Abstract

In this paper, we perform a thorough analysis of tree-algorithms with multi-packet reception (MPR) and successive interference cancellation (SIC). We first derive the basic performance parameters, which are the expected length of the collision resolution interval and the normalized throughput, conditioned on the number of contending users. We then study their asymptotic behaviour, identifying an oscillatory component that amplifies with the increase in MPR. In the next step, we derive the throughput for the gated and windowed access, assuming Poisson arrivals. We show that for windowed access, the bound on maximum stable normalized throughput increases with the increase in MPR. We also analyze \(d\)-ary tree algorithms with MPR and SIC, showing deficiencies of the analysis performed in the seminal paper on tree-algorithms with SIC by Yu and Giannakis.

I. INTRODUCTION

In the last decade, there have been significant theoretical advances in the area of random-access protocols, instigated by the novel use-cases pertaining to the Internet of Things (IoT). A typical IoT scenario involves a massive number of sporadically active users exchanging short messages. The sporadic user activity mandates the use of random-access protocols, however, their use in massive IoT scenarios faces the challenge of an increased requirement for efficient performance. Particularly, as the amount of exchanged data is low, the overhead of the random-access scheme should be minimal in order not to create the bottleneck in the overall communication setup.

A way to improve the performance of random-access protocols is to embrace the interference from the contending users. Effectively, this is achieved by employing MPR, enabled by the
advanced capabilities of the physical layer (i.e., via the use of advanced signaling processing). Tree-algorithms [1] and ALOHA [2], [3] are families of random-access protocols that by design suffer from collisions by contending users; as such, it is fitting to assume that protocols from these families will benefit from MPR. Indeed, it was shown that MPR improves the performance of slotted ALOHA, e.g., [4]–[6].

Another well-explored line of research in the context of slotted ALOHA is the use of SIC across slots.¹ In this class of protocols [7], the users transmit multiple replicas of their packets on purpose. Decoding of a packet replica occurring in a singleton slot enables removal of all the other related replicas, potentially transforming some of the collision slots into singletons from which packets of other contending users can be decoded, and thus propelling new iterations of SIC, etc. The use of SIC pushes the throughput performance significantly, asymptotically reaching the ultimate bound for the collision channel of 1 packet/slot [8], [9]. Finally, it was shown that a combination of MPR and SIC pushes the performance further than any of the two techniques separately [10].

A tree-algorithm based scheme exploiting SIC, named SICTA, was proposed by Yu and Giannakis in [11]. It was shown that the maximum stable throughput (MST) of SICTA reaches \( \ln 2 \approx 0.693 \) packet/slot, which is significantly better than the best performing variant of the algorithm without SIC [12]. The analysis in [11] considered the general case of \( d \)-ary splitting. However, in this paper, we show that the underlying model is incorrect for \( d > 2 \), making the conclusions effective only for the case of binary splitting. Finally, the use of MPR in tree-algorithms was analyzed in our recent work [13], where it was shown that MPR pushes the normalized² MST in the version of the scheme with the windowed access.

Motivated by the insights in [10], [13], in this paper we study the performance of tree-algorithms with \( K \)-MPR and SIC; that is, we assume that the receiver is capable of successfully decoding any collision of up to including \( K \) concurrent packet transmissions and can perform the SIC along the tree. We show a somewhat surprising fact that, for the gated access, the bound on the MST (normalized with \( K \)) decreases with \( K \), where this decrease is due to oscillations first identified in [14], whose amplitude grows with \( K \). On the other hand, in the case of the

¹Strictly speaking, SIC is just another form of MPR, and indeed many MPR schemes rely on interference cancellation. In this paper, we use the term SIC to denote the application of interference cancellation across slots, while we assume that MPR operates on individual slot basis.

²Normalized with respect to the assumed linear increase in physical resources to achieve MPR.
windowed access, the bound on normalized MST increases with $K$; however, a relatively large $K$ is required for this effect to play a significant role. Specifically, the contributions of this paper are the following:

1) We derive the expression for the expected length of a collision resolution interval (CRI) for binary tree-algorithm (BTA) with MPR and SIC, conditioned on the number of contending users $n$, which is the prerequisite for the further analysis.

2) We derive the asymptotic expressions for the expected CRI length as $n \to \infty$. In doing so, we extend the method elaborated in [14]. We also develop simple upper and lower bounds, adapting the approach discussed in [15].

3) We investigate the bounds on the MST for gated and windowed access method.

4) We identify the shortcomings in [11] related to calculation of the expected CRI length of $d$-ary tree-algorithms with SIC when $d > 2$, and show some insights about the throughput performance of this class of tree-algorithms, including MPR.

5) We extend the derived results for BTA with MPR (without SIC), preliminary investigated in [13].

The rest of the text is organized as follows. In Section II we state the background and briefly review the related work. Section III formulates the system model. In Section IV, we derive the basic performance parameters, which are the expected CRI and throughput, conditioned on the number of initially colliding users, followed by the derivation of their asymptotic values as well as upper and lower bounds. Section V investigates the MST performance of the scheme in the case of Poisson arrivals, both for the gated and the windowed access. Section VI considers the general, $d$-ary version of the scheme. Section VII concludes the paper.

II. BACKGROUND AND RELATED WORK

A. Tree Algorithms

Tree-algorithms were introduced by Capetanakis in the seminal paper [1]. The key ingredient of tree-algorithms is the collision-resolution protocol (CRP) which is driven by the feedback sent by the receiver. The basic variant of the CRP, denoted as BTA, operates as follows on a time-slotted multiple-access collision channel with feedback. Assume that $n$ users transmitted their packets in a slot:

- If $n = 0$, the slot is idle, and the corresponding feedback is sent by the receiver.
- If \( n = 1 \), there is a single transmission in the slot (the slot is singleton), the packet is decoded (i.e., the user that transmitted the packet becomes resolved), which is acknowledged by the receiver.
- If \( n > 1 \), a collision occurs and the receiver sends the corresponding feedback, initiating the collision resolution. The collided users split into two groups, e.g., group 0 and group 1; the decisions of which group to join are made uniformly at random and independently of any other user. In the next slot, the users in group 0 transmit. If the slot is idle (i.e., no user selected group 0) the users from group 1 transmit in the next slot. If the slot is singleton, the packet in it is decoded and the users from group 1 transmit in the next slot. Finally, if the slot is a collision slot, the users in group 0 split again in two groups and the procedure is recursively repeated. In this case, the users in group 1 wait until all packets from users in group 0 become decoded (the information of which is obtained via monitoring the feedback).
- The collision resolution ends when all \( n \) packets are decoded.

Fig. 1a) shows an example of the scheme. In practice, the CRP is combined with a channel-access protocol (CAP), which specifies when the arriving (i.e., active) users can access the channel. The basic variants of CAP are the gated (also known as blocked), windowed and free access; the details about the former two are presented in Section V. It was shown that the MST throughput of BTA with the gated access is 0.346 packet/slot [1].

This initial work inspired a number of research works on tree-algorithms. Here we mention the modified tree-algorithm, which omits the slots that are certain to repeat the immediate previous collision (e.g., slot 10 in Fig. 1a) would be skipped), boosting the MST with the gated access to 0.375 packet/slot [15]. Another significant improvement can be obtained by using the BTA in the windowed access framework, which boosts the MST to 0.429 packet/slot.

A further modification to the framework is made by considering \( d \)-ary splitting, a generalization in which the colliding users split into \( d \geq 2 \) groups. It was shown in [14] that the ternary tree-algorithms with biased splitting (biased meaning that the probabilities of choosing a group are not uniform over the groups) are the optimal choice. In this respect, a variant of the MTA scheme with clipped access (a modification of the windowed access) introduced in [12] is the best performing scheme in conventional setups (i.e., without MPR and SIC), achieving the MST of 0.4878 packet/slot.

Supplementing tree-algorithms with \( K \)-MPR capability has the potential to improve their
Fig. 1: Illustrative examples of binary tree-algorithms. A node of the tree represents a slot, the number inside the node represents the number of users (i.e., packets) colliding in the slot, and the number beneath represents the sequence number of the slot. a) BTA (the original version of the algorithm): It is assumed that initially 5 users collided, which progressively split in two groups until they become resolved (i.e., their packets decoded). b) BTA with 2 MPR: The receiver is able to decode collisions of 2 or less packets, which reduces the number of slots required to resolve all users. c) Binary tree-algorithm with SIC: The dashed nodes represent slots that are skipped, as the users belonging to the corresponding groups are resolved by cancelling the interference of the users resolved in the sibling node from the parent node, as indicated by the grey arrows.

Performance, as demonstrated in Fig. 1b). However, to the best of our knowledge, works studying the impact of $K$-MPR capability on tree-algorithms are scarce. We mention the work deriving an upper and lower bound on the MST (therein referred to as the capacity) for $K$-MPR tree algorithm [16]. The work in [17] proposes a $K$-MPR tree algorithms with an adaptive form of windowed access, where a part of the subsequent arrival window is added to the one being currently resolved, depending on the outcomes of the collision resolution. The work in [18] analyzes MPR in a tree-algorithm with continuous arrivals with a small number of users in the system (of the order of 10), proposing a transmission strategy that guarantees stability. Finally, the paper [13] performs the analysis of BTA with $K$-MPR in the standard windowed access
setup; it is interesting to note that, as $K$ grows, the MST of the scheme becomes increasingly close to the lower bound on capacity derived in [16].

A modification of the original scheme that employs SIC, denoted as SICTA, was introduced in [11]. In SICTA, the receiver stores collision slots; once a packet becomes decoded in a slot occurring after a split has been performed, the receiver removes its replica from the previous collision slot(s) using SIC, potentially instigating decoding of new packets and replica removal along the tree. Fig. 1c) shows an example of SICTA; obviously, the use of SIC enables skipping of the slots laying on the lower branches of the tree. The MST of binary SICTA is 0.693, which is a huge improvement over modified tree-algorithm (MTA). However, as already noted, the results presented in [11] for $d > 2$ do not hold, as demonstrated later.

We also mention the work presented in [19], proposing a hybrid multiple-access scheme in which the user signatures are resolved via a $K$-MPR tree-algorithm (both with and without SIC) and the user data via a polling mechanism. The analysis of the tree-algorithm-based part of the scheme is basic, only providing bounds on the expected length of CRI given the number of colliding users, and the main performance parameter is the net-rate taking into account the user data, which represents a dominant part of users’ transmissions.

Finally, for the sake of completeness, we mention the variant of tree-algorithms with the free access [14], in which the users are free to access the channel as soon as they experience a packet arrival. The MST performance of the ternary MTA with the free access falls between the one of the gated and one of the windowed access [14]. Further, the performance of tree-algorithms with the free access and with SIC or with MPR was investigated in [20]. However, we note that the approach to their analysis differs from the one presented in the paper, and this class of tree-algorithms is out of the paper scope.

B. Multi-Packet Reception

Research and design of multiple-access schemes that enable multi-packet reception has a long history; the canonical examples being CDMA, or Zadoff-Chu-preamble-based random-access used in 3GPP standards from LTE onwards [21]. There are also coding techniques specifically designed for this purpose – we mention the $K$-out-of-$n$ coding for multiple-access channels, see [22, Chapters 2 and 3], [23].

Some general models of MPR capability from the perspective of random-access protocol can be found in, e.g., [24], [25]. In this paper, we adopt the following model:
(i) if there are up to and including $K$ packets colliding in a slot, all packets are successfully decoded, and
(ii) if the number of colliding packets in a slot is greater than $K$, no packet can be successfully decoded.

This model can be understood as an extension of the collision channel model (the default channel model for the assessment of random-access algorithms). Specifically, it can be referred to as the $K$-collision channel.

The works studying random-access protocols with MPR typically abstain from modelling the investments required at the physical layer in order to enable the MPR. In this paper, we assume that the $K$-MPR capability requires $K$ times more (time-frequency) resources in comparison to single-packet reception case (i.e., the required number of resources is directly proportional to $K$). In effect, slots in $K$-collision channel are $K$ times larger compared to the standard (1-)collision channel, which is taken into account when assessing the performance, see Section III. This model is adequate for CDMA [26] or some $K$-out-of-$n$ coding schemes [19], [23], [27].

Finally, we remark that the assumed model is in a certain sense conservative. For instance, in non-orthogonal multiple-access schemes which rely on power-imbalances among users’ transmissions, capture and successive interference cancellation, e.g., [28], [29], the increase in time-frequency resources may not be needed. In this respect, the results presented in this paper can be considered as a lower-bound on performance for the cases when $K > 1$.

III. System Model

Consider $n$ active users and a common access point (AP). The users are contending to access the AP over a multiple-access $K$-collision channel with feedback by transmitting fixed-length packets. The time-frequency resources of the channel are divided into slots dimensioned to accommodate a single packet transmission. The users are synchronized on a slot basis via means of the feedback sent by the AP. The feedback channel is broadcast and assumed perfect. The feedback drives the contention process, as elaborated below.

The contention starts with all $n$ users transmitting in the first slot that appears on the channel and lasts until all users’ packets are successfully received. Henceforth, we also denote the event of successful reception of a user packet as the user resolution.
We now elaborate in details the CRP according to which the collisions are resolved. Our focus is on the binary tree-algorithms.\(^3\) Denote the slot number by \(j\), with the initial value \(j = 1\). The number of users transmitting in slot \(j\) is denoted by \(n_j\). After every slot \(j\), the AP transmits the feedback signal \(f_j\), where

\[
f_j = \begin{cases} 
0, & \text{if } n_j = 0 \\
 s, & \text{if } 0 < n_j \leq K \\
c, & \text{if } n_j > K \ . 
\end{cases} 
\]

(1)

In particular, \(f_j = 0\) denotes that \(j\) was an idle slot and \(f_j = c\) that \(j\) was a collision slot. When \(0 < n_j \leq K\), the packets transmitted in the slot were successfully decoded (i.e., the slot was successful), triggering SIC upward along the tree. In this case, the feedback signal is \(f_j = s = j - p + 1\), where \(p\) denotes the last slot along the tree in which all users have become resolved through the application of SIC, starting from the successful reception in slot \(j\).

Every user \(i\) maintains a counter, whose state in slot \(j\) is denoted by \(C_{i,j}\), with the initial value \(C_{i,1} = 0\), \(\forall i\). The state of the counter in slot \(j\) determines if the user will transmit in slot \(j\) or not. Specifically, if \(C_{i,j} = 0\), then user \(i\) transmits in slot \(j\). If \(C_{i,j} > 0\), user \(i\) abstains from transmitting in slot \(j\). Finally, if \(C_{i,j}\) becomes negative, i.e., \(C_{i,j} < 0\), this indicates that user \(i\) has become resolved and the user does not contend further. The state of the counter of user \(i\) is updated reception of the feedback, as follows

\[
C_{i,j+1} = \begin{cases} 
b_{i,j}, & \text{if } f_j = c \text{ and } C_{i,j} = 0 \\
C_{i,j} + 1, & \text{if } f_j = c \text{ and } C_{i,j} > 0 \\
C_{i,j} - s, & \text{if } f_j = s \\
b_{i,j}, & \text{if } f_j = 0 \text{ and } C_{i,j} = 1 \\
C_{i,j} + 1, & \text{if } f_j = 0 \text{ and } C_{i,j} > 1 
\end{cases} 
\]

(2)

where \(b_{i,j}\) is a Bernoulli random variable that takes value 0 with probability \(p\) and value 1 with probability \(1 - p\); if \(p = 1/2\), the splitting is fair. The topmost case in (2) corresponds to a split that occurs after the contention in slot \(j\), in which user \(i\) took part, resulted in a collision. If \(b_{i,j} = 0\) user \(i\) joins the generic group 0, and if \(b_{i,j} = 1\) the user joins group 1. The second case in (2) corresponds to a scenario in which user \(i\) did not transmit in slot \(j\), the slot resulted

\(^3\) Some insights on \(d\)-ary tree-algorithms with SIC, for \(d > 2\) are provided in Section VI.
in the collision, and the user increases its counter to reflect the fact that the ongoing collision resolution will last an additional slot. In the third case, the slot was successful, the SIC process was triggered, and the counter is decreased for the number of slots in which the users were resolved in this round. The fourth and the fifth (i.e. the last case) in (2) refers to the scenario in which an idle slot occurred, and the users in the parent slot perform an immediate split, while the other unresolved users increment their counters.

To facilitate a better understanding, the example in Fig. 2 illustrates the contention on 2-collision channel with SIC, and Table I lists the corresponding states of the users’ counters. It is assumed in the example that: (i) after slot 1, user 1, user 3 and user 4 chose group 0, while user 2 and user 5 chose group 1; (ii) after slot 2, no user chose group 0, and user 1, user 3 and user 4 chose group 1; and (iii) after slot 3, user 1 and user 4 chose group 0, while user 3 chose group 1.

The period elapsed from the first slot up to and including the last slot in which all $n$ users become resolved is denoted as CRI. The length of CRI in slots conditioned on $n$ is a random variable denoted by $l_n$. The basic performance parameter of interest is the expected value of $l_n$, denoted by $L_n$, i.e., $L_n = E[l_n]$. Another important performance parameter is the conditional

---

4We note that a similar protocol for updating the state of the users’ counters was presented in [11]. Among others, a major difference is that the feedback in the case of successful slot in [11] provides a sum of the number of resolved users and idle slots.
TABLE I: States of the counters of the users contending in the example in Fig. 2, listed in the respective columns.

The throughput

\[ T_n = \frac{1}{K} \frac{n}{L_n}. \]  \hspace{1cm} (3)

The throughput in (3) is the measure of the efficiency of resource use, where the normalization with \( K \) reflects the linear increase in resources required to achieve \( K \)-MPR.

Recall that the introduced CRP is just a building block of a complete random access protocol. Another block is a CAP which regulates how the activated users access the channel, this way determining the number of users \( n \) that enter the CRP. The considered CRP can be combined either with the gated CAP or windowed CAP, the details of which will be presented in Section V.

IV. ANALYSIS

In this section, we analyze the performance of the introduced CRP, i.e., the conditional CRI length and the conditional throughput.

The conditional length of a CRI, given \( n \) active users at its start, is

\[ l_n = \begin{cases} 1, & n = 0, 1, \ldots, K \\ l_i + l_{n-i}, & n > K. \end{cases} \]  \hspace{1cm} (4)

The expected conditional length of CRI \( L_n = E\{l_n\} \), for \( n > K \) is simply

\[ L_n = \sum_{i=0}^{n} \binom{n}{i} p^i (1-p)^{n-i} (L_i + L_{n-i}) \]  \hspace{1cm} (5)
where \( p \) is the probability of a user joining the first group. By developing (5), \( L_n \) can be calculated recursively through

\[
L_n = \begin{cases} 
1, & n \leq K \\
\frac{p^n + (1-p)^n - 2 \sum_{i=1}^{n-1} \binom{n}{i} p^{n-i} (1-p)^i L_i}{1-p^n - (1-p)^n}, & n > K.
\end{cases}
\]  

(6)

A. Direct Expression for \( L_n \)

For the derivation of the direct, i.e. non-recursive expression for \( L_n \), we rely on the method that relies on generating functions, elaborated in [14]. We start by introducing the conditional probability generating function (CPGF) of \( l_n \) is given by

\[ Q_n(z) = E \{ z^n \} \]  

(7)

where, due to (4), the following holds

\[ Q_0(z) = Q_1(z) = \cdots = Q_K(z) = z. \]  

(8)

For \( n > K \), we have

\[
Q_n(z) = \sum_{i=0}^{n} \binom{n}{i} p^i (1-p)^{n-i} Q_i(z) Q_{n-i}(z). \]

(9)

The (unconditional) probability generating function (PGF) of CRI, assuming that \( n \) obeys a Poisson distribution\(^5\) with a mean \( x \), is given by

\[
Q(x, z) = \sum_{n=0}^{\infty} Q_n(z) \frac{x^n}{n!} e^{-x}
\]

\[
= \sum_{n=0}^{\infty} \frac{x^n}{n!} e^{-x} \sum_{i=0}^{n} \binom{n}{i} p^i (1-p)^{n-i} Q_i(z) Q_{n-i}(z) +
\]

\[
+ (z - z^2) \sum_{k=0}^{K} \frac{x^k}{k!} e^{-x}
\]

(10)

where we exploited (8), (9), and the fact that for \( n \leq K \)

\[
\sum_{i=0}^{n} \binom{n}{i} p^{n-i} (1-p)^i Q_{n-i}(z) Q_i(z) = z^2.
\]

(12)

The first term on right-hand side (rhs) in (11) can be transformed into

\[
\sum_{n=0}^{\infty} Q_n(z) \frac{(px)^n}{n!} e^{-px} \sum_{i=0}^{\infty} \frac{Q_i(z)}{i!} e^{-(1-p)x}
\]

\[
= (1-p + p e^{x})^{-1} \sum_{n=0}^{\infty} Q_n(z) (px)^n \sum_{i=0}^{\infty} \frac{Q_i(z)}{i!} e^{-(1-p)x}
\]

(13)

\(^5\)This is an auxiliary assumption that will not limit the general nature of the derived results.
so that (11) becomes

\[ Q(x, z) = Q(px, z)Q((1 - p)x, z) + (z - z^2) \sum_{k=0}^{K} \frac{x^k}{k!} e^{-x}. \]  

(14)

Further, using the fact that \( \frac{dQ_n(z)}{dz} \big|_{z=1} = L_n \), from (10) we get

\[ \frac{\partial Q(x, z)}{\partial z} \bigg|_{z=1} = L(x) = \sum_{n=0}^{\infty} \frac{L_n x^n}{n!} e^{-x}. \]  

(15)

\( L(x) \) is also known as transformed generating function (TGF) of \( L_n \). Taking the partial derivative of (14) with respect to \( z \) at \( z = 1 \) yields

\[ L(x) = L(px) + L((1 - p)x) - \sum_{k=0}^{K} \frac{x^k}{k!} e^{-x} \]  

(16)

where we used the fact that \( Q(x, 1) = 1, \forall x \).

In the next step, we assume the following power series representation of \( L(x) \)

\[ L(x) = \sum_{n=0}^{\infty} \alpha_n x^n \]  

(17)

where it can be shown that

\[ L_n = \sum_{j=0}^{n} \frac{n!}{(n-j)!} \alpha_j. \]  

(18)

We now compute \( \alpha_j \), \( j = 0, 1, \ldots, n \). From (6), it follows that

\[ \alpha_j = \begin{cases} 1, & j = 0 \\ 0, & j = 1, \ldots, K. \end{cases} \]  

(19)

Substituting (17) into (16) and using Maclaurin series expansion for \( e^{-x} \) yields

\[ \sum_{n=0}^{\infty} \alpha_n (1 - p^n - (1 - p)^n) x^n = - \sum_{k=0}^{K} \frac{x^k}{k!} \sum_{n=0}^{\infty} (-1)^n \frac{x^n}{n!} \]

\[ = \sum_{n=0}^{\infty} \sum_{k=0}^{\min(n,K)} \frac{(-1)^{n-k+1}}{k!(n-k)!} x^n. \]  

(20)

For \( n \leq K \), it can be shown that

\[ \sum_{k=0}^{n} \frac{(-1)^{n-k+1}}{k!(n-k)!} = \begin{cases} -1, & n = 0 \\ 0, & 0 < n \leq K \end{cases} \]  

(21)
which, coupled with (19), transforms (20) into

\[
\sum_{n=K+1}^{\infty} \alpha_n (1 - p^n - (1 - p)^n) x^n =
\]

\[
= \sum_{n=K+1}^{\infty} \sum_{k=0}^{K} \frac{(-1)^{n-k+1}}{k!(n-k)!} x^n. \tag{22}
\]

Solving (22) for \(\alpha_n\), \(n \geq K\), we get

\[
\alpha_n = \sum_{k=0}^{K} \frac{(-1)^{n-k+1}}{k!(n-k)!} \cdot \frac{1}{1 - p^n - (1 - p)^n}. \tag{23}
\]

By substituting (19) and (23) in (18) for \(n > K\), and after some manipulation, we get

\[
L_n = 1 + \sum_{j=K+1}^{n} \binom{n}{j} \frac{(-1)^{j+1}}{1 - p^{j} - (1 - p)^{j}} \sum_{k=0}^{K} \binom{j}{k} (-1)^{-k}. \tag{24}
\]

Using the identity that holds for \(K < j\)

\[
\sum_{k=0}^{K} (-1)^{k} \binom{j}{k} = (-1)^{K} \binom{j-1}{K} \tag{25}
\]
Fig. 4: $T_n$ as function of $n$ for $K \in \{1, 2, 4, 8, 16, 32\}$.

(24) simplifies to

$$L_n = 1 + \sum_{j=K+1}^{n} \binom{n}{j} \left( \frac{j - 1}{j} \right) \frac{(-1)^{j-K+1}}{1 - p^j - (1 - p)^j}. \quad (26)$$

$$= 1 + \binom{n}{K} \sum_{j=K+1}^{n} \binom{n-K}{j-K} \frac{(j-K)(-1)^{j-K+1}}{j(1 - p^j - (1 - p)^j)}. \quad (27)$$

Finally, we get

$$L_n = 1 - \binom{n}{K} \sum_{j=1}^{n-K} \frac{j(-1)^{j}(n-K)}{(j+K)(1-p^{j+K} - (1 - p)^{j+K})}. \quad (28)$$

It is easy to show that (28) is minimized for $p = \frac{1}{2}$. In other words, fair splitting achieves minimal $L_n$, which is given by

$$L_n = 1 - \binom{n}{K} \sum_{j=1}^{n-K} \frac{j(-1)^{j}(n-K)}{(j+K)(1 - 2^{-j-K+1})}. \quad (29)$$

In the rest of the paper, we assume fair splitting.

Fig. 3 shows $K \cdot L_n$, i.e., the expected conditional length of CRI weighted by $K$, to make the comparison fair among the curves obtained for different $K$ (recall that the slot size increases linearly with $K$). Obviously, the curves for different $K$ tend to each other as $n$ increases, showing an essentially linear dependence on $n$. Also, a careful inspection reveals that the curves
show an oscillatory behaviour, with the oscillations periodicity depending on \( \log(n) \) and the oscillations amplitude increasing with \( K \). This oscillatory behaviour is more evident in Fig. 4, which shows the conditional throughput \( T_n \) as function of \( n \). The oscillations are non-vanishing, a fact identified in [14] for the binary tree-algorithms on the standard collision channel. We analytically investigate this phenomenon in the next subsection.

More importantly, both Fig. 3 and Fig. 4 suggest that the use of MPR does not improve the performance of the tree-algorithm conditioned on \( n \), when normalized with \( K \). In particular, Fig. 4 shows that, as \( n \to \infty \), \( T_n \) oscillates around the value of \( \ln(2) \approx 0.6931 \), irrespective of the value of \( K \). In Section V, we make further investigations of this issue.

**B. Asymptotic behaviour of \( L_n \)**

Here we turn to analysis of asymptotic behavior of \( L_n \), exploiting the approach presented in [14]. Rewriting (16) for the case of fair-splitting (i.e., \( p = 1/2 \)), we get

\[
L(x) - 2L\left(\frac{x}{2}\right) = -\sum_{k=0}^{K} \frac{x^k}{k!} e^{-x}.
\]

By differentiating (30) twice, we get

\[
L''(x) - \frac{x}{2} L''\left(\frac{x}{2}\right) = \left[ \frac{x^{K-1}}{(K-1)!} - \frac{x^K}{K!} \right] e^{-x} = g(x)
\]

which is a functional equation that satisfies the contraction condition and has the solution in the form [14]

\[
L''(x) = \sum_{m=0}^{\infty} \frac{1}{2^m} g\left(\frac{x}{2^m}\right) = \sum_{m=0}^{\infty} \frac{1}{2^m} \left[ \frac{x^{K-1}}{(K-1)!} - \frac{x^K}{K!} \right] e^{-\frac{x}{2^m}}.
\]

Integrating (32) twice, and taking into account the initial conditions \( L(0) = 1 \) and \( L'(0) = 0 \) that stem from (15), we obtain the following expression for the TGF

\[
L(x) = 1 + \sum_{m=0}^{\infty} 2^m - \sum_{m=0}^{\infty} 2^m e^{-\frac{x}{2^m}} \sum_{k=0}^{K} \frac{\left(\frac{x}{2^m}\right)^k}{k!}
\]

Exploiting (15) further, the previous equation can be transformed to

\[
\sum_{n=0}^{\infty} L_n \frac{x^n}{n!} = e^x + e^x \sum_{m=0}^{\infty} 2^m \left[ 1 - e^{-\frac{x}{2^m}} \sum_{k=0}^{K} \frac{\left(\frac{x}{2^m}\right)^k}{k!} \right].
\]
Using the Maclaurin series expansion for $e^x$, and after some manipulation, we transform (35) into
\[
\sum_{n=0}^{\infty} \frac{x^n}{n!} = \sum_{n=0}^{\infty} \frac{x^n}{n!} \times \left\{ 1 + \sum_{m=0}^{\infty} 2^m \left[ 1 - \sum_{k=0}^{\min\{n,K\}} \binom{n}{k} \frac{(1 - \frac{1}{2^m})^{n-k}}{2^{mk}} \right] \right\}. \tag{36}
\]

Equating coefficients for $x^n$, $n > K$, we get
\[
L_n = 1 + \sum_{m=0}^{\infty} 2^m \left[ 1 - \sum_{k=0}^{K} \binom{n}{k} \frac{(1 - \frac{1}{2^m})^{n-k}}{2^{mk}} \right]. \tag{37}
\]

In principle, from (37) one can derive the same expression for $L_n$ given by (29). However, we do not pursue this further. Instead, assuming that $K$ is fixed, we exploit the following approximations for $n \gg K$
\[
\left(1 - \frac{1}{2^m}\right)^{n-k} = e^{-\frac{\Theta(n-1)}{2 \frac{n}{2^m}}} \approx e^{-\frac{n}{2^m}} \tag{38}
\]
\[
\binom{n}{k} = \frac{n^k}{k!} \left(1 - \frac{k(k-1)}{2} \Theta(n-1) \right) \approx \frac{n^k}{k!} \tag{39}
\]
which, substituted into (37), yield
\[
L_n \approx 1 + \sum_{m=0}^{\infty} 2^m \left[ 1 - \sum_{k=0}^{K} \binom{n}{k} \frac{e^{-\frac{n}{2^m}}}{k!} \right]. \tag{40}
\]

Now, the task at hand is to isolate $n$ in (40), such that summation over $m$ can be performed. For this purpose, we exploit the method for the asymptotic analysis of harmonic sums [14], [30]. We introduce the following function
\[
g(x) = 1 - \sum_{k=0}^{K} \frac{x^k}{k!} e^{-x}. \tag{41}
\]

The Mellin transform of $g(x)$ is
\[
G(s) = \int_0^{\infty} g(x)x^{s-1} \, dx = -\Gamma(s) \left[ 1 + \sum_{k=1}^{K} \frac{\prod_{i=0}^{k-1} (s + i)}{k!} \right]
- (s + 1) \Gamma(s) \left[ 1 + \frac{s}{2!} + s \sum_{k=3}^{K} \frac{\prod_{i=2}^{k-1} (s + i)}{k!} \right]. \tag{42}
\]
where \( s \) is a complex variable laying in the fundamental strip (i.e., strip of convergence) given by \(-2 < \Re(s) < 0\) and \( \Gamma(s) \) is the meromorphic extension of the Gamma function. The inverse Mellin transform for \( x = n/2^m \) is given by

\[
g \left( \frac{n}{2^m} \right) = \frac{1}{2\pi j} \int_{\eta-j\infty}^{\eta+j\infty} G(s) \left( \frac{n}{2^m} \right)^{-s} ds =
\]

\[
- \frac{1}{2\pi j} \int_{\eta-j\infty}^{\eta+j\infty} \Gamma(s) \left[ 1 + \sum_{k=1}^{K} \prod_{i=0}^{k-1} \frac{s+i}{k!} \right] \frac{n^{-s}}{2^{-ms}} ds
\]

where \( \eta \) belongs to the fundamental strip. Substituting (43) into (40), and interchanging the order of summation and integration, we obtain

\[
L_n \approx 1 + \frac{1}{2\pi j} \int_{\eta-j\infty}^{\eta+j\infty} G(s)n^{-s} \sum_{m=0}^{\infty} 2^{(s+1)m}
\]

\[
= 1 + \frac{1}{2\pi j} \int_{\eta-j\infty}^{\eta+j\infty} G(s)n^{-s} \frac{1}{1-2^{s+1}} ds.
\]

The domain of absolute convergence of the series in (44) is \( \Re(s) < -1 \). Thus, the fundamental strip of the integrand

\[
H(s) = \frac{G(s)n^{-s}}{1-2^{s+1}}
\]

lies in the intersection of the domain of absolute convergence of the series and the fundamental strip of \( G(s) \), and is given by \(-2 < \Re(s) < -1\). In this strip lies \( \eta \) in (45).

We compute the integral in (45) using the residue theorem. In order to evaluate \( L_n \) for \( n \to \infty \), we close the path of integration in the half of the complex plane that is right to the fundamental strip, see Fig. 5. The gamma function decays exponentially fast as the absolute value of the imaginary component of the argument increases, thus, the integration on the horizontal parts of the contour tends to zero as \( |D| \to \infty \). The integral on the vertical line \( \Re(s) = \gamma, \gamma > 0 \), is bounded by \( O(n^{-\gamma}) \), also tending to zero for large \( n \) [31, Chapter 5.2.2], [30]. Thus, the integral in (45) is equal to the negative sum of the residues of the poles of \( H(s) \) within the contour (negative due to the contour orientation).

The factor \( n^{-s} \) trivially has no poles in the contour. Further, \( g(s) \) has a simple pole in 0 which is due to the corresponding pole of \( \Gamma(s) \). We have

\[
\text{Res}_{s=0} H(s) = -\Gamma(0) = -1.
\]

\[\text{For the sake of completeness, we note that the pole of } \Gamma(s) \text{ at } -1 \text{ is cancelled out by the zero } (s+1) \text{ of the function } G(s), \text{ see (42)}.\]
The factor $1/(1 - 2^{s+1})$ has simple poles at $s_p \in \mathcal{P} = \{-1 + 2\pi jm / \ln 2, m \in \mathbb{Z}\}$, and it can be shown that the value of the corresponding residues is $-1/\ln 2$. We first compute the value of the residue at $s_p = -1$

$$\text{Res}_{s=-1} H(s) = -\frac{G(-1)n}{\ln 2} = \frac{n}{K \ln 2}$$

(48)

where we used the fact that

$$G(-1) = -\left[1 - \sum_{k=2}^{K} \frac{(k-2)!}{k!}\right] = -\frac{1}{K}.$$  

(49)

Further, for $s_p \in \{-1 + 2\pi jm, m \in \mathbb{N}\}$, we have

$$\text{Res}_{s=s_p} H(s) =$$

$$-\frac{1}{\ln 2} \Gamma \left(-1 + \frac{2\pi jm}{\ln 2}\right) n e^{2\pi jm \log_2 n} A(K, m)$$

(50)

where

$$A(K, m) = 1 + \sum_{k=1}^{K} \prod_{i=0}^{k-1} \left(i - 1 + \frac{2\pi jm}{\ln 2}\right).$$  

(51)
Similarly, for \( s_p \in \{-1 - 2\pi jm, m \in \mathbb{N} \} \) we have

\[
\text{Res}_{s=s_p} H(s) = \frac{1}{\ln 2} \Gamma \left( -1 - \frac{2\pi jm}{\ln 2} \right) n e^{-2\pi jm \log_2 n} A(K,-m).
\]

Using the mirror-symmetry property that holds for the gamma function

\[
\Gamma(s^*) = \Gamma^*(s)
\]

where \(^*\) denotes the complex conjugate, and using the following identity (which can be trivially shown)

\[
A(K,-m) = A^*(K,m)
\]

we get

\[
\sum_{s_p \in \mathbb{P} \setminus \{0\}} \text{Res}_{s=s_p} H(s) = -\frac{2n}{\ln 2} \sum_{m=1}^{\infty} \Re \left( B(K,m) e^{2\pi jm \log_2 n} \right)
\]

\[
= -\frac{2n}{\ln 2} \sum_{m=1}^{\infty} |B(K,m)| \cos \left( 2\pi m \log_2 n + \arg(B(K,m)) \right)
\]

where

\[
B(K,m) = \Gamma \left( -1 + \frac{2\pi jm}{\ln 2} \right) A(K,m).
\]

Again, since the gamma function decays exponentially fast as the imaginary component of the argument increases, (56) can be approximated as

\[
\sum_{s_p \in \mathbb{P} \setminus \{0\}} \text{Res}_{s=s_p} H(s) \approx
\]

\[
-\frac{2n}{\ln 2} |B(K,1)| \cos \left( 2\pi \log_2 n + \arg(B(K,1)) \right).
\]

Putting all the pieces together, we obtain for the expected conditional length of CRI, when \( n \to \infty \), to be

\[
L_n \approx \frac{n}{K \ln 2} \times \frac{\ln 2}{1 - 2K|B(K,1)| \cos \left( 2\pi \log_2 n + \arg(B(K,1)) \right)}.
\]

The conditional throughput, when \( n \to \infty \), is

\[
T_n = \frac{n}{KL_n} \approx \frac{\ln 2}{1 - 2K|B(K,1)| \cos \left( 2\pi \log_2 n + \arg(B(K,1)) \right)}.
\]
This oscillatory component in $\log_2 n$ was identified in, e.g., [14], [30], [32]. In the case treated here, the difference is that its amplitude depends on $K$ and can not be neglected, as it affects the stability bound (further discussed in Section V).

The expression $2K|B(K,1)|$ can be easily computed for any $K$. The graph presented in Fig. 6 shows that its value increases with $K$, which is also confirmed in Fig. 3 and Fig. 4. Although of a little practical relevance, an interesting problem in its own right is to determine the behaviour of $K|B(K,1)|$ as $K \to \infty$. This problem is out of the paper scope; based on our preliminary investigation, we conjecture that there is an upper bound on the value of $K|B(K,1)|$ as $K \to \infty$.

Finally, we validate the presented analysis by comparing its output with the results presented in Fig. 4. For instance, $2K|B(K,1)|$ evaluates to 0.0607 for $K = 32$, implying that the asymptotic maximum and minimum values of $T_n$ are 0.7378 and 0.6536, respectively, see (60). Obviously, the curve for $T_n$ when $K = 32$ in Fig. 4 indeed tends to oscillate between these two values as $n$ increases.

### C. Simple bounds on $L_n$ and $T_n$

We conclude this section by developing simple, but useful bounds on $L_n$ and $T_n$, that do not require asymptotic evaluation presented. In particular, these bounds can be computed for any

finite $m$ and are valid for any $n \geq m$.

For $n > K$ and fair splitting, the expected conditional length of CRI reduces to

$$L_n = \frac{\sum_{i=0}^{n-1} \binom{n}{i} L_i}{2^{n-1} - 1}.$$  \hspace{1cm} (61)

Following the method introduced by Massey [15], we want to find the constant $\alpha_m$ for which the following holds:

$$L_n \leq \alpha_m n, \ n \geq m.$$  \hspace{1cm} (62)

For $n < m$, we can write

$$L_n \leq \alpha_m n + \sum_{i=1}^{M-1} \delta_{i,n} (L_n - \alpha_m n)$$  \hspace{1cm} (63)

where $\delta_{i,n}$ is the Kronecker delta, and where (63) holds by definition. In the induction step, we substitute (63) into (61), and after some manipulation, obtain

$$L_n \leq \alpha_m n + \frac{\sum_{i=0}^{m-1} \binom{n}{i} (L_i - \alpha_m i)}{2^{n-1} - 1}$$  \hspace{1cm} (64)

and the condition (62) will hold true for any

$$\alpha_m \geq \frac{\sum_{i=0}^{m-1} \binom{n}{i} L_i}{\sum_{i=0}^{m-1} \binom{n}{i} i}.$$  \hspace{1cm} (65)

as the summation in the second term on the right-hand side of (64) is non-positive in this case. The tightest upper bound is given by

$$\alpha_m = \sup_{n \geq m} \frac{\sum_{i=0}^{m-1} \binom{n}{i} L_i}{\sum_{i=0}^{m-1} \binom{n}{i} i}.$$  \hspace{1cm} (66)
In a completely analogous fashion, one can find the lower bound

\[ L_n \geq \beta_m n, \quad n \geq m \]  

(67)

where

\[ \beta_m = \inf_{n \geq m} \frac{\sum_{i=0}^{m-1} \binom{n}{i} L_i}{\sum_{i=0}^{m-1} \binom{n}{i}}. \]  

(68)

Note that the bounds in (66) and (68) can be made arbitrarily tight by increasing \( m \) and \( n \).

The corresponding bounds on conditional throughput are simply

\[ B_m = \frac{1}{K\beta_m} \geq T_n \geq \frac{1}{K\alpha_m} = A_m, \quad n \geq m. \]  

(69)

In Table II, we list \( \alpha_m, \beta_m, A_m \) and \( B_m \) (rounded up to four decimal places). Note the agreement between the bounds on \( T_n \) shown in the table, i.e., \( A_m \) and \( B_m \), and the results plotted in Fig. 4.

V. PERFORMANCE UNDER POISSON ARRIVALS

In this section, we provide insights into performance of a random access protocol that combines the CRP protocol introduced in Section III with the gated CAP and the windowed CAP. We adopt the standard performance evaluation approach by assuming Poisson arrivals in an infinite user population; the arrival intensity per slot is denoted by \( \lambda \). We are interested to identify the bounds on \( \lambda \) for which the random access protocol features a stable operation. In brief, the stability implies that the individual packets are successfully received with a finite delay almost surely [14].
A. Gated Access

The gated (also denoted as blocked) CAP is an obvious approach to deal with traffic arrivals. In particular, all users that arrive during a CRI have to wait until that CRI ends, i.e., they are blocked. Once the current CRI ends, all blocked users transmit in the next available slot, thus initiating the next CRI. Fig. 7 illustrates the principles of the gated access.

The stability conditions of the gated access were investigated in a number of works, e.g., in [14], [15]. The sufficient condition for stability is

\[ \lambda < \lambda_S \]  \hspace{1cm} (70)

and the sufficient condition for instability is

\[ \lambda > \lambda_U \]  \hspace{1cm} (71)

where the values of the bounds \( \lambda_S \) and \( \lambda_U \). Exploiting (59), we get

\[ \limsup_{n \to \infty} \frac{L_n}{n} = \frac{1 + 2K|B(K,1)|}{K \ln(2)} = L_S \]  \hspace{1cm} (72)

\[ \liminf_{n \to \infty} \frac{L_n}{n} = \frac{1 - 2K|B(K,1)|}{K \ln(2)} = L_U \]  \hspace{1cm} (73)

from which it follows that [14]

\[ \lambda_S = L_S^{-1} = \frac{K \ln(2)}{1 + 2K|B(K,1)|} \]  \hspace{1cm} (74)

\[ \lambda_U = L_U^{-1} = \frac{K \ln(2)}{1 - 2K|B(K,1)|} \]  \hspace{1cm} (75)

Table III lists values of \( \lambda_S/K \) and \( \lambda_U/K \) for several values of \( K \); again, the normalization with \( K \) makes the comparison fair.\(^7\) Obviously, as \( K \) increases, difference among \( \lambda_S/K \) and \( \lambda_U/K \) grows. This could be expected, since the amplitude of the oscillations in (59) grows with \( K \).

B. Windowed Access

Another way to deal with the traffic arrivals is to use windowed CAP (also denoted as the epoch mechanism). In this approach, the time axis related to the traffic arrivals is divided into equal-length windows and every window as associated to a separate CRI. Specifically, the users

\(^7\) Note that \( \lambda_S/K = \liminf_{n \to \infty} T_n \) and \( \lambda_U/K = \limsup_{n \to \infty} T_n \), where \( T_n \) is given by (60).

arriving in $i$-the window transmit in the first slot after the CRI of the users arriving in $(i-1)$-th window ends, thus starting their own CRI. Fig. 8 illustrates the windowed access.

Denoting the window length in slots by $\Delta$ (which does not have to be an integer), the probability of $n$ arrivals ($n \in \mathbb{N}$) in the window can be calculated as

$$
\Pr\{N = n\} = \frac{\lambda \Delta}{n!} e^{-\lambda \Delta},
$$

(76)
i.e., $n$ is a Poisson random variable (r.v.) with mean $\lambda \Delta$. The expected length of CRI is

$$
L(\lambda \Delta) = \mathbb{E}\{L_n|\lambda \Delta\} = \sum_{n=0}^{\infty} L_n \frac{(\lambda \Delta)^n}{n!} e^{-\lambda \Delta}.
$$

(77)
The necessary condition for stability is the following

$$
L(\lambda \Delta) < \Delta
$$

(78)
which is intuitively clear, as it ensures that arrivals in a window will be served (on average) in CRI that will last shorter than the window.\(^8\)

Exploiting the bounds derived in Section IV-C, it is easy to show that

$$
f(\alpha_m, m, \lambda \Delta) \leq L(\lambda \Delta) \leq f(\beta_m, m, \lambda \Delta)
$$

(79)
where

$$
f(x, k, z) = x \cdot z + \sum_{i=0}^{k} (L_i - x) \frac{z^i}{i!} e^{-z}.
$$

(80)

\(^8\)For stability to hold, the condition $\mathbb{E}\{L_n^2\} < \infty$ has also to be satisfied. This can be shown for $L(\lambda \Delta) < \Delta$, however, we omit the proof.
Fig. 8: Illustration of the windowed access: users arriving during \(i\)-th window are grouped and resolved in a separate, corresponding CRI.

The scheme will be stable if

\[
f(\beta_m, m, \lambda \Delta) < \Delta
\]  

which yields the bound on the arrival intensity

\[
\lambda < \sup_{\lambda \Delta > 0} \frac{\lambda \Delta}{f(\beta_m, m, \lambda \Delta)} = \lambda_S. \tag{82}
\]

Similarly, the windowed access scheme will be unstable when

\[
\lambda > \sup_{\lambda \Delta > 0} \frac{\lambda \Delta}{f(\alpha_m, m, \lambda \Delta)} = \lambda_U. \tag{83}
\]

Table IV lists values of \(\lambda_S/K\) and \(\lambda_U/K\), calculated using the values of \(\alpha_m\) and \(\beta_m\) given in Table II. Evidently, a tangible increase in the maximum normalized arrival intensity \(\lambda_S/K\) for which the windowed scheme features a stable operation requires a substantial increase in \(K\). The table also shows the maximum normalized arrival intensity \(\lambda^*_S/K\) for which the \(K\)-MPR BTA
Fig. 9: Sensitivity of the stability bound on the arrival intensity within a window as function of the average number of arrivals in the window $\lambda \Delta$.

with windowed access [13] and without SIC has a stable operation. The comparison between $\lambda_S/K$ and $\lambda_S^*/K$ reveals that, as $K$ increases, most of the gain comes from the MPR, while the contribution of SIC becomes limited.

In Fig. 9, we plot $F(\lambda \Delta) = \frac{\lambda \Delta}{Kf(\beta_m, m, \lambda \Delta)}$, see (82), as function of $\lambda \Delta$, i.e., the sensitivity of the stability bound on the normalized arrival intensity per slot as function of the arrival intensity within a window. The figure shows the characteristic oscillatory behaviour, which becomes more pronounced as $K$ increases. Nevertheless, the oscillations’ periodicity is rather large, implying that there is a certain tolerance on the potential estimation errors of $\lambda$ and/or dimensioning errors of window length $\Delta$. We also plot the sensitivity of the stability bound for the analogous protocol without SIC, investigated in [13]. Obviously, as $K$ increases, the bound has a clearly pronounced maximum, and after which the performance quickly deteriorates. It can be concluded that in this respect, the protocol with SIC is an advantageous solution.
VI. REMARKS ON D-ARY TREE ALGORITHMS WITH SIC

As discussed in Section II-A, d-ary tree algorithms (i.e., tree-algorithms in which the number of groups in which users can split is generalized to $d$)\textsuperscript{9}, show benefits in the original scenario (i.e., without SIC and MPR). In particular, it was shown that the ternary version of the algorithm (i.e., when $d = 3$) with optimized splitting probabilities outperforms the binary version. A natural question is whether analogous results can be established for the variant of tree algorithms examined in this paper.

In this respect, the analysis presented in [11, Section IV-A] is performed for $d$-ary tree algorithms with SIC when $K = 1$. However, the initial premise of the analysis is incorrect when $d > 2$. The premise states the following (verbatim):

$$l_n = \begin{cases} 
1, & \text{if } n = 0, 1 \\
\sum_{j=1}^{d} l_{I_j}, & \text{if } n \geq 2 
\end{cases} \tag{84}$$

where $I_j$ is the number of users selecting $j$-th group, $j \in \{1, 2, \ldots, d\}$. We illustrate its shortcomings through a simple example depicted in Fig. 10a), in which we assume $d = 3$, $n = 2$ (and $K = 1$). In slot 2, the receiver is able to decode the transmission occurring in it, and, after applying SIC, recover the remaining transmission in slot 1. As these two transmissions are the only ones, there is no need for further splitting, and the total duration of the CRI is 2 slots. However, according to (84), the CRI length in this example should be

$$l_2 = l_1 + l_1 + l_0 = 3. \tag{85}$$

In fact, if $n = 2$ and the first group has a single user, like in the Fig. 10a), the length of the CRI will be 2 slots, irrespective of the value of the splitting factor $d$ (given that $d \geq 2$). On the other hand, the example in Fig. 10b) shows the case when the CRI length is indeed 3 slots and agrees with the formula (84). In effect, the elegant conclusion drawn in [11] (verbatim)

$$(d - 1)(L'_n - 1) = d(L_n - 1) \tag{86}$$

where $L'_n$ is the expected conditional length of the CRI for the standard tree algorithm (STA), does not hold in general for $d > 2$, also invalidating the subsequent throughput analysis that exploited the results known for the STA.

\textsuperscript{9}From now on, we will refer to $d$ as the splitting factor
Fig. 10: Example of ternary splitting with SIC, $K = 1$.

Generalizing the insights shown in Fig. 10, for $K = 1$ we write

$$l_n = \begin{cases} 1, & n = 0, 1 \\ \sum_{j=1}^{d_{\text{min}}} l_j, & n \geq 2 \end{cases}$$

(87)

where $d_{\text{min}}$ is the minimum value of $o \in \{1, \ldots, d\}$ for which the following holds

$$\sum_{j=1}^{o} I_j \geq n - 1.$$  

(88)

The explanation of (87) is intuitively clear – the splitting process will stop as soon as there is a single user remaining from the original collision, no matter how many groups are left.

Generalizing (87) for the case with MPR, we obtain

$$l_n = \begin{cases} 1, & n = 0, 1, \ldots, K \\ \sum_{j=1}^{d_{\text{min}}} l_j, & n > K \end{cases}$$

(89)

where $d_{\text{min}}$ is the minimum value of $o \in \{1, \ldots, d\}$ for which it holds that

$$\sum_{j=1}^{o} I_j \geq n - K.$$  

(90)

Unfortunately, when $d > 2$, the expressions (87) and (89) can not be computed in the same manner as it can be done when $d = 2$. In particular, the summands in (87) and (89) are subject to the same recursion that holds for $L_n$, making the overall computation quickly intractable. Further investigations with respect to this problem are out of the scope of this paper. Instead, we present some illustrative results obtained through a simulation-based study.
Fig. 11: Throughput performance of $d$-ary tree-algorithms with SIC as function of $d$, $K = 1$: red dots represent MST results from [11], blue squares represent $T_n$ obtained via simulations for $n = 1000$.

Fig. 11 compares the results for MST with the gated access presented in [11] with the ones for $T_n$ when $n = 1000$, obtained by averaging over 10000 simulation runs, wherein both cases it is assumed that the splitting is fair and that $K = 1$. The latter can serve as a proxy for the MST for gated access for $K = 1$, by considering that

$$\lim_{n \to \infty} T_n = \frac{1}{\lim_{n \to \infty} L_n/n}$$

(91)

see Section V-A. Obviously, there is a huge difference among the two curves, which becomes more pronounced as $d$ increases. The overall conclusion is that $d = 2$ is the best choice, albeit with a much lower margin than the one in [11].

Finally, Fig. 12 shows the conditional throughput $T_n$ for the combination of the splitting factor $d = \{3, 8\}$ and $K \in \{1, 4, 16\}$; again, the results are obtained by averaging over 10000 simulation runs. The already identified oscillatory behavior around the mean value (which are roughly 0.663 and 0.48 for $d = 3$ and $d = 8$, respectively; see also Fig. 11) is clearly present and the amplitude of the oscillations visibly amplifies with $d$ (also compare with with Fig. 4). However, the analysis of this interesting phenomenon is out of the paper scope.
VII. DISCUSSION AND CONCLUSIONS

The method for the derivation of the asymptotic values of the expected conditional CRI length and the throughput presented in Section IV-B can be extended to the case of BTA with fair splitting and $K$-MPR (without SIC) [13]. Here we give the final expressions without a formal proof. Specifically, for $n \geq K$, the expected conditional CRI length is

$$L_n^* = 1 + 2 \sum_{m=0}^{\infty} 2^m \left[ 1 - \sum_{k=0}^{K} \binom{n}{k} \frac{(1 - \frac{1}{2^m})^{n-k}}{2^{mk}} \right]$$

which is asymptotically

$$L_n^* \approx 1 + 2 \sum_{m=0}^{\infty} 2^m \left[ 1 - \sum_{k=0}^{K} \left( \frac{n}{2^m} \right)^k e^{-\frac{2^m}{k!}} \right].$$

Using the Mellin-transform based asymptotic analysis, we get

$$L_n^* \approx -1 + \frac{2n}{K \ln 2} \times (1 - 2K |B(K, 1)|) \cos(2\pi \log_2 n + \arg(B(K, 1)))$$

$$\approx \frac{2n}{K \ln 2} \times (1 - 2K |B(K, 1)|) \cos(2\pi \log_2 n + \arg(B(K, 1))).$$
The conditional throughout is then simply

\[ T^*_n \approx \frac{\ln 2}{2 [1 - 2K|B(K, 1)| \cos (2\pi \log_2 n + \arg (B(K, 1)))]} \]  

(96)

The last expression confirms the result identified in [13], that the conditional throughout of BTA with \( K \)-MPR oscillates around the value of \( \ln 2 / 2 \approx 0.347 \) as \( n \to \infty \).

We now turn to the comparison between the considered scheme with analogous schemes from the slotted ALOHA family that exploit MPR and SIC. We mention Irregular Repetition Slotted ALOHA (IRSA) [8], a frame slotted ALOHA protocol in which active users transmit several replicas of their packets in the frame. Asymptotically, IRSA supports load thresholds \( G^* \) (defined as the ratio of the number of users and slots in the frame) close to 1 with the user resolution probability tending to 1, when the number of replicas transmitted per user is drawn according to a predefined, optimized distribution. Essentially, this performance parameter is equivalent to the throughput. In [33] it was shown that, when IRSA is coupled with MPR, the normalized load threshold \( G^*/K \) for a fixed maximum number of replicas per user, decreases with \( K \) when \( n \to \infty \). A similar insight, in terms of the upper bound on \( G^*/K \) was shown in [34]. On the other hand, the work in [10] showed that for the generalized variant of IRSA, denoted as Coded Slotted ALOHA (CSA), the converse bound on \( G^*/K \) increases with \( K \), quickly becoming very close to 1, and that, asymptotically, spatially-coupled CSA operates close to the bound, which is out of the reach of the scheme considered in this paper. This evidence may lead to a conclusion that IRSA based schemes represent a better choice. However, for a finite number of contending users, the maximum normalized load which the probability of successful user resolution is close to 1 in IRSA is \( G/K \lesssim 0.7 \) [34],\(^{10}\) which is comparable to the MST of the scheme considered in this paper. It should also be noted that slotted ALOHA-based protocols, in general, require some form of stabilization, while IRSA-like protocols additionally require (i) optimization of the frame length, (ii) optimization of the distribution that governs the choice of the number of replicas, and (iii) placement of the pointers in the packet headers, required for the SIC. In contrast, tree-protocols are inherently stable for loads up to the MST, and in case of the windowed access, require just the optimization of the window length. Thus, for systems that support a frequent feedback (i.e., after every uplink slot), tree-algorithms with MPR and SIC may represent a suitable random-access solution.

\(^{10}\)Also growing with \( K \), in contrast to the asymptotic behaviour.
Finally, we comment on an approach through which the performance of the scheme could be pushed further. Specifically, as shown in [35], one of the factors limiting the performance of tree algorithms with SIC is a too high fraction of singleton slots in comparison to IRSA-like protocols, which are unavoidable due to the very nature of the collision resolution process. A way to address this drawback and push the throughput performance is to form a set of partially-split trees pertaining to the same initial collision and perform SIC over the whole set. It remains to be seen how the addition of MPR to the framework would affect the performance of such scheme.
