ABSTRACT
A key challenge in the task of human pose and shape estimation is occlusion, including self-occlusions, object-human occlusions, and inter-person occlusions. The lack of diverse and accurate pose and shape training data becomes a major bottleneck, especially for scenes with occlusions in the wild. In this paper, we focus on the estimation of human pose and shape in the case of inter-person occlusions, while also handling object-human occlusions and self-occlusion. We propose a framework that synthesizes occlusion-aware silhouette and 2D keypoints data and directly regresses to the SMPL pose and shape parameters. A neural 3D mesh renderer is exploited to enable silhouette supervision on the fly, which contributes to great improvements in shape estimation. In addition, keypoints-and-silhouette-driven training data in panoramic viewpoints are synthesized to compensate for the lack of viewpoint diversity in any existing dataset. Experimental results show that we are among state-of-the-art on the 3DPW dataset in terms of pose accuracy and evidently outperform the rank-1 method in terms of shape accuracy. Top performance is also achieved on SSP-3D in terms of shape prediction accuracy.

KEYWORDS
3D human pose and shape estimation, occlusion-aware, neural mesh renderer, silhouette, 2D keypoint.

1 INTRODUCTION
Human pose and shape estimation from a single image is a challenging 3D vision problem. It may promote many promising applications, such as human-computer interaction, computer graphics, virtual fitting room, video understanding, etc. Recent years have witnessed the rise of various deep-learning-based methods [15, 22, 23, 25, 29]. Such methods provide impressive 3D human pose estimation results using a single RGB image. However, occlusion remains a major challenge for images in the wild, where self-occlusions, person-object occlusions and inter-person occlusions are common. It is hard to achieve good performance when recovering the full 3D human body shape without explicitly taking occlusions into account. In this paper, we mainly focus on estimating the full 3D human pose and shape from a single RGB image under various occlusion cases.

By exploiting a parametric human body model SMPL [18], the task of human pose and shape estimation are usually converted into SMPL parameters estimation. SMPLify [3] fit the SMPL parameters that give rise to a mesh consistent with image evidence, i.e., 2D keypoints. Omran et al. [20] regressed the SMPL parameters with a Convolutional Neural Network. Kolotouros et al. [16] directly regressed the 3D locations of the mesh vertices using a Graph-CNN. With further development, some targeted questions have been raised. To estimate human shape better, [24] proposed a method by synthesising the input data with different shape. For the object-occluded case, [31] presented a method that utilizes a partial UV map to represent an object-occluded human body. Compared with the object-occluded cases, the person-occluded cases involve more complex scenes and yet are quite common in reality. Fig.1 shows some of such tricky cases. There are two main challenges. The first challenge is the lack of training data. Existing datasets do not contain enough samples with occlusions. Moreover, since training data is traditionaily collected by motion capture (MoCap) systems, and due to the limitations of existing MoCap systems, data collection of inter-person occlusions can hardly scale up. The other challenge is that severe inter-person occlusions would introduce challenging ambiguities into the network prediction, and thus confuse the full 3D human body shape estimation.

\textsuperscript{*}Equal contribution  
\textsuperscript{†}Corresponding author
To tackle the obstacles, inspired by [24], we propose to make use of synthetic keypoints-and-silhouette-driven training data and explicitly design an occlusion-aware framework during training. More specifically, silhouettes that reflect various inter-person occlusions are synthesized, and 2D keypoints are masked out if considered occluded. Using keypoints and silhouettes as the intermediate representation, large amount of inter-person occlusion samples can be generated with a low cost. Moreover, supervision of the silhouettes is enforced during training using a neural 3D mesh renderer integrated with the framework. The loss is backpropagated to the SMPL pose and shape parameters, which proves to enhance the human pose and shape estimation performance. Moreover, in many existing datasets, the cameras are installed in fixed positions. To further facilitate the network training and empower it with better generalization ability, we propose a viewpoint augmentation strategy to synthesize infinite viewpoint variation, creating keypoints-and-silhouette-driven training data from panoramic views on top of any existing dataset.

The overall flowchart of the proposed framework is shown in Fig. 2. Module A synthesizes the training data on-the-fly with the view augmentation and inter-person occlusions. The data then passes through the encoder and iterative regressor. The rendering and comparison structure is used to supervise the network. During inference, we just need the keypoint detector [7] and DensePose [6] to obtain the keypoints-and-silhouette data as input.

The main contributions of this work are summarized as follows:

- We propose a robust occlusion-aware 3D pose and shape estimation framework that exploits synthetic keypoints-and-silhouette-driven training data, which overcomes the data scarcity especially for person-occluded scenes in the wild.
- Neural 3D mesh renderer is integrated with the framework to provide silhouette supervision during training, which contributes to much more accurate shape estimation.
- A viewpoint augmentation strategy is introduced to synthesize infinite viewpoint variation, creating keypoints-and-silhouette-driven training data from panoramic views on top of any existing dataset.

2 RELATED WORK

In this section, we discuss recent 3D human pose and shape estimation approaches, as well as the methods that handle the occlusion problem.

Optimization-based methods: Optimization-based approaches attempt to fit a parametric body model, like SMPL [18] or SCAPE [1], to 2D observations. SMPLify [3] was the first method to automatically estimate 3D pose and shape from a single unconstrained image by fitting the SMPL to 2D keypoint detections. Beyond SMPLify using 2D keypoint detections, some different cues, like body surface landmarks [17], silhouettes [17] or body part segmentations [29], are added in the fitting procedure. More recently, works have demonstrated fits for more expressive models [10, 26] including face, body, and hand to images. These approaches produce reliable results with good 2D observations. However, they are sensitive to initialisation and rely heavily on the quality of 2D information.

Regression-based methods: To this end, recent works rely almost exclusively on deep neural networks to regress the 3D human pose and shape parameters. Owing to the lack of training data with full 3D shape ground truth, 2D annotations including 2D keypoints, silhouettes, or parts segmentation are usually essential. This information can be used as intermediate representation [12, 27], or as supervision [12, 23]. Kolotouros et al. [16] directly regress the
3D location of the mesh vertices from a single image instead of predicting model parameters using a Graph-CNN. Fundamentally, regression-based methods are dependent on the sample diversity of the training data. However, since obtaining 3D training data is awfully expensive, most datasets only contain a limited number of human bodies. This is also the reason why the existing datasets are insufficient to support robust and accurate human body shape estimation in the wild.

Occlusion: Huang and Yang [9] proposed a method that can recover 3D pose when a person is partially or severely occluded in the scene from monocular images. However, the occlusions are limited to simple rectangles. A grammar-based model was introduced by [5] using explicit occlusion part templates. To avoid specific design for occlusion patterns, Ghiasi et al. [4] presented a method to model occlusion by learning deformable models with many local part mixture templates using large quantities of synthetically generated training data that was aimed at explicitly learning the appearance and statistics of occlusion patterns. Zhang et al. [31] presented a method that utilizes a partial UV map to represent an object-occluded human body, and the full 3D human shape estimation is ultimately converted as an image inpainting problem. The above methods mainly deal with the object-human occlusion problems. Bin et al. [2] presented a method that augments images by pasting segmented body parts with various semantic granularity. This method has a certain generalization ability to shield the human body from each other.

Synthetic training data: When the dataset is not enough to solve the problem, synthetic data is one option. Several papers have explored the use of synthetic data in training systems for human pose and shape estimation. To make up for the scarcity of in-the-wild training data with diverse and accurate body shape labels, [24] proposed STRAPS, a system that utilizes proxy representations, such as silhouettes and 2D joints, as inputs to a shape and pose regression neural network, which is trained with synthetic training data. Some cutting and pasting methods, like [2, 5, 31], to yield novel samples.

3 TECHNICAL APPROACH
In the following section, we first describe the Skinned Multi-Person Linear model (SMPL) briefly and the basic notations defined in this paper. More details about the data generation are then provided. After that, the regression network and the loss function are presented in detail.

3.1 SMPL Model
SMPL is a skinned vertex-based model that accurately represents a wide variety of body shapes in natural human poses. The SMPL model provides the function \( M(\theta, \beta) \) that takes as input the pose parameters \( \theta \) and the shape parameters \( \beta \) and returns the body mesh \( v \in \mathbb{R}^{N \times 3} \) with \( N = 6890 \) vertices. The 3D joints by \( J^{3D} = f^u \), where \( J \in \mathbb{R}^{K \times N} \) is a linear regressor has been pre-trained. Models trained using these datasets may depend on the camera’s perspective and have poor generalization ability. To this end, this paper adopts a viewpoint augmentation strategy to generate intermediate representations, i.e., keypoints and silhouettes, under different camera parameters. Using these intermediate representations can make full use of this feature and reduce the model’s dependence on a specific camera perspective. In the implementation, since the first three values of the SMPL model pose parameters control the global orientation of the human body model, we alter these parameters to modify the current human body orientation relative to the camera. Modifying the global orientation of the human body model does not modify the 3D posture of the human body, but the projection on the 2D image is quite different. The keypoints and contour maps of the input model in this paper are all two-dimensional data. This greatly enriches the training data when the camera viewpoint in the training data is limited. The specific formula is given as follows:

\[
\hat{\theta} = \theta + \pi \ast N(\mu, \sigma^2)
\]

where \( \theta \) means the global orient in \( \theta \) parameters and \( N \) means a normal distribution function with a mean (\( \mu \)) 0 and variance (\( \sigma \)) of 1.

3.3 Synthetic Data Generation
As shown in Fig.3, two pairs of SMPL parameters \((\theta_1, \beta_1), (\theta_2, \beta_2)\) are sampled from any training dataset. The camera translation vector \( t_1 \) is generate randomly, while the camera intrinsic matrix \( K \) and rotation matrix \( R \) are fixed. Then, we obtain \( t_2 \) based on \( t_1 \) by adding a shift. In order to get various shape data, we replace \( \beta_1 \) with a new random vector \( \beta_2 \) generated by sampling each shape parameter \( \beta_2^i \) \( \sim N(\mu, \sigma^2) \) [24]. We use \( \theta_1 \) and \( \theta_2 \) by replacing the global orientation with the orientation \( \hat{\theta} \) obtained by viewpoint augmentation method instead of the original \( \theta_1 \) and \( \theta_2 \). Then, the 3D vertices \( v_1 \) and \( v_2 \) corresponding to \((\theta_1, \beta_1)\) and \((\theta_2, \beta_2)\) are rendered [12] into silhouette \( S_1, S_2 \in [0, 1]^{H \times W} \). The final silhouette is calculated by (2).

\[
S = S_1 - S_2
\]

As shown in Fig.4, inter-person occlusion samples are generated with different levels of human body overlap.

For 2D joints, the 3D joints \( j^{3D} \) corresponding to \((\theta_1, \beta_1)\) are projected into 2D joints \( j^{2D} \in \mathbb{R}^{K \times 2} \) using prospective projection. \( j^{2D} \) is encoded into 2D Gaussian joint heatmaps, \( G \in \mathbb{R}^{K \times H \times W} \). We obtain the final input \( X \in \mathbb{R}^{(K+1) \times H \times W} \) by concatenating \( S \) and \( G \). Note that the noises in keypoints detection will introduce noises into the 2D joint heatmap encoding. To handle occluded joints explicitly, we randomly remove some body parts from the human body and add occluding boxes to the silhouette in \( S \) during training.

3.4 Regression network
Our method is architecture-agnostic. We use the baseline network architecture as in [11, 15, 24], which consists of a convolutional encoder for feature extraction and an iterative regressor that outputs predicted SMPL pose, shape and camera parameters (\( \theta, \beta \) and
Figure 3: Synthesizing the silhouette. First, two pairs of SMPL parameters \((\theta_1, \beta_1), (\theta_2, \beta_2)\) are sampled. After viewpoint and shape augmentation is performed, a neural mesh renderer generates the 2D silhouettes. Finally, the pair of silhouette is used to synthesize the human body overlap.

Figure 4: Examples of synthetic data generation with different levels of inter-person occlusions.

\(\tilde{\mathbf{I}}\) from the extracted feature. Same as [24], the SMPL default discontinuous Euler rotation vectors are replaced by a continuous 6-dimensional rotation representation of \(\hat{\theta}\) proposed by [32].

The weak-perspective camera model is adopted in this paper, represented by \(\tilde{\mathbf{I}} = [\hat{s}, \hat{t}]\) where \(\hat{s} \in \mathbb{R}\) means scale and \(\hat{t} \in \mathbb{R}^2\) represents \(x - y\) camera translation. These parameters allow us to generate the mesh corresponding to the regressed parameters, \(\hat{\mathbf{v}} = M(\hat{\theta}, \hat{\beta})\), as well as the 3D joints \(\hat{f}^3d = f\hat{\theta}\) and their 2D reprojection \(\hat{f}^2d = \Pi(\hat{f}^3d)\).

**Neural 3D Mesh Renderer.** Differentiable rendering is a novel field which allows the gradients of 3D objects to be calculated and propagated through images. We follow the common self-supervision pipeline with differentiable rendering and don’t need correspondence to images. A neural 3D mesh renderer [12] is integrated into our framework to provide silhouette supervision during training.

The loss function is defined as

\[
\mathcal{L}_S = \frac{1}{H \times W} \times \|\hat{S} - S\|_2^2
\]

where \(S\) is the target silhouette image, \(\hat{S}\) is silhouette rendered from \(\hat{\theta}\) and \(H, W\) are the height and width of the target silhouette \(S\). The reconstruction of 3D shape is an ill-posed problem when a single view is used during training. Additional loss functions are added to provide strong supervision.

The first term \(\mathcal{L}_v\) performs the supervision between predicted 3D vertices and ground-truth 3D vertices, which is,

\[
\mathcal{L}_v = \|\hat{\mathbf{v}} - \mathbf{v}\|_2^2
\]
The second term $L_{j3d}$ performs the supervision between predicted 3D joints and ground-truth 3D joints, which is,

$$L_{j3d} = \| \hat{j}_{3d} - j_{3d} \|_2^2$$  \hspace{1cm} (5)

The $L_\theta$ and $L_\beta$ loss items can provide strong 3D supervision.

$$L_\theta = \| \hat{\theta} - \theta \|_2^2$$  \hspace{1cm} (6)

$$L_\beta = \| \hat{\beta} - \beta \|_2^2$$  \hspace{1cm} (7)

In order to enforce image-model alignment, we add the loss for the projected 2D joints

$$L_{j2d} = \frac{1}{K} \sum_{i=1}^{K} \| j_{2d} - \hat{j}_{2d} \|_2^2$$  \hspace{1cm} (8)

where the value of $o_{ij}$ indicates the visibility (1 if visible, 0 otherwise) for $i$-th 2D keypoints (K in total). The final loss function can be described as follows:

$$L = \frac{1}{\sigma_\gamma} L_\gamma + \frac{1}{\sigma_\jmath} L_{j2d} + \frac{1}{\sigma_\theta} L_\theta + \frac{1}{\sigma_\beta} L_\beta + \frac{1}{\sigma_{j3d}} L_{j3d}$$

$$+ \frac{1}{\sigma_S} L_S + \log \left( \sigma_p \sigma_{j1d} \sigma_0 \sigma_\beta \sigma_{j2d} \sigma_S \right)$$  \hspace{1cm} (9)

where losses are adaptively combined using homoscedastic uncertainty [13]. In the next section, we will analyze the contribution of the silhouette loss $L_S$ in 3D shape estimation accuracy.

4 EXPERIMENTS

4.1 Datasets

This section gives a description of the datasets we use for training and evaluation.

AMASS is a large and varied database of human motion that unifies 15 different optical marker-based mocap datasets by representing them within a common framework and parameterization. Some of the SMPL parameters are selected to train our network.

UP-3D combines two LSP datasets and the single-person part of MPII-HumanPose dataset. It is used to train our network.

3DPW is captured via IMUs and contains both indoor and outdoor scenes. It provides abundant 2D/3D annotations, such as 2D pose, 3D pose, SMPL parameters, human 3D mesh, etc. It includes inter-person occlusion, object-human occlusion, and non-occluded/truncated cases. Being a rare in-the-wild 3D human pose and shape dataset, 3DPW is the most suitable for testing our work. 3DPW is used for training and evaluation with the same split as in [24].

SPP-3D contains 311 in-the-wild images of 62 tightly clothed sports persons (selected from the Sport-1M video dataset) with a diverse range of body shapes, along with corresponding pseudo-ground-truth SMPL shape and pose labels.

3DOH50K is the first 3D human pose dataset that introduces object-human occlusions upon purpose when recording. It contains 1290 test images. This dataset is used for evaluation.

Dataset Statistics. Our work mainly focuses on human pose and shape estimation with inter-person occlusions. We compare different datasets to give insights about the types of occlusion and the number of people in Table 1.

4.2 Implementation details

Network Architecture. For a fair comparison with previous methods, we use fine-tuned ResNet-18 [8] as the default encoder and ResNet-50 as the additional encoder. The encoder produces a feature vector $\phi \in \mathbb{R}^{312}$. The iterative regression network consists of two fully connected layers. During inference, we use darkpose [30] to get 2D keypoints of 3DPW and use Mask-RCNN [7] to get 2D keypoint predictions of other datasets. We use DensePose [6] to get silhouette predictions. All implementations are done in PyTorch [21]. More setting details are given in the supplementary material.

Setting Details. The input silhouettes are cropped and resized to 256 × 256, while keeping the aspect ratio of 1:2. COCO keypoint order is used and the number of keypoint is 17. The input tensor is 18 × 256 × 256. The loss weights are set to be $\sigma_\gamma = 1.0, \sigma_{j3d} = 1.0, \sigma_\theta = 0.1, \sigma_\beta = 0.1, \sigma_{j2d} = 0.1, \sigma_S = 0.1$. We use the Adam optimizer [14] with a batch-size of 140 and initial learning rate of 0.0001 to train our encoder and regressor. The mean values in iterative regression are the same with SPIN [15]. The training step takes 10 days with 100 epochs on a single 3090 GPU.

Training Datasets. For a fair comparison with the previous method STRAPS [24], we use the training data provided by the STRAPS [24]. The training data are collected from AMASS, 3DPW and UP-3D. In the training step, we use the ground-truth SMPL parameters and do not use any pair of image and 3D label.

Evaluation Metrics. We adopt Procrustes-aligned [19] mean per joint position error (MPJPE_PA) for evaluating the 3D pose accuracy. To evaluate the 3D surface error, we employ Procrustes-aligned per-vertex euclidean error in a neutral pose (PVE_T-SC) and mean intersection-over-union (miOUI) on SSP-3D.

4.3 Comparisons to the State-of-the-Art

To demonstrate the effectiveness of our method, we perform quantitative evaluations on 3DPW, 3DOH50K and SSP-3D. In Table 2, the methods in the upper rows do not use any paired images and 3D labels. Separated by the horizontal line, the methods in the bottom rows use the paired ground-truth 3D labels and images during training. Our method does not directly use any real images in the training step.

3DPW. We evaluate the test dataset in 3DPW. As shown in Table 2, our method achieves 12 percent improvement compared with [24]. Although our method does not use paired images and 3D labels, it shows competitive performance with the state-of-the-art that requires training data comprised of paired images and 3D labels. Imposing less restrictions on the training data means our
Figure 5: Qualitative comparison with the state-of-the-art methods. Some samples with different levels of inter-person occlusions from 3DPW dataset are shown. Compared with STRAPS [24] and ROMP [28], our method gives more accurate pose and shape predictions for the person-occluded cases.

Table 2: Comparisons with the state-of-the-art methods STRAPS [24], HMR [11], SPIN [15], ROMP [28] and OOH [31] on 3DPW, 3DOH50K and SSP-3D. Number marked with * were evaluated using the open-sourced official code. Number marked with - were provided by [24], all other numbers are reported by the respective papers. In order to be more concise, the methods without using the paired ground-truth 3D labels and images during training are marked in bold black and other methods are marked in light green.

method can scale up easier without relying on paired images and labels. On the other hand, although the rank-1 method ROMP [28] reports higher MPJPE-PA accuracy, the proposed method clearly shows better performance on the silhouette for human with various shapes, as shown in Fig.6.

SSP-3D. In SSP-3D dataset, it contains 62 subjects. While dealing with occlusion issues, the proposed method shows better performance on shape estimation in the item of PVE-T-SC.

3DOH50K. In 3DOH50K dataset, the samples have severe occlusions. As shown in Table 2, better performance is achieved compared with [24] on handling object-human occlusions. The other
methods also use the Human3.6M dataset to train the model while ours does not. Therefore, it would not be fair to directly compare our results to theirs.

Finally, to show the effectiveness of our method on handling inter-person occlusions, some examples are shown in Fig.5. On the other hand, to compare the shape estimation of the human body more intuitively, some examples with diverse body shapes are demonstrated in Fig.6.

**Silhouette loss.** To study the effect of the neural-mesh-rendering-enabled silhouette loss $L_S$ in (3), we compare two models trained with (i) baseline, and (ii) adding the silhouette loss. The results are shown in Table 3. The qualitative comparison with the baseline and silhouette loss are shown in Fig.7. The silhouette loss improves both the network convergence and the final performance. For the model with silhouette supervision, training converges within 100 epochs, whereas the baseline model takes 250 epochs. Note that
Figure 8: Effects of view augmentation (VA) and inter-person occlusion augmentation (IPOA). The model with both VA and IPOA yields the best performance.

**View Augmentation and Inter-person Occlusion Augmentation.** We also investigate the effects of view augmentation (VA) and inter-person occlusion augmentation (IPOA). As shown in Table 4, our method can improve the accuracy under both evaluation standards. Some qualitative results of adding the VA and IPOA modules are visualized and compared in Fig. 8. The model with both VA and IPOA can handle unusual viewpoints and severe occlusions well, which yields the best performance.

**Our Method with Ground Truth 2D Inputs.** We report the performance of our method using ground-truth keypoints and silhouettes. The results are shown in Table 5. Compared with noisy 2D keypoint detections and silhouettes, using ground-truth 2D inputs improve the accuracy by a large margin. This indicates that if equipped with a better 2D keypoint detector and silhouette segmentation method, much better results will be yielded.

Table 5: Evaluation on the 3DPW dataset using ground-truth keypoints and silhouette.

</tbody>
</table>

We also evaluate the effects of using different percentage of data for inter-person occlusion synthesis. 40, 80 and 100 percentage of the data are processed respectively, and the corresponding results are compared in Table 6. Using 100 percentage of training data to synthesize occlusions, the best accuracy is achieved on the 3DPW dataset. This reasons well since occlusions are extremely common in 3DPW.

Figure 9: MPJPE_PA on 3DPW with different confidence thresholds.
In the 2D keypoint detector, each joint prediction is associated with a confidence score. When the predicted confidence score is above a threshold, the joint is considered detected correctly. The keypoints with confidence lower than the threshold are removed. We test the effects of adjusting the confidence threshold. The results on 3DPW are shown in Table 7. For samples with severe occlusions, by removing the poorly detected 2D keypoints properly, better results are achieved. The line chart about the MPJPE_PA is shown in Fig. 9. Empirically, setting the threshold to be 0.4 yields the best performance.

5 CONCLUSIONS

In this paper, we propose a new framework that synthesizes occlusion-aware silhouette and 2D keypoints representations to overcome data scarcity when regressing the human pose and shape, which proves to work well on inter-person occlusions as well as other occlusion cases. Differentiable rendering is integrated to enable silhouette supervision on the fly, contributing to higher accuracy in the pose and shape estimation. A new method for synthesizing keypoints-and-silhouette-driven data in panoramic viewpoints is presented to increase viewpoint diversity on top of existing dataset. Experimental results demonstrate that thanks to these strategies, the proposed framework is among the start-of-the-art methods on the 3DPW in terms of pose accuracy and evidently outperforms the rank-1 method in terms of shape accuracy. Top performance is also achieved on SSP-3D in terms of human shape estimation accuracy. The occlusion-aware synthetic data generation strategy, neural-mesh-renderer-enabled silhouette supervision and viewpoint augmentation strategy can be applied to various other 3D human pose and shape estimation approaches to improve the overall performance of the community.

Future work. Our occlusion-aware method can be extended to the crowded people case. Video information can also be considered to obtain more consistent and accurate human pose and shape. Additionally, compared with other methods, limited training data is used for now. In the next step, more datasets like Human3.6M will be added in the training procedure to train the model.
