(Dated: 4 January 2022)

We study superconducting properties in multilayer thin films consisting of superconducting $\text{La}_{1.85}\text{Sr}_{0.15}\text{CuO}_4$ (LSCO) and Mott insulator Sr_2IrO_4 (SIO) and report enhanced superconductivity in optimized sample. These multilayer heterostructures show an increase in superconducting transition temperature (T_C) as compared to the single layer LSCO films. The temperature dependence of SIO single layer is also investigated under thermal activation, Arrhenius-type behaviour, and variable-range hopping mechanisms for different temperature regimes. The decrease in T_C beyond an optimum thickness of LSCO in these multilayers is analyzed in the framework of a model based on the assumption of induced superconductivity in SIO-LSCO interface due to the doping of La and/or oxygen deficiencies into SIO layers.

I. INTRODUCTION

The studies of transition metal oxide interfaces in the recent decade have led to the discovery of new two-dimensional electronic and magnetic phases stabilized by the broken inversion symmetry at the interface, direct and oxygen mediated overlap of transition metal orbitals across the interface, charge transfer and even disorder and atomic intermixing.¹⁻⁸ In the context of superconductivity, the interface between two non-superconducting parent compounds can become a unique two-dimensional superconductor.^{1,2,5,9} While the origin of such behaviour is not fully understood, the observation gives strong impetus to research on new class of interfaces which may possibly sustain such behaviour. One transition metal oxide which has been catching attention from the perspective of stabilizing a superconducting phase is Sr_2IrO_4 (SIO).^{10,11} This $5d$ transition metal oxide is structurally akin to the Mott insulator La_2CuO_4 which becomes superconducting on doping with Sr and Ba. The SIO is an antiferromagnet below $T_N = 240$ K. A Mott insulating behaviour emerges from the strong spin - orbit interaction splitting of the t_{2g} orbital into two groups of states labelled as $J_{eff} = 1/2$ and $3/2$.^{12,13} Many similarities between La_2CuO_4 and SIO have led to theoretical works suggesting superconductivity on appropriate doping or structure modifications.¹⁴⁻²² Indeed, some recent experiments on doped-SIO give strong indication of unusual metallic state,²³ insulator-metal transition,²⁴ resemblance with hole-doped cuprate superconductors,²⁵ and incipient superconductivity in this compound.²⁶⁻²⁹

Here, we describe a different strategy to induce superconductivity in SIO. Our experiment involves a layer-by-layer deposition of a superlattice of $\text{La}_{1.85}\text{Sr}_{0.15}\text{CuO}_4$ (LSCO) and SIO of the type $[(\text{LSCO})_m/(\text{SIO})_n]_5$ with fixed $n = 2$ nm and m varying from 2 nm to 50 nm. A significant increase in T_C of $\approx 25\%$ is achieved with respect to $m = 2$ and $\approx 10\%$ over the T_C of bulk-like 100 nm thick LSCO film. We interpret these results in the framework of interfacial doping of the SIO.

II. EXPERIMENT

The growth of superconducting LSCO and Mott insulator SIO as well as their multilayer heterostructures was realized on (001) oriented SrLaO_4 (SLAO) substrates by using a multitarget pulsed laser deposition technique ($\lambda = 248$ nm) at 800°C in 230 mTorr of oxygen pressure. After deposition of the samples, the deposition chamber was completely filled with oxygen to atmospheric pressure and then the samples were allowed to cool down to room temperature at a rate of 10°C per minute with one-hour annealing at 500°C to realize full oxygenation of the structure.³⁰ A film growth rate in the range of ≈ 0.006 - 0.012 nm/pulse was realized under these deposition conditions. The present study includes a series $[(\text{LSCO})_m/(\text{SIO})_n]_{\times 5}$ heterostructures with $m = 2$ nm to 50 nm while keeping the n constant at 2 nm.

An X-ray diffractometer (PANalytical X'Pert PRO) equipped with $\text{CuK}\alpha_1$ X-ray source with wavelength $\lambda = 0.154$ nm, was used to study the crystallographic structure and interface quality of prepared multilayer samples in θ - 2θ , ω , φ , and X-ray reflectivity modes. The standard four-probe technique was used to measure in-plane superconducting response of the films through resistivity $\rho(T)$ measurement using. Prior to transport measurement, Ar^+ ion milling process was utilized for sample patterning in four-probe geometry. The longitudinal voltage drop across the sample was measured for both positive and negative currents and then averaged out to correct for any thermal effects. For a good electrical contact and homogeneous current distribution across the ends of the thin film, silver contact pads were used. The current-voltage (I-V) response was also recorded at several temperatures in the presence of a magnetic field applied in parallel and also in perpendicular geometry with respect to the sample plane.

III. RESULTS AND DISCUSSION

The θ - 2θ X-ray diffraction profiles clearly reveal the presence of LSCO layer in the multilayer $[\text{LSCO}(10 \text{ nm})/\text{SIO}(2 \text{ nm})]_{\times 5}$ as shown in Fig. 1(a). The well-defined (006) and (008) Bragg peaks from the film are visible very close to the substrate peaks, indicating the (00ℓ) oriented c -axis growth of LSCO layers. Rocking curves (ω -scan) for the LSCO (006) reflection were measured to determine the out-of-plane mosaic spread. The values of full width at half maximum are less than 1.8° (data not shown here), suggesting that the samples have good crystallinity and strong (00ℓ) texturing. The inset in Fig. 1(a) shows the θ - 2θ scans about (101) and (200) peaks. From these scans the lattice parameter of LSCO layer are determined which are $a = 0.3771 \text{ nm}$, $b = 0.3778 \text{ nm}$, and $c = 1.3208 \text{ nm}$. Note that, there is a small biaxial compressive strain ($\epsilon_{xx} = \epsilon_{yy} = -0.34\%$) in the ab -plane resulting elongated c -axis of the LSCO layer. Further, the epitaxial growth of the multilayers has been confirmed by φ -scans. Figure 1(b) shows the φ -scans measured about (103) peaks of LSCO film and SLAO substrate revealing sharp peaks only at integral multiple of $\pi/2$, suggesting the presence of four-fold cubic symmetry in these multilayer structures. The matching of the peaks for LSCO and SLAO in φ -scans indicates in-plane lattice matching with the epitaxial relation: $[100] \text{ LSCO} \parallel [100] \text{ SLAO}$. Though, we could not resolve the diffraction peaks from SIO the layer due to very thin layer of SIO used here, good resolved low-angle Kiessig fringes can be seen in the X-ray reflectivity curve for the sample $[\text{LSCO}(20 \text{ nm})/\text{SIO}(2 \text{ nm})]_{\times 5}$ as shown in Fig. 1(c), which not only provides the information about the uniform growth of LSCO-SIO superlattice structure but also used to estimate the thickness and roughness of the individual layers. The fitting of reflectivity curve yields the interface roughness between SLAO substrate and LSCO layer is of $(0.3 \pm 0.1) \text{ nm}$ whereas between LSCO and SIO layers is $\approx (0.5 \pm 0.1) \text{ nm}$. The measured layer thicknesses are in accord with thickness as estimated from the growth rate.

Before moving towards the electrical transport investigation of these multilayers, we first present the temperature dependence of in-plane resistivity $[\rho(T)]$ for 10 nm thick SIO single layer grown on SLAO substrate under the same deposition conditions as used for preparing the multilayers. Figure 2 shows the typical semi-conducting behaviour ($d\rho/dT < 0$) of resistivity with a room-temperature resistivity is about $0.08 \Omega\text{-cm}$. The similar order of magnitude of room temperature resistivity of single crystalline thin SIO film is reported.³² The resistivity increases by three order of magnitude as the temperature is lowered to 5 K. We also plotted $\ln \rho$ versus T^{-1} in the same fig. 2 for better understanding of $\rho(T)$. It was really very hard to fit the data in the whole range with single known model.³¹ We have identified three different temperature regions in which distinct temperature dependency were figured out. 1) 180

FIG. 1. (Color online) (a) The θ - 2θ X-ray diffraction profile of $[\text{LSCO}(10)/\text{SIO}(2)]_{\times 5}$ multilayer grown on SLAO in the vicinity of (006) and (008) reflections of the SLAO (001) substrate. The main intense peak is from the SLAO substrate whereas the left side shoulder peak is from the LSCO layer. The inset shows the X-ray diffraction profile measured about (101) and (200) peaks. (b) The φ -scans about (103) plane of LSCO layer and SLAO substrate. (c) The GIXR curve for $[\text{LSCO}(20)/\text{SIO}(2)]_{\times 5}$ multilayer along with the fit. (Numbers in parentheses indicate respective layer thickness in nm).

$K < T < 300 \text{ K}$ (region-I), in which a logarithmic dependence $[\rho \propto \exp(-\alpha T)]$ is observed; 2) $120 \text{ K} < T < 170 \text{ K}$ (region-II), an Arrhenius-type behaviour, and 3) $20 \text{ K} < T < 50 \text{ K}$ (region-III), a 3- d variable-range-hopping (VRH) is observed. The governing equations for all these three regions are summarized below.

$$\rho(T) = \rho_0 \exp(-\alpha T) \quad 180K < T < 300K \quad (1a)$$

$$\rho(T) = \rho_0 \exp\left(\frac{\Delta}{k_{\beta} T}\right) \quad 120K < T < 170K \quad (1b)$$

$$\rho(T) = \rho_0 \exp\left(\frac{T_0}{T}\right)^{1/4} \quad 20K < T < 50K \quad (1c)$$

Here, ρ_0 , α , and T_0 are the fitting parameters; k_{β} is the Boltzmann constant and Δ is the gap energy. For the region-I, the value of ρ_0 and α are $1.09 \Omega\text{-cm}$ and $8.81 \times 10^{-2} \text{ K}^{-1}$, respectively. The fitted data according to Eq. 1(a) is also plotted in Fig. 2. The absence of Arrhenius-type behaviour in this temperature window, is confirmed by plotting $\ln \rho$ versus T^{-1} data, which is not a straight line. Moving towards middle temperature range where a straight line fitting is obtained for $\ln \rho$ versus T^{-1} , indicating Arrhenius behaviour given by Eq. 1(b). The fitted data for this temperature range is also plotted in Fig. 2 and the fitting parameters are ρ_0

FIG. 2. (Color online) Temperature dependence of resistivity for 10 nm thick SIO film. For the sake of clarity, $\ln \rho$ versus T^{-1} is also plotted. The whole temperature range is divided in three different regions I, II and III. In the respective temperature ranges, the resistivity data is fitted with Eq. 1(a), (b) and (c), respectively (For more details see text). For better clarity of VRH fitting, a linear plot of $\ln \rho$ versus $T^{-1/4}$ is given in the inset.

$= 6.63 \times 10^{-2} \Omega\text{-cm}$ and $\Delta = 44 \text{ meV}$. A similar type of temperature dependence has been reported for epitaxial SIO thin films³² as well as bulk crystal³³ and our estimated value of gap energy is comparable with those reported values. It is worthwhile to mention here that the room temperature resistivity of 2 nm and 4 nm SIO single layer films was very high as compared to 10 nm SIO single layer film as for multilayer structures, 2 nm SIO was used in each deposition. In the low temperature range, the resistivity data is fitted with Eq. 1(c) and $\ln \rho$ versus $T^{-1/4}$ plot is found to be a straight line in this temperature range (see inset of Fig. 2) which gives fitting parameters $\rho_0 = 4.22 \times 10^{-3} \Omega\text{cm}$ and $T_0 = 1.22 \times 10^5 \text{ K}$. In this temperature region, this weaker temperature dependence suggests minimal long-range Coulomb repulsions between electrons. It is known that for VRH this exponent indicates the dimensionality of the conductor. The $T^{-1/(n+1)}$ dependence of electrical resistivity suggests an n -dimensional conductor. Hence, for our case, fitting shows a three-dimensional VRH conductivity. Cao *et al.*³⁴ also obtained the different VRH exponents 1/2 and 1/4 for a very wide temperature range for the case of single crystal of SIO.

We now come to the central result of this paper as shown in Figure 3(a) which depicts the temperature dependence of normalized resistance of different LSCO/SIO multilayers along with that of 100 nm thick single layer film of LSCO grown under the same deposition condition. The 100 nm LSCO film exhibits a T_C onset around 39.4 K. We observe distinctly higher T_C for the multilayer

FIG. 3. (Color online) (a) The temperature dependence of normalized resistance $[R(T)/R(300\text{K})]$ for 100 nm thick single layer LSCO film and $[\text{LSCO} (m)/\text{SIO} (2)]_{\times 5}$ multilayers with $m = 2, 20, 30, 40$ and 50 nm , grown on SLAO substrate. (b) The variation of superconducting transition temperature (T_C) with LSCO layer thickness along with the T_C values measured for 100 and 250 nm thick single layer LSCO film. Here, dashed line is only guide to eye and the full line is data fitting according to Eq. (3), as discussed in the text.

samples with LSCO thickness in the range $m = 20$ to 40 nm as compared to that for single layer LSCO films of 100 and 250 nm thick. Here, the T_C is defined as the onset temperature of the superconducting transition. The maximum T_C enhancement of $\approx 43 \text{ K}$ is observed for the sample with $m = 30 \text{ nm}$. A noteworthy increase in T_C of $\approx 25 \%$ is achieved with respect to the multilayer sample with $m = 2 \text{ nm}$ and $\approx 10 \%$ over the T_C of bulk-like 100 nm thick LSCO film. The T_C values increases with increasing LSCO film thickness and attain maximum (for $m = 30 \text{ nm}$) and then start to decrease as can be seen from Fig. 3(b). Since, SIO layer is more resistive than LSCO layer, the T_C in these multilayers will be sensitive to the sequence of the layers and also to the thickness of the each layers. This may suggest that the observed phenomenon is not related to interface. But there must be some perturbed interfacial region which may cause the variation in T_C with LSCO layer thickness which will be discussed later.

Figure 4(a) shows isothermal I-V curves taken at different measurement temperatures for the sample with $m = 30 \text{ nm}$. We note that the superconducting critical current (I_C) depends on the thickness and the temperature of the sample. At a fixed value of m , I_C reduces with increasing temperature and can be seen from the contour plot shown in Fig. 4(b). This figure shows the observed variation of I_C with temperature for different multilayer structures.

From Fig. 3(a), we can see that the normal-state re-

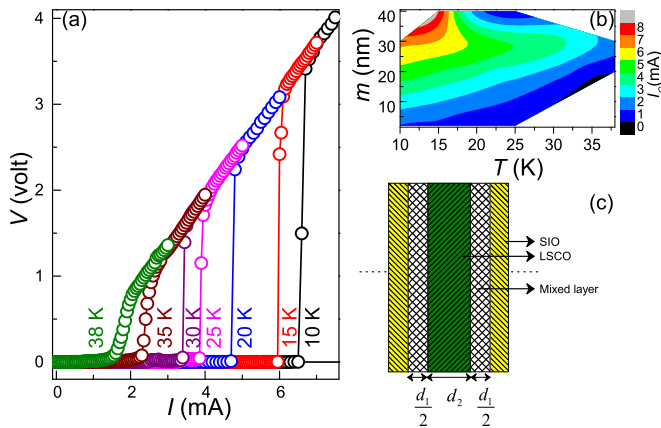

FIG. 4. (Color online) (a) I-V characteristics for [LSCO(30)/SIO(2)] \times 5 multilayer measured at different temperature without applying any magnetic field. (b) The critical current distribution with temperature for multilayers with different LSCO layer thicknesses. (c) The schematic model for proximity effect between superconducting LSCO layer and mixed layer of SIO and LSCO. This mixed layer is assumed symmetrically on the both side of LSCO layer. (For more details, see text.) .

sistance of these multilayers changes with LSCO layer thickness suggesting some probability that the T_C values are somehow affected by the proximity region within the individual superconducting LSCO layers. Hence, any kind of change or variation in normal-state properties of the LSCO layer will dominantly affect the superconducting properties of these multilayers. Apart from these, layer coupling due to minute doping from one layer to another or intermixing between the layers, may also be very relevant in our case. It would be very difficult to understand the mechanism of increase in T_C via considering all aspects mentioned above.

To get into more depth about the variation in T_C , we have to look into the possibility of doping into SIO layer. As it is earlier proposed that the doping of electrons or holes in SIO can lead to achieve superconducting phases.^{10,11,27} Since SIO is a $J = \frac{1}{2}$ Mott insulator with strong spin-orbit coupling, any minor change in stoichiometry results a notable change in the lattice parameters and also low-temperature transport properties due to doping and/or oxygen vacancies. Korneta *et al.* reported the metallic behaviour on electron-doped (oxygen deficient) Sr₂IrO_{4- δ} with almost a nine order of huge magnitude change in the low temperature resistivity [$\rho(T = 1.8 \text{ K})$] as δ slightly changes from 0 to 0.04.¹⁸ The substitution of La atoms on Sr-sites in SIO also makes it electron-doped which is also proposed to exhibit high- T_C superconductivity.¹⁹

From Fig. 3(b), the decrease in T_C of the multilayer system with increasing LSCO layer thickness beyond an optimum thickness of 30 nm, can be understood as a

superconducting proximity effect. There are various calculations made for the proximity effect between thin layers. Cooper–de Gennes model³⁵ is one of them, which is based on the effective pairing interaction between the layers. But finite transparency of boundaries between different layers is not accounted for this model. So for the boundaries with smaller transparency, McMillan proposed a tunneling model³⁶ which further modified by Golubov³⁷ considering arbitrary transparency of the boundary via assuming the link between the different layers is single-particle tunneling. To apply the later model, one requires knowledge of T_C and coherence length values for each layer, along with a parameter that governs the boundary conditions on the superconducting order parameter at the layers interface. Due to less knowledge of SIO layers as a superconducting candidate, it is really hard to use this model without knowing aforesaid values. We have tried to fit our experimental data using Gennes model and found a good agreement. To realize this, we have considered the possibility of intermixing of layers near the LSCO and SIO interface or doping/migration of La atoms into the SIO layer. Thus our multilayer samples can be understood in a sense where each of LSCO layer is covered both side by mixed LSCO-SIO layer and then entire this LSCO/mixed-layer structure is separated by insulating SIO layer. A sketch of this model is given in Fig. 4(c). These two regions with thicknesses d_1 and d_2 , respectively, must have different values of T_C . This mixed layer will have different T_C value other than its intrinsic value. The doping of La and/or oxygen deficiencies into SIO layers are the main basis of this model. To begin this, we need to know the effective pairing interaction in these two layers, which is given by

$$\lambda_{eff} = \frac{\sum_{i=1}^2 N_i d_i \lambda_i}{\sum_{i=1}^2 N_i d_i} \quad (2)$$

where N_i , d_i , and λ_i are the density of states at the Fermi level, the layer thickness and the pairing parameter, respectively, in the two layers. Here, layer 1 is the LSCO-SIO mixed layer and layer 2 is LSCO. In order to get correctly averaged pairing parameter, we assumed the presence of these mixed layers of same thicknesses on both sides of the LSCO layer. Thus T_C of the system can be calculated from the formula given by³⁶

$$T_C = \frac{\Theta_D}{1.45} \exp \left[\frac{-1.04 (1 + \lambda_{eff})}{\lambda_{eff} - \mu^* (1 + 0.62 \lambda_{eff})} \right] \quad (3)$$

with Θ_D is the Debye temperature and μ^* is the Coulomb coupling parameter. The fitted value of the parameter $N_1 d_1 / N_2$ is 6.22 nm, gives $d_1 = 2.5$ nm, which further indicates the presence of a ≈ 1.25 nm thick mixed layer on either side of the LSCO layer. Although this procedure is of course very approximate, the resulting values of T_C for these multilayers systems with different LSCO

layer thickness is in good agreement to the model and can be seen in Fig. 3(b). On this ground, we can say that with the decrease in LSCO layer thickness from 50 nm to 30 nm, Cooper pairs try to spend smaller time in LSCO layers and more in mixed layers due to proximity effect between the mixed and LSCO layer, this would increase the T_C due to the dominance of larger pairing interaction in mixed layers. A similar kind of analysis was proposed and the superconducting transport properties were analyzed for Nb/Ge multilayer system by assuming passive influence on the superconducting order parameter associated with the proximity effect.³⁸ The presence of somewhat disordered Nb/Ge interfacial layer mainly controls the T_C of Nb/Ge multilayers.

IV. CONCLUSIONS

We have presented a detailed study of LSCO-SIO multilayers as a model system to understand the proximity effect between the layers. The temperature dependence of SIO single layer is also analyzed in the context of thermal activation, Arrhenius-type behaviour, and variable-range hopping mechanisms for different temperature regimes. With the increase in LSCO layer thickness, the LSCO-SIO multilayer system shows an increase in T_C as high as $\approx 43\text{K}$, 10 % higher than the single layer LSCO film. After attaining a maximum, T_C decreases with further increasing LSCO layer thickness. For smaller LSCO thickness Cooper pairs spends lesser time due to the dominance of larger pairing interaction in the mixed layers. Although we have tried to give the explanation for the thickness dependence of T_C , the poor information about SIO binds us from detailed investigation. A high resolution interface study is required for the better understanding. Our results definitely will give a direction to achieve proposed superconductivity in Sr_2IrO_4 and also excite the intriguing field of layer superconductors.

V. ACKNOWLEDGEMENTS
