3} - \frac{r}{6},$$

where the last inequality follows from the concavity of $x \mapsto \arccos x$ in $[0, \frac{1}{2}]$.

It follows that each neighbor of v at distance at most r from v is covered by R_θ with probability at least $\frac{1}{3} - \frac{r}{6}$. Therefore, the expected number of neighbors of v covered by R_θ is at least $\sum_{r \in [0,1]} (\frac{1}{3} - \frac{r}{6}) x_r(v)$. Since each R_θ has diameter 1, the vertices of R_θ induce a clique in G and thus R_θ contains at most $\omega(G)$ vertices. It follows that $\sum_{r \in [0,1]} (\frac{1}{3} - \frac{r}{6}) x_r(v) \leq \omega(G)$ and thus $\sum_{r \in [0,1]} (2-r) x_r(v) \leq 6\omega(G)$, as desired. \square

The following is a direct consequence of Lemma 2.4.

Corollary 2.5. *For each vertex v of a unit-disk graph G embedded in the plane and $r \in [0, 1]$, $d(v) + (1-r)d_r(v) \leq 6\omega(G)$. In particular $d_{1/2}(v) \leq 12\omega(G) - 2d(v)$.*

Proof. By Lemma 2.4, $6\omega(G) \geq \sum_{s \in [0,1]} (2-s)x_s(v) = \sum_{s \in [0,r]} (2-s)x_s(v) + \sum_{s \in [r,1]} (2-s)x_s(v) \geq (2-r)d_r(v) + d(v) - d_r(v) = (1-r)d_r(v) + d(v)$. By taking $r = \frac{1}{2}$, we obtain $d(v) + \frac{1}{2}d_{1/2}(v) \leq 6\omega(G)$, and thus $d_{1/2}(v) \leq 12\omega(G) - 2d(v)$, as desired. \square

In the next section will need the following useful observation of [12] (see also [8]).

Lemma 2.6 ([12]). *Let G be a unit-disk graph embedded in the plane, such that the y -coordinates of any two vertices of G differ by at most $\sqrt{3}/2$. Then $\chi(G) = \omega(G)$.*

We deduce the following easy corollary (which holds in the LOCAL model, so it does not require nodes to know their own coordinates in the plane).

Corollary 2.7. *Let G be a unit-disk graph embedded in the plane, such that the y -coordinates of any two vertices of G differ by at most $\sqrt{3}/2$, and the x -coordinate differ by at most ℓ , for some real number ℓ . Then G can be colored with $\chi(G) = \omega(G)$ colors by a deterministic distributed algorithm running in $O(\ell)$ rounds in the LOCAL model.*

Proof. Take any shortest path $P = v_1, v_2, \dots, v_k$ in G . Then for any $1 \leq i \leq k-2$, $\|v_i - v_{i+2}\| > 1$, since otherwise P would not be a shortest path in G . Since y -coordinates differ by at most $\sqrt{3}/2$, it follows that the x -coordinates of v_i and v_{i+2} differ by at least $\frac{1}{2}$, and the x -coordinates of the vertices v_i with i odd are monotone (say increasing with loss of generality). Hence, the x -coordinates of v_1 and v_k differ by at least $k/4$, and by definition, $k \leq 4\ell$. As a consequence, any connected component of G has diameter at most 4ℓ , and thus any connected component can be colored optimally by a deterministic distributed algorithm running in $O(\ell)$ rounds in the LOCAL model. \square

3. LOCATION-AWARE COLORING

The techniques we use in this section are inspired by the work of Halldórsson and Konrad [13], who proved that any interval graph G can be colored with at most $(1+\epsilon)\omega(G)$ colors (for any $\epsilon > 0$) in $O(\frac{1}{\epsilon} \log^* n)$ rounds in the LOCAL model.

A *layering* of a graph G is a partition $L_0, L_1, L_2, \dots, L_\ell$ of $V(G)$ into (possibly empty) sets (called *layers*), such that for any edge uv of G , either u and v lie in the same layer, or u and v lie in consecutive layers, i.e. layers L_i and L_{i+1} , for some $0 \leq i \leq \ell - 1$.

For any integer k , we denote by $[k]$ the set $\{1, 2, \dots, k\}$. We say that a coloring c_1 of a graph G extends a coloring c_2 of an induced subgraph $G[S]$ of G if for any $v \in S$, $c_1(v) = c_2(v)$.

We start by proving the following recoloring lemma, which is inspired by the work of [13, 27] on (circular-)interval graphs, but holds in greater generality.

Lemma 3.1. *Let G be a k -colorable graph, and let L_0, L_1, \dots, L_ℓ be a layering of G such that $G[L_0]$ and $G[L_\ell]$ are complete graphs. Then any k -coloring of $G[L_0 \cup L_\ell]$ can be extended to a coloring of G with at most $k + \frac{4k}{\ell-2} + 2$ colors.*

Proof. Let c_0 be the target coloring of $G[L_0 \cup L_\ell]$, and let c_1 be any k -coloring of G . Since L_0 is a clique, the colors of the vertices of L_0 are pairwise distinct, so by permuting the names of the k colors in c_1 we can assume without loss of generality that for any $v \in L_0$, $c_1(v) = c_0(v)$. It remains to recolor the vertices of L_ℓ to map them to their target color from c_0 .

Let $A = \{a_1, a_2, \dots, a_t\}$ be a subset of $[k]$ and let $\phi : A \rightarrow B$ be a bijection such that $B = \phi(A)$ is also a subset of $[k]$. Let $1 \leq i \leq \ell - 1$, and let c be a proper coloring of G . By *swapping A and $\phi(A)$ in c at depth i* , we mean performing the following modification in the coloring c . In L_i , for any $1 \leq j \leq t$, each vertex colored a_j is recolored with color $k + j$ and if $\phi(a_j) \notin A$, each vertex colored $\phi(a_j)$ is recolored with color $k + t + j$. Then, in $\bigcup_{i' > i} L_{i'}$, for any $1 \leq j \leq t$, each vertex colored a_j is recolored with color $\phi(a_j)$. Note that the vertices of L_i now use colors from $[k + 2t]$, but all the vertices in further layers still use colors from $[k]$. Note also that if c is a proper coloring before the swap and L_{i-1} only uses colors from $[k]$, then c is still proper after the swap. Moreover, by definition, for each vertex $v \in L_\ell$, if $c(v) = a_j$ before the swap, then $c(v) = \phi(a_j)$ after the swap.

We now order arbitrarily the elements of $c_1(L_\ell) \subseteq [k]$ as a_1, a_2, \dots, a_p . Since L_ℓ is a clique, for any $1 \leq i \leq p$, there is a unique vertex $v \in L_\ell$ with $c_1(v) = a_i$. Let $\phi(a_i) := c_0(v)$ (note that ϕ is a permutation of $c_1(L_\ell)$). Our goal is thus to replace each color a_i by $\phi(a_i)$ in L_ℓ , by maintaining the property that the coloring c_1 is proper, and without changing the colors of the elements of L_0 . We do this as follows: we partition $c_1(L_\ell)$ into $s = \lfloor \ell/2 \rfloor$ sets A_1, A_2, \dots, A_s of size at most $\lceil k/s \rceil \leq \frac{k}{\lfloor \ell/2 \rfloor} + 1 \leq \frac{2k}{\ell-2} + 1$, and for each $i = 1, \dots, s$ in increasing order, we swap A_i and $\phi(A_i)$ in c_1 at depth $2i - 1$.

Since we do not perform any color swapping in sets L_i with i even, we indeed have the property that for any L_i where a color swapping is performed, only colors from $[k]$ are used in L_{i-1} . It thus follows from the observations above that after performing these s color swappings, we obtain a proper coloring c_1 coinciding with c_0 in $L_0 \cup L_\ell$, and using at most $k + 2t \leq k + \frac{4k}{\ell-2} + 2$ colors, as desired. \square

FIGURE 2. The division of a stripe into rectangles R_i (proof of Lemma 3.2).

Note that the hypothesis that $G[L_0]$ and $G[L_\ell]$ are complete graphs can be replaced by the weaker condition that all the vertices of L_0 have distinct colors in the target coloring, and similarly for L_ℓ .

Using Lemma 3.1 and Corollary 2.7, we now prove the following lemma, which will be used in the proofs of Theorem 3.3 and Theorem 3.4.

Lemma 3.2. *Let G be a unit-disk graph embedded in the plane, such that the y -coordinates of any two vertices of G differ by at most $\sqrt{3}/2$. Then for any $0 < \epsilon \leq 1$, G can be colored with at most $(1 + \epsilon)\omega(G) + 2$ colors by a deterministic distributed algorithm running in $O(1/\epsilon)$ rounds in the location-aware LOCAL model.*

Proof. Let $\omega = \omega(G)$. We can assume that all the vertices of G are contained in some horizontal stripe \mathcal{S} of height $\sqrt{3}/2$. We divide \mathcal{S} into a sequence of rectangles R_1, R_2, \dots of height $\sqrt{3}/2$ and width $\lceil 4/\epsilon \rceil + 2 > 2$. The regions bounded by these rectangles are denoted by R_1, R_2, \dots , and in the location-aware LOCAL model each vertex has access to its own coordinates and thus knows in which rectangle R_i it lies. For any rectangle R_i , we denote by S_i^- the subset of R_i consisting of all the points at distance at most $\frac{1}{2}$ from the left side of R_i , and similarly we denote by S_i^+ the subset of R_i consisting of all the points at distance at most $\frac{1}{2}$ from the right side of R_i (see Figure 2). Note that S_i^+ and S_i^- are rectangles of height $\sqrt{3}/2$ and width $\frac{1}{2}$. For any rectangles R_i and R_{i+1} , the right side of R_i coincides with the left side of R_{i+1} . By Corollary 2.7, the union of the regions $S_i^+ \cup S_{i+1}^-$ can be colored deterministically in $O(1)$ rounds with ω colors (here we use the fact that S_i^+ and S_{i+1}^- are at distance more than $2 - \frac{1}{2} - \frac{1}{2} = 1$ apart, so there are no edges between them).

Note that for every $i \geq 1$, R_i has a natural layering L_0, L_1, \dots, L_k where $L_0 = S_i^-$ and $L_k = S_i^+$, and $k = \lceil 4/\epsilon \rceil + 2$: it suffices to divide $R_i \setminus (S_i^- \cup S_i^+)$ into consecutive rectangles L_1, \dots, L_{k-1} of height $\sqrt{3}/2$ and width 1 (for convenience we identify each rectangle L_j with the subset of vertices of G lying in L_j). We assume for convenience that these rectangles L_j are closed on their left side and open on their right side, so all the edges are inside a rectangle L_j or between two consecutive rectangles L_j and L_{j+1} , and thus the partition L_0, \dots, L_k is indeed a layering of R_i . We can thus apply Lemma 3.1 and extend the coloring of $S_i^- \cup S_i^+$ to R_i , using at most

$$\omega + \frac{4\omega}{\lceil 4/\epsilon \rceil + 2 - 2} + 2 \leq \omega + \epsilon\omega + 2 = (1 + \epsilon)\omega + 2$$

colors. Since all regions $R_i \setminus (S_i^- \cup S_i^+)$ are at distance more than 1 apart, there are no conflicts between the extensions of the coloring to these regions. Using the same argument as in the proof of Corollary 2.7, each connected component of the subgraph of G induced by R_i has diameter $O(1/\epsilon)$, and thus the extension can be done in $O(1/\epsilon)$ rounds, as desired. \square

We are now ready to prove the main result of this section.

Theorem 3.3. *For any $0 < \epsilon \leq 1$, a coloring of any unit-disk graph G with at most $(3 + \epsilon)\omega(G) + 6$ colors can be computed in $O(1/\epsilon)$ rounds by a deterministic distributed algorithm in the location-aware LOCAL model.*

Proof. Let $\omega = \omega(G)$. We start by covering $V(G)$ by consecutive horizontal stripes $\mathcal{S}_1, \mathcal{S}_2, \dots$, each of height $\sqrt{3}/2$ (see Figure 3, left). Note that any two stripes \mathcal{S}_j and \mathcal{S}_{j+3} are at distance at least $2 \cdot \sqrt{3}/2 = \sqrt{3} > 1$ apart, so there are no edges connecting a vertex lying in \mathcal{S}_j and a vertex lying in

\mathcal{S}_{j+3} . It follows from this observation and Lemma 2.6 that for each $i \in \{0, 1, 2\}$, the set of vertices lying in the union of all stripes \mathcal{S}_j with $j \equiv i \pmod{3}$ induces a graph of chromatic number at most ω . We will color each of these 3 graphs with a disjoint set of at most $(1 + \epsilon/3)\omega + 2$ colors (this will give a coloring of G with at most $3 \cdot (1 + \epsilon/3)\omega + 6 = (3 + \epsilon)\omega + 6$ colors, as desired). As there are no edges between the vertices lying in \mathcal{S}_j and the vertices lying in \mathcal{S}_{j+3} , it is enough to color the vertices of each stripe with at most $(1 + \epsilon/3)\omega + 2$ colors, in parallel (recall that in the location-aware LOCAL model, each vertex has access to its own coordinates and thus knows in which stripe it lies). Using Lemma 3.2, this can be done in $O(1/\epsilon)$ rounds of communication, which concludes the proof of Theorem 3.3. \square

FIGURE 3. Covering $V(G)$ by horizontal stripes in the proof of Theorem 3.3 (left) and Theorem 3.4 (right).

It was proved in [8] that for any unit-disk graph G , $\chi_f(G) \leq 2.155\omega(G)$. Using the same ideas as in the proof of Theorem 3.3, we give an efficient distributed version of this result.

To give an intuition of the proof, note that the fractional chromatic number of G can be equivalently defined as the infimum $x > 0$ such that there is a probability distribution over the independent sets of G , such that with respect to this distribution, each vertex has probability at least $1/x$ to be in a random independent set. A way to define such a good distribution in a unit-disk graph G is to start at some random vertical coordinate, and then tile the plane as in Figure 3, right. The union of all vertices lying in grey stripes induces a perfect graph and can thus be colored with $\omega(G)$ colors. We now take a random color class among the $\omega(G)$ color classes, and it can be easily checked that each vertex has probability at least $\frac{\sqrt{3}/2}{1+\sqrt{3}/2} \cdot \frac{1}{\omega(G)} \approx \frac{1}{2.155\omega(G)}$ to lie in this random independent set, see [8]. Below we combine this idea with the approach of Theorem 3.3 to give a distributed version of this proof.

Theorem 3.4. *For any sufficiently large integer q , a $(p:q)$ -coloring of any unit-disk graph G with $\frac{p}{q} \leq 2.156\omega(G) + 4.31$ can be computed in $O(1)$ rounds by a deterministic distributed algorithm in the location-aware LOCAL model.*

Proof. Let $\omega = \omega(G)$. We start by covering $V(G)$ by consecutive horizontal stripes $\mathcal{S}_1, \mathcal{T}_1, \mathcal{S}_2, \mathcal{T}_2, \dots$, such that the stripes \mathcal{S}_i have height $\sqrt{3}/2$ and the stripes \mathcal{T}_i have height 1. It will be convenient to assume that each stripe contains its top boundary and excludes its bottom boundary.

For any $i \geq 1$ and $j \geq 0$, we denote by \mathcal{S}_i^j and \mathcal{T}_i^j the stripes \mathcal{S}_i and \mathcal{T}_i translated by the vector $(0, -\frac{j}{q} \cdot (1 + \frac{\sqrt{3}}{2}))$ (see Figure 3, right). Note in particular that $\mathcal{S}_i^q = \mathcal{S}_{i+1}$ and $\mathcal{T}_i^q = \mathcal{T}_{i+1}$.

As in the proof of Theorem 3.3, it follows from Lemma 3.2 that for any $0 \leq j \leq q-1$, the subgraph of G induced by the set X_j of vertices lying in $\bigcup_{i \geq 1} \mathcal{S}_i^j$ can be colored with at most $(1 + \epsilon)\omega + 2$

colors in $O(1/\epsilon)$ rounds, for any $\epsilon > 0$. Consider such a coloring of these vertices with a set C_j of at most $(1 + \epsilon)\omega + 2$ colors, and assume that all sets C_j ($0 \leq j \leq q - 1$) are pairwise disjoint, so in total at most $q(1 + \epsilon)\omega + 2q$ colors are used. Note that each vertex of G is covered by at least $\lfloor \frac{\sqrt{3}/2}{(1 + \sqrt{3}/2)/q} \rfloor \geq 0.4641q$ sets X_j (where the inequality holds for any sufficiently large q), and thus any vertex receives at least $0.4641q$ distinct colors. As $\frac{q(1 + \epsilon)\omega + 2q}{0.4641q} \leq 2.155\omega + 4.31$ for any sufficiently small (but constant) $\epsilon > 0$, the result follows. \square

4. COLORING WITHOUT COORDINATES

We start by giving a bound on the average degree of two adjacent vertices.

Lemma 4.1. *For every two vertices u and v in a unit-disk graph G embedded in the plane such that $\frac{1}{2} \leq \|u - v\| \leq 1$, we have $\frac{1}{2}(d(u) + d(v)) \leq 5.675\omega(G)$.*

Proof. Let $\delta = \|u - v\| \in [\frac{1}{2}, 1]$ and $\omega = \omega(G)$. Given a bounded subset R of the plane, we denote by $\mu(R)$ the number of vertices of G lying in R . Note that for any vertex x of G , $d(x) = \mu(D_1(x))$, and thus it is enough to prove that $\frac{1}{2}(\mu(D_1(u)) + \mu(D_1(v))) \leq 5.675\omega(G)$. We will give two different upper bounds on $\frac{1}{2}(\mu(D_1(u)) + \mu(D_1(v)))$, and the minimum of the two will be at most 5.675ω for every $\delta \in [\frac{1}{2}, 1]$.

FIGURE 4. Two adjacent vertices in the proof of Lemma 4.1.

For the first bound, consider the region $S_u \subset D_1(u)$ (bounded by the fat red curve) and the region $S_v \subset D_1(v)$ (bounded by the fat blue curve) in Figure 4, left. Note that each of S_u and S_v can be covered by 5 regions of diameter 1, and thus

$$(1) \quad \mu(S_u) \leq 5\omega \quad \text{and} \quad \mu(S_v) \leq 5\omega.$$

By Lemma 2.4, we also have

$$(2) \quad \sum_{r \in [0,1]} (2 - r)\mu(C_r(u)) \leq 6\omega \quad \text{and} \quad \sum_{r \in [0,1]} (2 - r)\mu(C_r(v)) \leq 6\omega$$

(recall that $C_r(u)$ is the circle of radius r centered in u). Note that $d(u) = \mu(D_1(u)) = \sum_{r \in [0,1]} \mu(C_r(u))$ and $d(v) = \mu(D_1(v)) = \sum_{r \in [0,1]} \mu(C_r(v))$.

Subject to these inequalities (and with ω fixed), our goal is to maximize $\frac{1}{2}(\mu(D_1(u)) + \mu(D_1(v)))$ over all unit-disk graphs of clique number at most ω . Instead of optimizing over finite points sets it will be convenient to optimize over finite point sets carrying some (nonnegative, non necessarily integral) weights. In this context, $\mu(R)$ is simply defined as the sum of the weights of the points lying in R (the objective function $\frac{1}{2}(\mu(D_1(u)) + \mu(D_1(v)))$ and the linear constraints (1) and (2), which were defined using μ , are modified accordingly). The solution of this linear relaxation will give an upper bound for our original (integral) optimization problem.

Note that the constraints and the objective are themselves linear, and symmetric with respect to the line (xy) and to the perpendicular bisector of the segment $[xy]$. In particular, we can assume that some optimal solution has the same symmetries (it suffices to take the average of some optimal solution and the symmetric image of this solution). Using this argument, in some optimal solution we have $\mu(D_1(u) \setminus D_1(v)) = \mu(D_1(v) \setminus D_1(u)) = m$, for some $m \geq 0$, and we can modify this solution by deleting all the points in the symmetric difference of $D_1(u)$ and $D_1(v)$ and adding weight m to the point w_2 . We obtain a (symmetric) optimal solution in which all points are in the intersection of $D_1(u)$ and $D_1(v)$. Now, if a weighted point set satisfies this property as well as (1) and (2), and contains a point z distinct from w_1, w_2, w_3 (and their images by the two symmetries mentioned above), then z can be moved so that $\|u - z\| + \|v - z\|$ increases and thus no constraint is violated. Here w_3 is considered to be arbitrarily close from R_u , but outside of it, and similarly its symmetric image w'_3 is considered to be arbitrarily close from R_v , but outside of it. Together with the symmetry of the constraints and objective, this shows that we can assume without loss of generality that in some optimal solution, the support of the weighted point set is included in $\{w_1, w_2, w_3, w'_3\}$, and the weight of w_3 is equal to the weight of w'_3 .

Once this has been observed, it remains to solve the following finite linear program (here $x_1 = \mu(\{w_1\})$, $x_2 = \mu(\{w_2\})$, and $x_3 = \mu(\{w_3\}) = \mu(\{w'_3\})$).

$$\begin{aligned} \max_{x_1, x_2, x_3} \quad & x_1 + x_2 + 2x_3 \\ \text{s.t.} \quad & x_2 + x_3 \leq 5\omega \\ & \left(2 - \sqrt{\frac{\delta^2}{4} + \left(1 - \sqrt{1 - \frac{\delta^2}{4}}\right)^2}\right) \cdot x_1 + x_2 + \left(3 - \sqrt{1 + \delta^2 - \delta\sqrt{3}}\right) \cdot x_3 \leq 6\omega \\ & x_1, x_2, x_3 \geq 0 \end{aligned}$$

where we have used $d(u, w_1) = d(v, w_1) = \sqrt{\delta^2/4 + (1 - \sqrt{1 - \delta^2/4})^2}$ and $d(u, w_3) = d(v, w'_3) = \sqrt{1 + \delta^2 - \delta\sqrt{3}}$. Let us denote by $f_5(\delta)$ the optimum of this linear program. We compute $f_5(\delta)$ for $\delta \in [\frac{1}{2}, 1]$ numerically using SageMath (see Appendix A); the function $\frac{f_5(\delta)}{\omega}$ is plotted in Figure 5 (red curve).

We now turn to our second upper bound on $\frac{1}{2}(\mu(D_1(u)) + \mu(D_1(v)))$. Consider the region $R_u \subset D_1(u)$ (bounded by the fat red curve) and the region $R_v \subset D_1(v)$ (bounded by the fat blue curve) in Figure 4, right. This time, each of the regions R_u and R_v can be covered by 4 regions of diameter 1, and thus

$$(3) \quad \mu(R_u) \leq 4\omega \quad \text{and} \quad \mu(R_v) \leq 4\omega.$$

FIGURE 5. Two upper bounds on $\frac{1}{2\omega}(d(u) + d(v))$ when $\|u - v\| = \delta$. The function $\frac{f_5(\delta)}{\omega}$ is plotted in red, and the function $\frac{f_4(\delta)}{\omega}$ is plotted in blue.

As before, by Lemma 2.4, we also have

$$(4) \quad \sum_{r \in [0,1]} (2-r)\mu(C_r(u)) \leq 6\omega \quad \text{and} \quad \sum_{r \in [0,1]} (2-r)\mu(C_r(v)) \leq 6\omega$$

Note that $d(u) = \mu(D_1(u)) = \sum_{r \in [0,1]} \mu(C_r(u))$ and $d(v) = \mu(D_1(v)) = \sum_{r \in [0,1]} \mu(C_r(v))$.

We will also need to consider a third region, called R_{uv} , and which is depicted in green in Figure 4, right. For convenience we assume that R_{uv} does not contain w_2 . The vertices w_4, w'_4 have been chosen on $C_1(v)$ and $C_1(u)$ respectively, such that $d(u, w_4) = d(v, w'_4)$ and $d(w_4, w'_4) = 1$. The region is symmetric with respect to the line (uv) and to the perpendicular bisector of the segment $[xy]$. Moreover it can be checked that each of the top and bottom halves of the region R_{uv} has diameter 1, and thus

$$(5) \quad \mu(R_{uv}) \leq 2\omega.$$

The objective is again to maximize $\frac{1}{2}(\mu(D_1(u)) + \mu(D_1(v)))$ over all weighted point sets satisfying (3), (4), and (5). As before, we can assume that in some optimal solution, the support of the weighted point set is included in the intersection of $D_1(u)$ and $D_1(v)$. If a weighted point set satisfies this property in addition to (3), (4), and (5), and contains a point z distinct from w_1, w_2, w_3 , and w_4 (and their images by the two symmetries mentioned above), then z can be moved so that $\|u - z\| + \|v - z\|$ increases and thus no constraint is violated. Here w_3 is considered to be arbitrarily close from R_u , but outside of it (and similarly for the symmetric image w'_3 of w_3). The vertex w_4 is also arbitrarily close from $C_1(v)$ and R_{uv} , but disjoint from them (and similarly for the symmetric image w'_4 of w_4). Together with the symmetry of the constraints and objective, this shows that we can assume without loss of generality that in some optimal solution, the support of the weighted point set is included in $\{w_1, w_2, w_3, w'_3, w_4, w'_4\}$ and moreover $\mu(\{w_3\}) = \mu(\{w'_3\})$ and $\mu(\{w_4\}) = \mu(\{w'_4\})$. The optimization problem can thus again be formulated as a finite linear program, as follows (here $x_1 = \mu(\{w_1\})$, $x_2 = \mu(\{w_2\})$, $x_3 = \mu(\{w_3\}) = \mu(\{w'_3\})$, and $x_4 = \mu(\{w_4\}) = \mu(\{w'_4\})$).

$$\begin{aligned}
& \max_{x_1, x_2, x_3, x_4} && x_1 + x_2 + 2x_3 + 2x_4 \\
& \text{s.t.} && x_2 + x_3 + x_4 \leq 4\omega \\
& && x_1 + 2x_3 \leq 2\omega \\
& && \left(2 - \sqrt{\frac{\delta^2}{4} + \left(\frac{\sqrt{3}}{2} - \sqrt{1 - \frac{(1+\delta)^2}{4}} \right)^2} \right) \cdot x_1 + x_2 + \left(3 - \sqrt{1 + \delta^2 - \delta} \right) \cdot x_3 \\
& && \quad + \left(3 - \sqrt{1 - \delta} \right) \cdot x_4 \leq 6\omega \\
& && x_1, x_2, x_3, x_4 \geq 0,
\end{aligned}$$

where we have used $d(u, w_1) = d(v, w_1) = \sqrt{\delta^2/4 + \left(\sqrt{3}/2 - \sqrt{1 - (1+\delta)^2/4}\right)^2}$, $d(u, w_3) = d(v, w'_3) = \sqrt{1 + \delta^2 - \delta}$, and $d(u, w_4) = d(v, w'_4) = \sqrt{1 - \delta}$. Let us denote by $f_4(\delta)$ the optimum of this linear program. We compute $f_4(\delta)$ for $\delta \in [\frac{1}{2}, 1]$ numerically using SageMath (see Appendix A); the function $\frac{f_4(\delta)}{\omega}$ is plotted in Figure 5 (blue curve).

We can now check that when $\delta \in [\frac{1}{2}, 1]$, $\min\{f_4(\delta), f_5(\delta)\}$ is maximized when $\delta = 1$, with $f_5(1) = 5.6746\omega$ and $f_4(1) = 6\omega$ (note that $f_4(1/2) = 5.6698\omega < f_5(1)$). It follows that for any u, v with $\|u - v\| \in [\frac{1}{2}, 1]$, $\frac{1}{2}(d(u) + d(v)) \leq 5.6746\omega$, as desired. \square

This bound easily implies that there is an efficient distributed algorithm coloring G with at most $5.68\omega(G)$ colors.

Theorem 4.2. *Every unit-disk graph G can be colored with at most $5.68\omega(G)$ colors by a randomized distributed algorithm in the LOCAL model, running in $O(\log^3 \log n)$ rounds w.h.p. Moreover, if $\omega(G) = O(1)$, the coloring can be obtained deterministically in $O(\log^* n)$ rounds.*

Proof. Let $\omega = \omega(G)$, let A be the set of vertices of degree more than 5.675ω , and let B be the remaining vertices. We claim that any connected component of $G[A]$, the subgraph of G induced by A , is a clique. Indeed, any two adjacent vertices in $G[A]$ are at distance at most $\frac{1}{2}$ by Lemma 4.1 and thus if $G[A]$ contains a path uvw , then u and w are at distance $\frac{1}{2} + \frac{1}{2} \leq 1$, and so u and w are adjacent. Since $G[A]$ is a union of cliques, it can be colored with at most ω colors in $O(1)$ rounds (each connected component has diameter at most 2, and contains at most ω vertices). For each vertex $v \in B$, let $L(v)$ be the set of colors from $1, 2, \dots, 5.68\omega$ that do not appear among the colored neighbors of v . Let us denote by $d_A(v)$ and $d_B(v)$ the number of neighbors of v in A and B , respectively. Note that for each $v \in B$, $|L(v)| \geq 5.68\omega - d_A(v) \geq d_B(v) + \epsilon\Delta$ for a sufficiently small (but constant) $\epsilon > 0$, since $d_A(v) + d_B(v) \leq 5.675\omega$ and $\omega \geq \Delta/6$. This is an instance of the $(\deg + \epsilon\Delta)$ -list coloring problem, which can be solved in $O(\log^3 \log n)$ rounds w.h.p in general (Theorem 2.1), and deterministically in $2^{O(\sqrt{\log \omega})} + O(\log^* n)$ rounds (Corollary 2.3). The resulting coloring is a coloring of G with at most 5.68ω colors, as desired. \square

As an interesting application of Lemma 4.1, we now obtain an improved upper bound on the average degree of any unit-disk graph.

Theorem 4.3. *Every unit-disk graph G has average degree at most $5.68\omega(G)$.*

Proof. Set $\epsilon = 6 - 5.675 = 0.325$ (all the computations in the proof are with respect to this specific choice of ϵ) and $\omega = \omega(G)$, and consider a fixed embedding of G in the plane. By Lemma 4.1, any two vertices u, v with $\|u - v\| \in [\frac{1}{2}, 1]$ have average degree at most $(6 - \epsilon)\omega$.

Each vertex v of G starts with a charge $w(v) = d(v)/\omega$, so that the average charge is precisely the average degree of G divided by ω . The charge is then moved according to the following rule: for any $\delta \geq 0$, each vertex with degree $(6 - \epsilon - \delta)\omega$ takes $\frac{\delta}{(6 - \epsilon - \delta)\omega}$ from the charge of each neighbor. For each $v \in V(G)$, let $w'(v)$ be the resulting charge of v . Note that the total charge has not changed and thus the average of $w'(v)$ over $v \in V$ is still the average degree of G divided by ω . We now prove that $w'(v) \leq 6 - \epsilon + 0.005 = 5.68$ for each vertex $v \in V$, which directly implies that G has average degree at most 5.68ω .

Consider first a vertex v of degree at most $(6 - \epsilon)\omega$. Then $d(v) = (6 - \epsilon - \delta)\omega$ for some $\delta \geq 0$. By the discharging rule, v takes $\frac{\delta}{(6 - \epsilon - \delta)\omega}$ from the charge of each of its $(6 - \epsilon - \delta)\omega$ neighbors, and might also give some of its charge to its neighbors. Thus $w'(v) \leq 6 - \epsilon - \delta + (6 - \epsilon - \delta)\omega \frac{\delta}{(6 - \epsilon - \delta)\omega} = 6 - \epsilon$.

Consider now a vertex v of degree more than $(6 - \epsilon)\omega$. Then $d(v) = (6 - \epsilon + \delta)\omega$ for some $0 < \delta \leq \epsilon$. By Corollary 2.5, $d_{1/2}(v) \leq 2(\epsilon - \delta)\omega$, and thus $D = D_1(v) \setminus D_{1/2}(v)$ contains at least $(6 - \epsilon + \delta)\omega - 2(\epsilon - \delta)\omega \geq (6 - 3\epsilon + 3\delta)\omega$ vertices.

By Lemma 4.1, each vertex of D has degree at most $(6 - \epsilon - \delta)\omega$. Observe that the function $x \mapsto \frac{x}{6 - \epsilon - x}$ is increasing for our choice of ϵ and for $x \in [0, \epsilon]$, thus each vertex of D takes at least $\frac{\delta}{(6 - \epsilon - \delta)\omega}$ from the charge of v (while v does not receive any charge from its neighbors). It follows that

$$w'(v) \leq 6 - \epsilon + \delta - (6 - 3\epsilon + 3\delta)\omega \frac{\delta}{(6 - \epsilon - \delta)\omega} = 6 - \epsilon + \frac{2\epsilon\delta - 4\delta^2}{6 - \epsilon - \delta} \leq 5.68,$$

for any $0 \leq \delta \leq \epsilon$ (for our choice of ϵ). □

In the next section, we propose an approach to improve upon Theorem 1.8 (and get closer to Conjecture 1.7) using Fourier analysis.

5. FOURIER ANALYSIS AND THE AVERAGE DEGREE OF UNIT-DISK GRAPHS

5.1. The question. A function that will be crucial in the remainder is $\chi_r : \mathbb{R}^2 \rightarrow \{0, 1\}$, the indicator function of the disk of radius $r > 0$ centered in $\mathbf{0} = (0, 0)$.

$$\chi_r(x) = \begin{cases} 1 & \text{if } \|x\| \leq r, \\ 0 & \text{otherwise.} \end{cases}$$

We will be mostly interested in $\chi_{1/2}$ and χ_1 .

Let $f : \mathbb{R}^2 \rightarrow \mathbb{R}^{\geq 0}$ be a Lebesgue-integrable function. As $f(x) = |f(x)|$ for any $x \in \mathbb{R}^2$, we have

$$\int_{\mathbb{R}^2} f(x) dx = \int_{\mathbb{R}^2} |f(x)| dx = \|f\|_1.$$

We will be interested in integrating f on disks of radius $r > 0$ centered in points x . This can be described easily with a convolution product.

$$\int_{y \in D_r(x)} f(y) dy = \int_{\|x-y\| \leq r} f(y) dy = \int_{\mathbb{R}^2} f(y) \chi_r(y-x) dy = (f * \chi_r)(x),$$

where $D_r(x)$ denotes the disk of radius r centered in x , and $f * \chi_r$ denotes the convolution product of f and χ_r .

Question 5.1. *What is the minimum constant $c > 0$ such that for any Lebesgue-integrable function $f : \mathbb{R}^2 \rightarrow \mathbb{R}^{\geq 0}$,*

$$\mu_f := \int_{\mathbb{R}^2} f(x) \cdot (f * \chi_1)(x) dx \leq c \cdot \|f\|_1 \cdot \|f * \chi_{1/2}\|_\infty?$$

Note that $D_1(x)$ can be covered by a constant number of disks of radius $\frac{1}{2}$, so there is a constant $c > 0$ such that $\|f * \chi_1\|_\infty \leq c \cdot \|f * \chi_{1/2}\|_\infty$, and thus the question above is well defined.

Take $R = [0, N]^2$ and let $\mathbf{1}_R$ denote the indicator function of R . Note that $\|\mathbf{1}_R\|_1 = N^2$ and $\|\mathbf{1}_R * \chi_{1/2}\|_\infty = \pi/4$ for $N \geq 1$. On the other hand, for all $x \in [1, N-1]^2$, $(\mathbf{1}_R * \chi_1)(x) = \pi$ and thus $\mu_f = (\pi - o(1))N^2 = (4 - o(1))\|\mathbf{1}_R\|_1 \cdot \|\mathbf{1}_R * \chi_{1/2}\|_\infty$, as $N \rightarrow \infty$. This shows that $c \geq 4$ in Question 5.1. We will see in Section 5.4 a finer example that shows that $c \geq 4.0905$ in Question 5.1.

5.2. Application to unit-disk graphs. Let us explain the connection to our original problem of bounding the average degree of unit-disk graphs as a function of their clique number.

Take a unit-disk graph G embedded in the plane, and consider the associated (finite) point multiset $P = V(G)$ in \mathbb{R}^2 . By translation, we can assume that $P \subseteq [0, N]^2$, for some real $N > 0$. Fix some integer $M \gg N$, set $\delta := N/M$; and divide $[0, N]^2$ into M^2 squares R_{ij} (for $i, j \in \{1, \dots, M\}$) of size $\delta \times \delta$ (and area δ^2). Define the following function $f : \mathbb{R}^2 \rightarrow \mathbb{R}^{\geq 0}$.

$$f(x) = \begin{cases} 0 & \text{if } x \notin [0, N]^2, \\ \frac{1}{\delta^2} |P \cap R_{ij}| & \text{if } x \in R_{ij}. \end{cases}$$

In words, $f(x)$ is the number of points of P in the square containing x , scaled by a factor δ^2 .

Note that for any $i, j \in \{1, \dots, M\}$,

$$\int_{R_{ij}} f(x) dx = \delta^2 \cdot \frac{1}{\delta^2} |P \cap R_{ij}| = |P \cap R_{ij}|.$$

It follows that $\|f\|_1 = |P| = |V(G)|$. More generally for any fixed disk $D \subseteq \mathbb{R}^2$ of positive radius, $\int_D f(x) dx \rightarrow |P \cap D|$ as $\delta \rightarrow 0$ (or equivalently, as $M \rightarrow \infty$).

As any disk of radius $\frac{1}{2}$ has diameter at most 1, the points of P lying in such a disk form a clique in G , and thus P intersects every such clique in at most $\omega(G)$ points. It follows that $\|f * \chi_{1/2}\| \leq (1 + o(1))\omega(G)$ (where the $o(1)$ term is with respect to $\delta \rightarrow 0$, or equivalently, as $M \rightarrow \infty$).

For sufficiently small $\delta > 0$, for any point $p \in P$ and $\delta \times \delta$ square R containing p , $\int_R f(x)(f * \chi_1)(x) dx$ counts the number of points of P (possibly with repetitions) coinciding with p , times the number of points in the disk of radius 1 centered in p (which is the same as the number of neighbors of p in

G). It follows that as $\delta \rightarrow 0$, $\mu_f \rightarrow \sum_{v \in V(G)} d(v)$, the sum of the degrees of G . So for any constant $c > 0$ answering Question 5.1, we have

$$\sum_{v \in V(G)} d(v) \leq c \cdot |V(G)| \cdot (1 + o(1)) \cdot \omega(G),$$

and thus the average degree of G is at most $(c + o(1)) \cdot \omega(G)$.

What about the reverse direction? Given some function f showing that the answer to Question 5.1 is at least c_0 , for some $c_0 > 0$, we can translate this into a discrete distribution of points in the plane as follows. We consider a sufficiently large grid of dimension $N \times N$, and sufficiently small step $\delta > 0$, and for some sufficiently large real $k > 0$ we place $\lceil kf(x) \rceil$ points of P at each point x of the grid. If f behaves well (for instance if f is continuous and periodic), the ratio between the average degree and the disk clique number (recall that this is the maximum number of points in a disk of radius $\frac{1}{2}$) of the associated unit-disk graph G will be close to c_0 . However it might be possible that maximum cliques in the unit-disk graph G do not come from disks of radius $\frac{1}{2}$, but other shapes of diameter 1 (see Section 5.4). In this case the average degree of G is not necessarily close to $c_0 \cdot \omega(G)$.

5.3. Tools. Given a Lebesgue-integrable function $f : \mathbb{R}^2 \rightarrow \mathbb{R}$, the Fourier transform of f is given by

$$\hat{f}(\xi) = \int_{\mathbb{R}^2} f(x) e^{-2\pi i x \cdot \xi} dx,$$

where $x \cdot \xi$ denotes the dot product of x and ξ . Note that for any function $f : \mathbb{R}^2 \rightarrow \mathbb{R}^{\geq 0}$,

$$\hat{f}(\mathbf{0}) = \int_{\mathbb{R}^2} f(x) dx = \int_{\mathbb{R}^2} |f(x)| dx = \|f\|_1.$$

When \hat{f} is also integrable, we have that the reverse equality

$$f(x) = \int_{\mathbb{R}^2} \hat{f}(\xi) e^{2\pi i x \cdot \xi} d\xi$$

holds almost everywhere (and it holds everywhere if f is continuous).

It is well known that for any $\xi \in \mathbb{R}^2$,

$$\hat{\chi}_1(\xi) = \frac{J_1(2\pi\|\xi\|)}{\|\xi\|},$$

where J_1 denotes the Bessel function of the first kind. Note that $J_1(x) \sim x/2$ when $x \rightarrow 0$, so $\hat{\chi}_1(\mathbf{0}) = \pi$ is well defined by continuity. Observe that for $r > 0$ $\chi_r(x) = \chi_1(x/r)$ for every $x \in \mathbb{R}^2$, and thus by the time-scaling property of Fourier transforms, we have

$$\hat{\chi}_r(\xi) = r^2 \hat{\chi}_1(r\xi) = \frac{r J_1(2\pi r \|\xi\|)}{\|\xi\|}$$

for any $\xi \in \mathbb{R}^2$ (as above, $\hat{\chi}_r(\mathbf{0}) = \pi r^2$ is well defined by continuity).

An important property of the convolution product is that it behaves well under Fourier transforms. For any $\xi \in \mathbb{R}^2$ and $r > 0$,

$$\widehat{(f * \chi_r)}(\xi) = \hat{f}(\xi) \hat{\chi}_r(\xi) = \hat{f}(\xi) \frac{J_1(2\pi r \|\xi\|)}{\|\xi\|}.$$

So we have

$$(f * \chi_{1/2})(x) = \int_{\mathbb{R}^2} \hat{f}(\xi) \frac{J_1(\pi\|\xi\|)}{\|\xi\|} e^{2\pi i x \cdot \xi} d\xi \leq \|f * \chi_{1/2}\|_\infty,$$

for any $x \in \mathbb{R}^2$.

If we denote by $\mathbf{1}$ the constant function with $\mathbf{1}(x) = 1$ for any $x \in \mathbb{R}^2$, then $\hat{\mathbf{1}}(\xi) = \delta(\xi)$, where δ denotes the Dirac delta function¹. In this case the equality above tells us that for any $x \in \mathbb{R}^2$,

$$(\mathbf{1} * \chi_r)(x) = \int_{\mathbb{R}^2} \delta(\xi) \frac{r J_1(2\pi r \|\xi\|)}{\|\xi\|} e^{2\pi i x \cdot \xi} d\xi = \hat{\chi}_r(\mathbf{0}) = \pi r^2,$$

which is just a complicated way to say that the area of a disk of radius r is πr^2 .

For f and g square-integrable, the Parseval formula stipulates that

$$\int_{\mathbb{R}^2} \overline{f(x)} g(x) dx = \int_{\mathbb{R}^2} \overline{\hat{f}(\xi)} \hat{g}(\xi) d\xi.$$

Assuming that f is square-integrable, then so is $f * \chi_r$ (this follows from the Minkowski integral inequality), and thus we have

$$\int_{\mathbb{R}^2} \overline{f(x)} \cdot (f * \chi_r)(x) dx = \int_{\mathbb{R}^2} \overline{\hat{f}(\xi)} \cdot \widehat{(f * \chi_r)}(\xi) d\xi$$

for any $r > 0$. If moreover, f is a real function, it follows that

$$\mu_f = \int_{\mathbb{R}^2} f(x) \cdot (f * \chi_1)(x) dx = \int_{\mathbb{R}^2} \hat{f}(\xi) \cdot \hat{f}(\xi) \frac{J_1(2\pi\|\xi\|)}{\|\xi\|} d\xi = \int_{\mathbb{R}^2} \|\hat{f}(\xi)\|^2 \cdot \frac{J_1(2\pi\|\xi\|)}{\|\xi\|} d\xi$$

On the other hand, we have

$$\int_{\mathbb{R}^2} \|\hat{f}(\xi)\|^2 \cdot \frac{J_1(\pi\|\xi\|)}{2\|\xi\|} d\xi = \int_{\mathbb{R}^2} f(x) \cdot (f * \chi_{1/2})(x) dx \leq \|f * \chi_{1/2}\|_\infty \int_{\mathbb{R}^2} f(x) dx \leq \|f * \chi_{1/2}\|_\infty \cdot \|f\|_1$$

So if we had $J_1(2\xi) \leq \frac{c}{2} \cdot J_1(\xi)$ for any $\xi \geq 0$, and for some (hopefully small) constant $c > 0$, this would directly imply $\mu_f \leq c \|f\|_1 \cdot \|f * \chi_{1/2}\|_\infty$. However, the former does not hold, as the two functions oscillate independently.

An important observation here (in connection with the next section), is that for any $z \in [0, 1.18]$, $J_1(2\pi z) \leq 2 \cdot J_1(\pi z)$, with equality only if $z = 0$. This shows that in the disk $D_{1.18}(\mathbf{0})$ of radius 1.18 centered in $\mathbf{0}$,

$$\int_{D_{1.18}(\mathbf{0})} \|\hat{f}(\xi)\|^2 \cdot \frac{J_1(2\pi\|\xi\|)}{\|\xi\|} d\xi \leq 4 \cdot \int_{D_{1.18}(\mathbf{0})} \|\hat{f}(\xi)\|^2 \cdot \frac{J_1(\pi\|\xi\|)}{2\|\xi\|} d\xi,$$

so if the support of \hat{f} lies in $D_{1.18}(\mathbf{0})$, we have $\mu_f \leq 4 \cdot \|f * \chi_{1/2}\|_\infty \cdot \|f\|_1$, with equality if and only if the support of \hat{f} is $\{0\}$, which is equivalent to say that f is a constant function. So if we want to find examples where $\mu_f > 4 \cdot \|f * \chi_{1/2}\|_\infty \cdot \|f\|_1$, we need to make sure that the support of \hat{f} intersects the complement of $D_{1.18}(\mathbf{0})$.

¹Dirac delta functions can be formally defined using distributions or generalized functions, see for example Rudin [22, Chapter 6].

5.4. A finer example. Consider the function $f : \mathbb{R}^2 \rightarrow \mathbb{R}^{\geq 0}$ defined by $f((x, y)) := 1 + \sin(2Bx)$, where B is the first positive zero of the Bessel function J_1 , that is B is the smallest positive real such that $J_1(B) = 0$. It is known that $B \approx 3.8317$. We will use Fourier analysis on f , which is definitely not Lebesgue-integrable. Nevertheless, this can be justified using the framework of *tempered distributions*, to which f belongs since it is bounded. For the sake of readability, we do not enter these technical details and refer the reader to standard textbooks on distributions, e.g., Rudin [22, Chapters 6 and 7].

Take some real number $N = k \cdot \frac{\pi}{B}$, for some integer $k \geq 2$ (note that $\frac{\pi}{B}$ is the period of f), and let $g : \mathbb{R}^2 \rightarrow \mathbb{R}$ be defined as $g(x) = f(x) \cdot \mathbf{1}_{[0, N]^2}(x)$. Note that $\|g\|_1 = N^2$ (since N is a multiple of the period of g), and $\|g * \chi_{1/2}\|_\infty = \|f * \chi_{1/2}\|_\infty$ (as g is periodic and we have chosen N large enough). As we have seen above, the value of $\|f * \chi_{1/2}\|_\infty$ can be computed using

$$(f * \chi_{1/2})(x) = \int_{\mathbb{R}^2} \hat{f}(\xi) \frac{J_1(\pi\|\xi\|)}{2\|\xi\|} e^{2\pi i x \cdot \xi} d\xi,$$

In order to use this equality, we observe that for any $\xi \in \mathbb{R}^2$,

$$\hat{f}(\xi) = \delta(\xi) + \frac{1}{2i}(\delta(\xi - \frac{2B}{2\pi}) - \delta(\xi + \frac{2B}{2\pi})),$$

where δ denotes the Dirac delta function. This shows that $\hat{f}(\xi) = 0$ unless $\xi = 0$ or $\xi = \pm \frac{B}{\pi}$ (we observe, in connection with the final comment of the previous section, that $\frac{B}{\pi} \approx 1.22 > 1.18$). If $\xi = \pm \frac{B}{\pi}$, then $J_1(\pi\|\xi\|) = 0$, by definition of B . It follows that the only non-zero term in the integral is for $\xi = 0$, where $\frac{J_1(\pi\|\xi\|)}{2\|\xi\|} e^{2\pi i x \cdot \xi} = \frac{\pi}{4}$. By the definition of the Dirac delta function, the integral evaluates as

$$(f * \chi_{1/2})(x) = \int_{\mathbb{R}^2} \hat{f}(\xi) \frac{J_1(\pi\|\xi\|)}{2\|\xi\|} e^{2\pi i x \cdot \xi} d\xi = \frac{\pi}{4},$$

This shows that $\|g * \chi_{1/2}\|_\infty = \|f * \chi_{1/2}\|_\infty = \frac{\pi}{4}$.

It remains to evaluate

$$\mu_g = \int_{\mathbb{R}^2} g(x) \cdot (g * \chi_1)(x) dx = \int_{[0, N]^2} f(x) \cdot (g * \chi_1)(x) dx.$$

We can compute μ_g for N a multiple of π/B by using the Parseval formula as before, this time to f and $g * \chi_1$. Note that f is not square-integrable in this case, but it is a tempered distribution and g has compact support and is thus a test function, so we can still use Parseval formula [22, Chapter 7] in this case (we omit the definitions of tempered distributions and test functions here, the reader is referred to [22] for more details). We first compute that $\hat{g}(0) = N^2 = \|g\|_1$, $\hat{g}(\frac{2B}{2\pi}) = \frac{N^2}{2i}$ and $\hat{g}(\frac{-2B}{2\pi}) = \frac{-N^2}{2i}$. Now:

$$\begin{aligned}
\mu_g &= \int_{[0,N]^2} f(x) \cdot (g * \chi_1)(x) dx \\
&= \int_{\mathbb{R}^2} f(x) \cdot (g * \chi_1)(x) dx - \int_{[-1,N+1]^2 \setminus [0,N]^2} f(x) \cdot (g * \chi_1)(x) dx \\
&= \int_{\mathbb{R}^2} f(x) \cdot (g * \chi_1)(x) dx - O(N) \\
&= \int_{\mathbb{R}^2} \overline{\hat{f}(\xi)} \cdot \hat{g}(\xi) \cdot \frac{J_1(2\pi\|\xi\|)}{\|\xi\|} d\xi - O(N) \\
&= \int_{\mathbb{R}^2} (\delta(\xi) + \frac{1}{2i}(\delta(\xi + \frac{2B}{2\pi}) - \delta(\xi - \frac{2B}{2\pi}))) \cdot \hat{g}(\xi) \cdot \frac{J_1(2\pi\|\xi\|)}{\|\xi\|} d\xi - O(N) \\
&= \int_{\mathbb{R}^2} \|g\|_1 \left(\lim_{\xi \rightarrow 0} \left(\frac{J_1(2\pi\|\xi\|)}{\|\xi\|} \right) + \frac{1}{4} \cdot \frac{\pi J_1(2B)}{B} + \frac{1}{4} \cdot \frac{\pi J_1(-2B)}{B} \right) - O(N) \\
&= \pi \|g\|_1 \left(1 + \frac{J_1(2B)}{2B} \right) - O(N),
\end{aligned}$$

where we used that $f(x) \cdot (g * \chi_1(x))$ is zero outside of $[-1, N + 1]^2$ and is always at most 2, that $\lim_{\xi \rightarrow 0} \frac{J_1(2\pi\|\xi\|)}{\|\xi\|} = \pi$ and that the J_1 function is even. Now, $\frac{J_1(2B)}{2B} \approx 0.04527$ and $\|g\|_1 = N^2$, and thus we obtain that for N large enough,

$$\mu_g \approx 4.0905 \cdot \|g\|_1 \cdot \|g * \chi_{1/2}\|_\infty.$$

Therefore we have $c \geq 4.0905$ in Question 5.1. Recall that the disk clique number of a unit-disk graph G , denoted by $\omega_D(G)$, is the largest size of set of points contained within a disk of radius $\frac{1}{2}$ in G . Discretizing the function g introduced above as described in Section 5.2 yields the following theorem.

Theorem 5.2. *There exists a unit-disk graph G of average degree at least $4.0905\omega_D(G)$.*

Proof. We consider a 2-dimensional grid of dimension $N \times N$ and step $\delta > 0$, and we place $\lceil kg(x) \rceil$ points at each point x of the grid for the function $g(x) := (1 + \sin(2Bx)) \cdot \mathbf{1}_{[0,N]^2}(x)$. This set of points defines a unit-disk graph G . As explained in Section 5.2, for N and k large enough and δ small enough, the ratio between the average degree of G and its disk clique number $\omega_D(G)$ will converge to $\frac{\|g \cdot (g * \chi_1)\|_1}{\|g\|_1 \|g * \chi_{1/2}\|_\infty}$. By the calculations above, this ratio is larger than 4.0905 for sufficiently large N , thus establishing Theorem 5.2. \square

Note however that (as alluded to in Section 5.2), the unit-disk graph G obtained from this construction does not contradict Conjecture 1.7. Indeed, numerical computations show that some smooth versions of Reuleaux triangles are slightly denser than disks of radius $\frac{1}{2}$ with respect to f (and g), and in fact these computations seem to indicate that the ratio between the average degree and the clique number in the corresponding unit-disk graph G is close to 3.93 (see Figure 6 for a picture of a maximum clique with respect to this distribution, with density significantly larger than $\pi/4$).

FIGURE 6. The points of a maximum clique with respect to $f : (x, y) \mapsto 1 + \sin(2Bx)$. The function f is plotted in red, but not on the same scale as the points of the clique (in blue).

6. CONCLUSION

Given a sequence of pairs $\mathcal{P} = (p_i, r_i)_{1 \leq i \leq n}$, where each p_i is a point in the plane and each r_i is a positive real, the *disk graph* on \mathcal{P} is the graph with vertex set $\{p_1, p_2, \dots, p_n\}$, in which two vertices p_i and p_j are adjacent if and only if $\|p_i - p_j\| \leq r_i + r_j$. Disk graphs model wireless communication networks using omni-directional antennas of possibly different powers (where the power of the i -th antenna is proportional to the real number r_i), and disk graphs where all the reals r_i are equal are precisely unit-disk graphs. A natural question is whether results similar to the results we obtain here can be proved for disk graphs. A major difference is that disk graphs do not have their maximum degree bounded by a function of their clique number ω (the class of disk graphs contains the class of all trees for instance). However disk graphs have average degree bounded by a constant times ω , and this can be used to obtain $O(\log n)$ round algorithms coloring these graphs with few colors [1]. In the same spirit as Question 1.6 we can ask the following.

Question 6.1. *What is the minimum real $c > 0$ such that a coloring of any n -vertex disk graph G with $c \cdot \omega(G)$ colors can be obtained in $O(\log n)$ rounds in the LOCAL model?*

A final comment is that all the results and techniques developed in this paper also hold for unit-disk graphs embedded on the torus (rather than the plane), provided the area of the torus is sufficiently large (see [4] for more on unit-disk graphs on the torus). It does not seem to be known that for these graphs $\chi(G) \leq 3\omega(G)$. The best that can be achieved using existing techniques seems to be $\chi(G) \leq (3 + \epsilon)\omega(G)$, where $\epsilon \rightarrow 0$ as the area of the torus tends to ∞ (regardless of complexity concerns). It follows that with our current approach, avoiding the ϵ in the bound Theorem 1.2 might be a difficult task.

Acknowledgments. The authors would like to thank Wouter Cames van Batenburg and François Pirot for the interesting discussions. The authors would also like to thank the reviewers of the conference version of the paper for their comments and suggestions, and Mohsen Ghaffari for his kind explanations on the status of the $(\deg + \epsilon\Delta)$ -list coloring and $(\deg + 1)$ -list coloring problems.
