Abstract

We consider the problem of minimizing a convex function that is evolving in time according to unknown and possibly stochastic dynamics. Such problems abound in the machine learning and signal processing literature, under the names of concept drift and stochastic tracking. We provide novel non-asymptotic convergence guarantees for stochastic algorithms with iterate averaging, focusing on bounds valid both in expectation and with high probability. Notably, we show that the tracking efficiency of the proximal stochastic gradient method depends only logarithmically on the initialization quality, when equipped with a step-decay schedule. The results moreover naturally extend to settings where the dynamics depend jointly on time and on the decision variable itself, as in the performative prediction framework.

1 Introduction

Stochastic optimization underpins much of machine learning theory and practice. Significant progress has been made over the last two decades in the finite-time analysis of stochastic approximation algorithms; see e.g. [1, 2, 7, 8, 9, 28, 32, 38, 39]. The predominant assumption in this line of work is that the distribution generating the data is fixed throughout the run of the process. There is no shortage of problems, however, where this assumption is grossly violated for reasons beyond the learner’s control. Indeed, data often shifts and evolves over time for reasons that may be independent of the learning process. In this work, we present finite-time efficiency estimates in expectation and in high probability for the tracking error of the proximal stochastic gradient method under time drift. Our results concisely explain the interplay between the learning rate, the noise variance in the gradient oracle, and the strength of the time drift. While conventional wisdom and previous work recommend the use of constant step sizes under time drift, we show that in important regimes a significantly better step size schedule is one that is geometrically decaying to a “critical step size”.

Setting the stage, consider the sequence of stochastic optimization problems

$$\min_x \varphi_t(x) := f_t(x) + r_t(x)$$

indexed by time $t \in \mathbb{N}$. In typical machine learning and signal processing settings, the function $f_t$ corresponds to an average loss that varies in time, while the regularizer $r_t$ models constraints or
promotes structure (e.g. sparsity) in the variable $x$. Two examples are worth highlighting. The first is a classical problem in signal processing—called filtering or stochastic tracking [26,36]—wherein the learning algorithm aims to track over time a moving target driven by an unknown stochastic process. The second example is the concept drift phenomenon [19,37] in online learning, wherein the true hypothesis may be changing over time.

The main goal of a learning algorithm for problem (1) is to generate a sequence of points $\{x_t\}$ that minimize some natural performance metric. To make progress, we impose the standard assumption that $r_t$ is proper, closed and convex, while each function $f_t$ is $\mu$-strongly convex with $L$-Lipschitz continuous gradient. The online proximal stochastic gradient method (PSG) naturally applies to the sequence of problems (1). At each time $t$, the method simply takes a step

$$x_{t+1} = \operatorname{prox}_{\eta r_t}(x_t - \eta_t \tilde{\nabla} f_t(x_t)),$$

where the vector $\tilde{\nabla} f_t(x_t)$ is an unbiased estimator of the true gradient of $f_t$ at $x_t$, the constants $\eta_t > 0$ are user-specified, and $\operatorname{prox}_{\eta r_t}(-)$ is the proximal map of the scaled regularizer $\eta r_t$. In this work, we analyze two types of tracking error for PSG: the squared distance $\|x_t - x_t^*\|^2$ and the suboptimality gap $\varphi_t(x_t) - \varphi_t(x_t^*)$. Here, $x_t^*$ denotes the minimizer of the function $\varphi_t$ and may evolve stochastically in time. We next outline the main results of the paper.

1.1 Tracking the distance

We begin with a simple one-step bound on distance tracking of the constant-step PSG:

$$\mathbb{E}\|x_t - x_t^*\|^2 \lesssim \left(1 - \frac{\mu \eta}{\sigma^2}\right) \|x_0 - x_0^*\|^2 + \frac{\eta \sigma^2}{\mu} + \left(\frac{\Delta}{\mu \eta}\right)^2. \quad (2)$$

Here $\eta \in (0,1/2L]$ is the constant step size used by PSG, $\sigma^2$ upper-bounds the variance of the stochastic gradient, and $\Delta^2$ upper-bounds the minimizer variations $\mathbb{E}\|x_t^* - x_{t+1}^*\|^2$. Inequality (2) asserts that the tracking error $\mathbb{E}\|x_t - x_t^*\|^2$ decays linearly in time $t$, until it reaches the “noise+drift” error $\eta \sigma^2/\mu + (\Delta/\mu \eta)^2$. Notice that the “noise+drift” error cannot be made arbitrarily small by tuning $\eta$. This is perfectly in line with intuition: a step size $\eta$ that is too small prevents the algorithm from catching up with the minimizers $x_t^*$. We note that the individual error terms due to the optimization and noise are classically known to be tight for PSG; tightness of the drift term is proved in [30, Theorem 3.2]. Though the estimate (2) is likely known, we were unable to find a precise reference in this generality.

Letting $t$ tend to infinity in (2), the optimization error tends to zero, leaving only the noise+drift term. Optimizing this remaining term over $\eta$, it is natural to define the asymptotic distance tracking error of PSG and the corresponding optimal learning rate as

$$\mathcal{E} := \min_{\eta \in (0,1/2L]} \left\{ \frac{\eta \sigma^2}{\mu} + \left(\frac{\Delta}{\mu \eta}\right)^2 \right\} \quad \text{and} \quad \eta_* := \min \left\{ \frac{1}{2L}, \left(\frac{2 \Delta^2}{\mu \sigma^2}\right)^{1/3} \right\}. \quad (3)$$

Two regimes of variation are brought to light: the high drift-to-noise regime $\Delta/\sigma \geq \sqrt{\mu/16 L^3}$, and the low drift-to-noise regime $\Delta/\sigma < \sqrt{\mu/16 L^3}$. The high drift-to-noise regime is uninteresting from the viewpoint of stochastic optimization because the optimal learning rate is as large as in the deterministic setting, $\eta_* = 1/2L$. In contrast, the low drift-to-noise regime is interesting because it necessitates using a smaller learning rate that exhibits a nontrivial scaling with the problem parameters. Consequently, for the rest of the introduction we focus on the low drift-to-noise regime.

A central question is to find a learning rate schedule that achieves a tracking error $\mathbb{E}\|x_t - x_t^*\|^2$ that is within a constant factor of $\mathcal{E}$ in the shortest possible time. The simplest strategy is to
execute PSG with the constant learning rate $\eta_\star$. Then a direct application of (2) yields the efficiency estimate $\mathbb{E}\|x_t - x_\star_t\|^2 \lesssim \mathcal{E}$ in time $t \lesssim (\sigma^2/\mu^2\mathcal{E}) \log (\|x_0 - x_\star_0\|^2/\mathcal{E})$. This efficiency estimate can be significantly improved by gradually decaying the learning rate using a “step-decay schedule”, wherein the algorithm is implemented in epochs with the new learning rate chosen to be the midpoint between the current learning rate and $\eta_\star$. Such schedules are well known to improve efficiency in the static setting, as was discovered in [14, 15], and can be used here. The end result is an algorithm that produces a point $x_t$ satisfying
\[
\mathbb{E}\|x_t - x_\star_t\|^2 \lesssim \mathcal{E} \quad \text{after time} \quad t \lesssim \frac{L}{\mu} \log \left( \frac{\|x_0 - x_\star_0\|^2}{\mathcal{E}} \right) + \frac{\sigma^2}{\mu^2 \mathcal{E}}. \tag{4}
\]
Remarkably, this efficiency estimate looks identical to that in the classical static setting [27], with $\mathcal{E}$ playing the role of the target accuracy $\varepsilon$. In particular, note that (4) is independent of the dimension of the ambient space. The estimate (4) is a baseline guarantee for PSG. Since the result is stated in terms of the expected tracking error $\mathbb{E}\|x_t - x_\star_t\|^2$, it is only meaningful if the entire algorithm can be repeated from scratch multiple times on the same problem. There is no shortage of situations in which a learning algorithm is operating in real time and the time drift is irreversible; in such settings, the algorithm may only be executed once. Such settings call for efficiency estimates that hold with high probability, rather than only in expectation. With this in mind, we will show that under mild light tail assumptions, restarted PSG with probability at least $1 - \delta$ produces a point $x_t$ satisfying $\|x_t - x_\star_t\|^2 \lesssim \mathcal{E} \log (1/\delta)$ after the same order of iterations as in (4). The proof follows closely the probabilistic techniques developed in [18] for bounding moment generating functions.

1.2 Tracking the optimal value

The results outlined so far have focused on tracking the minimizer $x_\star_t$; stronger guarantees may be obtained for tracking the minimal value $\varphi_\star_t$. To this end, we will require stronger assumptions on the variation of the functions $f_t$ beyond control on the minimizer drift $\|x_\star_t - x_\star_{t+1}\|^2$. Namely, following the online learning literature [19], we will be concerned with the gradient drift
\[
G_{i,t} := \sup_x \|\nabla f_i(x) - \nabla f_i(x)\|
\]
and assume the bound $\mathbb{E}[G_{i,t}^2/\mu^2] \leq \Delta^2 |t|$. Thus the second moment of the gradient drift should grow at most quadratically in the time horizon. Assuming henceforth that $r_t \equiv r$, this condition on the gradient drift implies $\mathbb{E}\|x_\star_t - x_\star_{t+1}\|^2 \leq \Delta^2$, a weaker assumption used in Section 1.1.

Analogously to (2), we show that PSG generates a point $\hat{x}_t$ (an average iterate) satisfying
\[
\mathbb{E}[\varphi_t(\hat{x}_t) - \varphi_\star_t] \lesssim \left( 1 - \frac{\mu \eta^2}{2} \right) \left( \varphi_0(x_0) - \varphi_\star_0 \right) + \eta \sigma^2 + \frac{\Delta^2}{\mu \eta^2}. \tag{5}
\]
Again, the efficiency estimate decouples nicely into three terms, signifying the error due to optimization, gradient noise, and time drift. Taking the limit as $t$ tends to infinity, the asymptotically optimal function gap tracking error is precisely the optimal distance tracking error $\mathcal{E}$ scaled by $\mu$. Similarly to (4), we will show that restarted PSG produces a point $\hat{x}_t$ satisfying
\[
\mathbb{E}[\varphi_t(\hat{x}_t) - \varphi_\star_t] \lesssim \mathcal{G} \quad \text{after time} \quad t \lesssim \frac{L}{\mu} \log \left( \frac{\varphi_0(x_0) - \varphi_\star_0}{\mathcal{G}} \right) + \frac{\sigma^2}{\mu \mathcal{G}}, \tag{5}
\]
where $\mathcal{G} := \mu \mathcal{E}$ is the optimal asymptotic tracking error of the function gap. Again, the similarity to the static setting [27], with $\mathcal{G}$ playing the role of a target accuracy, is striking. We provide two high probability extensions of this estimate. The first applies when the gradient noise and the gradient drift are bounded. Then restarted PSG with probability at least $1 - \delta$ produces a point $\hat{x}_t$ satisfying
When the noise and drift are not bounded, and instead only have light tails, the guarantee on the tracking error that we can prove incurs an extra factor of $\sqrt{\log(1/\delta)}$. We leave it as an open question if this is necessary. The proofs are based on the generalized Freedman inequality of [18]—a remarkably flexible tool for analyzing stochastic gradient-type algorithms.

1.3 Extensions to decision-dependent problems with time drift

We have so far focused on stochastic optimization problems that undergo a temporal shift. A primary reason for this phenomenon in machine learning, and data science more broadly, is that data distributions often evolve in time independently of the learning process. Recent literature, on the other hand, highlights a different source of distributional shift due to decision-dependent or performative effects. Namely, the distribution generating the data in iteration $t$ may depend on, or react to, the current “state” $x_t$. For example, deployment of a classifier by a learning system, when made public, often causes the population to adapt their attributes in order to increase the likelihood of being positively labeled—a process called “gaming”. Even when the population is agnostic to the classifier, the decisions made by the learning system (e.g. loan approval) may inadvertently alter the profile of the population (e.g. credit score). The goal of the learning system therefore is to find a classifier that generalizes well under the response distribution. Recent research in strategic classification [5, 10, 12, 17] and performative prediction [31, 33] has highlighted the prevalence of this phenomenon.

Combining time-dependence and decision-dependence yields the class of problems (1) where the loss function $f_t(x)$ takes the special form $f_t(x) = \mathbb{E}_{w \sim D_t(x)} \ell(x, w)$. Here $D_t(x)$ is a distribution that depends on both time $t$ and the decision variable $x$. Thus for any fixed time $t$, the problem (1) becomes exactly the one considered in [31, 33]. Following this line of work, instead of tracking the true minimizer of $\varphi_t$—typically a challenging task—we will settle for tracking the equilibrium points $\bar{x}_t$. These are the points satisfying

$$\bar{x}_t \in \arg \min_x \mathbb{E}_{w \sim D_t(\bar{x}_t)} \ell(x, w) + r(x)$$

Equilibrium points are sure to exist and are unique under mild Lipschitzness and strong convexity assumptions. We refer the reader to [33] for a compelling motivation for considering such equilibrium points. The problem of tracking equilibrium points is yet again an instance of (1), but now with the different function $f_t(x) = \mathbb{E}_{w \sim D_t(\bar{x}_t)} \ell(x, w)$, induced by the equilibrium distributions. The PSG algorithm is not directly applicable since one cannot sample from $D_t(\bar{x}_t)$ directly. Instead, a natural algorithm for this problem class in each iteration samples $w_t$ from the current distribution $D_t(x_t)$ and declares $x_{t+1} = \text{prox}_{\eta r}(x_t - \eta \nabla \ell(x_t, w_t))$. Notice that the vector $\nabla \ell(x_t, w_t)$ is a biased estimator of $\nabla f_t(x_t)$, because $w_t$ is sampled from the wrong distribution. Nonetheless, as pointed out in [13], the gradient bias is small for any fixed time, decaying linearly with the distance to $\bar{x}_t$. Using this perspective, we show that all guarantees for PSG in the time-dependent setting naturally extend to this biased PSG algorithm for tracking equilibrium points, with essentially no loss in efficiency.

1.4 Related work

Our current work fits within the broader literature on stochastic tracking, online optimization with controlled increments, and high probability guarantees in stochastic optimization. We now survey the most relevant literature in these areas.
Stochastic tracking and filtering. Stochastic gradient-type algorithms for stochastic tracking and filtering have been the subject of extensive research in the past century. Most works have focused on the so-called least mean-squares (LMS) algorithm and its variants, which can be viewed as a stochastic gradient method on a least-squares loss-based objective. Other stochastic algorithms that have been studied in these settings with a larger cost per iteration include recursive least-squares and the Kalman filter [16]. Recent works have revisited these methods from a more modern viewpoint [6, 30, 41]. In particular, the paper [30] focuses on (accelerated) gradient methods for deterministic tracking problems, while [41] analyzes a stochastic gradient method for online problems that is adaptive to unknown parameters. The paper [6] analyzes the dynamic regret of stochastic algorithms for time-varying problems, focusing both on lower and upper complexity bounds. Though the proof techniques in our paper share many aspects with those available in the literature, the results we obtain are distinct. In particular, the guarantees (4) and (5) for the restarted PSG, along with their high probability variants, are new to the best of our knowledge.

Online optimization with controlled increments. Online learning under concept drift was first considered by [29] and further developed in several papers [4, 22]. In this literature, the data distribution is fixed over time, and the rate of variation is stated in terms of the probability of disagreement of consecutive target functions which is assumed to be upper bounded. Another line of work assumes a time partitioning with an expert in each time interval, and the goal is to compete with the expert in each segment. Closer to this work is [19, 21], where in the framework of online convex optimization the bounds are stated in terms of maximum regret over any contiguous time interval; see also [6, 11, 35]. In contrast to these works, in our framework we state our bounds in the same spirit as in classical stochastic approximation, that is, in terms of distance to optimum and objective function gap, and we present results holding both in expectation and with high probability.

High probability guarantees in stochastic optimization. A large part of our work revolves around high probability guarantees for stochastic optimization. Classical references on the subject in static settings and for minimizing regret in online optimization include [3, 20, 27, 34]. There exists a variety of techniques for establishing high probability guarantees based on Freedman’s inequality and doubling tricks; see e.g. [3, 20]. A more recent line of work [18] establishes a generalized Freedman inequality that is custom-tailored for analyzing stochastic gradient-type methods, and results in best known high probability guarantees. Our arguments closely follow the paradigm of [18] based on the generalized Freedman inequality.

Performative prediction and decision-dependent learning. Recent works on strategic classification [5, 10, 12, 17] and performative prediction [31, 33] have highlighted the importance of strategic behavior in machine learning. That is, common learning systems exhibit a feedback mechanism, wherein the distribution generating the data in iteration $t$ may depend on, or react to, the current “state” of an algorithm $x_t$. The recent paper [33] puts forth a convenient framework for thinking about such problems, while [31] develops stochastic algorithms for this setting. The subsequent work [13] shows that a variety of stochastic algorithms for performative prediction can be understood as biased variants of the same algorithms on a certain static problem in equilibrium. Building on the techniques in [13], we show how all our results for time-dependent problems extend to problems that simultaneously depend on time and on the decision variable. We note that during the final stage of completing this paper, the closely related and complementary work [42] was
posted on arXiv. The paper considers decision-dependent projected gradient descent under time drift in the distributional framework proposed in [33], establishing distance tracking bounds in expectation and in high probability under sub-Weibull gradient noise. In particular, the light tail assumptions used in [42] for obtaining high probability guarantees are significantly weaker than those in our paper. On the other hand, we analyze both distance tracking and function gap tracking, allow presence of general convex regularizers, and propose a step-decay schedule for improved efficiency.

1.5 Outline

The outline of the paper is as follows. Section 2 formalizes the problem setting of time-dependent stochastic optimization and records the relevant assumptions. Sections 3-4 and 6 summarize the main results of the paper. Specifically, Section 3 focuses on efficiency estimates for tracking the minimizer, Section 4 focuses on efficiency estimates for tracking the minimal value, and Section 6 outlines extensions to decision-dependent settings, building on the framework proposed in [33]. Proofs of results in Sections 3-4 appear in Section 5, while proofs of results in Section 6 appear in Section 7. Additional proofs appear in Appendix A, while illustrative numerical results appear in Appendix B.

2 Framework and assumptions

2.1 Stochastic optimization under time drift

Throughout Sections 2-4, we consider the sequence of stochastic optimization problems

$$
\min_x \varphi_t(x) := f_t(x) + r_t(x)
$$

indexed by time $t \in \mathbb{N}$. We make the standard standing assumption that (i) each regularizer $r_t: \mathbb{R}^d \to \mathbb{R} \cup \{\infty\}$ is proper, closed and convex, and (ii) each function $f_t: \mathbb{R}^d \to \mathbb{R}$ is $\mu$-strongly convex and $C^1$-smooth with $L$-Lipschitz continuous gradient for some common parameters $\mu, L > 0$. The minimizer and minimal value of (6) will be denoted by $x^*_t$ and $\varphi^*_t$, respectively. Throughout, $\| \cdot \|$ denotes the $\ell_2$-norm on $\mathbb{R}^d$ induced by the dot product $\langle \cdot, \cdot \rangle$.

As motivation, we describe two classical examples of (6) that are worth keeping in mind and that guide our framework: stochastic tracking of a drifting target and online learning under a distributional drift.

Example 2.1 (Stochastic tracking of a drifting target). The problem of stochastic tracking, also called filtering in the signal processing literature, is to track a moving target $x^*_t$ from observations

$$
b_t = c_t(x^*_t) + \epsilon_t,
$$

where $c_t(\cdot)$ is a known measurement map and $\epsilon_t$ is a mean-zero noise vector. A typical time-dependent problem formulation takes the form

$$
\min_{x} \mathbb{E} \ell_t(b_t - c_t(x)) + r_t(x),
$$

where $\ell_t(\cdot)$ derives from the distribution of $\epsilon_t$ and $r_t(\cdot)$ encodes available side information about the target $x^*_t$. Common choices for $r_t$ are the 1-norm and the squared 2-norm. The motion of the target $x^*_t$ is typically driven by a random walk or a diffusion [16,36].

More precisely, a short version of our paper consisting of Sections 1-5 was submitted to a conference in May ’21, the paper appeared on arXiv in July ’21, and our full paper was posted on arXiv in August ’21.
Algorithm 1 Online Proximal Stochastic Gradient

**Input:** initial $x_0$ and step-size sequence $\{\eta_t\}^{T}_{t=0} \subset (0, \infty)$.

**Step** $t = 0, \ldots, T$:

Set $g_t = \tilde{\nabla} f_t(x_t)$

Set $x_{t+1} = \text{prox}_{\eta_t r_t}(x_t - \eta_t g_t)$

---

**Example 2.2** (Online learning under distributional drift). The problem of online learning under a distributional drift is to learn while the data distribution may change over time. More formally, one problem formulation takes the form

$$\min_x \mathbb{E}_{w \sim D(u_t)} \ell(x, w) + r(x),$$

where $D(u_t)$ is a data distribution that depends on an unknown parameter sequence $\{u_t\}$, which itself may evolve stochastically. The evolution of $u_t$ is often assumed to be piecewise constant in $t$ in online learning [19, 37].

The goal of our work is to obtain efficiency estimates for this procedure that hold both in expectation and with high probability.

The guarantees we obtain allow both the iterates $x_t$ and the minimizers $x^*_t$ to evolve stochastically. This is convenient for example when tracking a moving target $x^*_t$ whose motion may be governed by a stochastic process such as a random walk or a diffusion (see Example 2.1). Throughout, we define the minimizer drift at time $t$ to be the random variable

$$\Delta_t := \|x^*_t - x^*_{t+1}\|.$$

### 2.2 Running assumption on the stochastic process

Setting the stage, given $\{x_t\}$ and $\{g_t\}$ as in Algorithm 1, we let

$$z_t := \nabla f_t(x_t) - g_t$$

denote the gradient noise at time $t$ and we impose the following assumption modeling stochasticity in the online problem throughout Sections 3 and 4.

**Assumption 2.3** (Stochastic framework). There exists a filtered probability space $(\Omega, \mathcal{F}, \mathbb{F}, \mathbb{P})$ with filtration $\mathbb{F} = (\mathcal{F}_t)_{t \geq 0}$ such that $\mathcal{F}_0 = \{\emptyset, \Omega\}$ and the following holds for all $t \geq 0$:

(i) $x_t, x^*_t : \Omega \rightarrow \mathbb{R}^d$ are $\mathcal{F}_t$-measurable,
(ii) $z_t : \Omega \rightarrow \mathbb{R}^d$ is $\mathcal{F}_{t+1}$-measurable with $\mathbb{E}[z_t \mid \mathcal{F}_t] = 0$.

The first item of Assumption 2.3 simply says that $x_t$ and $x^*_t$ are fully determined by information up to time $t$. The second item of Assumption 2.3 asserts that the gradient noise $z_t$ is fully determined by information up to time $t + 1$ and has zero mean conditioned on the information up to time $t$; for example, this holds naturally in Example 2.2 if we take $g_t = \nabla \ell(x_t, w_t)$ with $w_t \sim D(u_t)$ provided the loss $\ell(\cdot, w_t)$ is $C^1$-smooth.

Clearly, an efficiency estimate for Algorithm 1 must take into account the variation of the functions $f_t$ in time $t$. Two of the most popular metrics for measuring such variations are the minimizer drift $\Delta_t$ and the gradient variation $\sup_x \| \nabla f_t(x) - \nabla f_{t+1}(x) \|$. Given identical regularizers, a bound on the gradient variation always implies a bound on the minimizer drift.

**Lemma 2.4** (Gradient variation vs. minimizer drift). Suppose $i, t \geq 0$ are such that the regularizers $r_i$ and $r_t$ are identical. Then we have

$$
\mu \| x^*_i - x^*_t \| \leq \| \nabla f_i(x^*_i) - \nabla f_i(x^*_t) \|.
$$

*Proof.* Let $r$ denote the common regularizer: $r = r_t = r_i$. Then the first-order optimality condition

$$
0 \in \partial \varphi_i(x^*_i) = \nabla f_i(x^*_i) + \partial r(x^*_i)
$$

implies $-\nabla f_i(x^*_i) \in \partial r(x^*_i)$, so the vector $v := \nabla f_i(x^*_i) - \nabla f_i(x^*_t)$ lies in $\partial \varphi_i(x^*_t)$. Hence the $\mu$-strong convexity of $\varphi_i$ and the inclusion $0 \in \partial \varphi_i(x^*_t)$ imply $\mu \| x^*_i - x^*_t \| \leq \| v \|$. $\square$

### 3 Tracking the minimizer with the last iterate

In this section, we present bounds on the tracking error $\| x_t - x^*_t \|^2$ that are valid both in expectation and with high probability under light tail assumptions. Further, we show that a geometrically decaying learning rate schedule may be superior to a constant learning rate in terms of efficiency.

#### 3.1 Bounds in expectation

We begin with bounding the expected value $\mathbb{E}[\| x_t - x^*_t \|^2]$. For simplicity, we state the main results under the assumption that the second moments $\mathbb{E}[\Delta^2_t]$ and $\mathbb{E}[z_t]^2$ are uniformly bounded. More general guarantees that take into account weighted averages of the moments and allow for time-dependent learning rates follow from Lemma 5.1 in Section 5.1 which contains the formal statements and proofs of the present section.

**Assumption 3.1** (Bounded second moments). There exist constants $\Delta, \sigma > 0$ such that the following holds for all $t \geq 0$.

1. **(Drift)** The minimizer drift $\Delta_t$ satisfies $\mathbb{E}[\Delta^2_t] \leq \Delta^2$.
2. **(Noise)** The gradient noise $z_t$ satisfies $\mathbb{E}[z_t]^2 \leq \sigma^2$.

The following theorem establishes a one-step improvement guarantee for Algorithm 1 and serves as the basis for much of what follows.

**Theorem 3.2** (Expected distance). Suppose that Assumption 3.1 holds. Then the iterates produced by Algorithm 1 with constant learning rate $\eta \leq 1/2L$ satisfy the bound:

$$
\mathbb{E}[\| x_t - x^*_t \|^2] \lesssim (1 - \mu \eta)^t \| x_0 - x^*_0 \|^2 + \frac{\eta \sigma^2}{\mu} + \left( \frac{\Delta}{\mu \eta} \right)^2.
$$
Interplay of optimization, noise, and drift. Theorem 3.2 states that when using a constant learning rate, the error $E\|x_t - x^*_t\|^2$ decays linearly in time $t$, until it reaches the “noise+drift” error $\eta \sigma^2/\mu + (\Delta/\mu \eta)^2$. Notice that the “noise+drift” error cannot be made arbitrarily small. This is perfectly in line with intuition: a learning rate that is too small prevents the algorithm from catching up with $x^*_t$. We note that the individual error terms due to the optimization and noise are classically known to be tight for PSG; tightness of the drift term is proved in [30, Theorem 3.2].

With Theorem 3.2 in hand, we are led to define the following asymptotic tracking error of Algorithm 1 corresponding to $\eta \sigma^2/\mu + (\Delta/\mu \eta)^2$. Two regimes of variation are brought to light by the above computation: the learning rate vs. rate of variation.

Learning rate vs. rate of variation. A central question is to find a learning rate schedule that achieves a tracking error $E\|x_t - x^*_t\|^2$ that is within a constant factor of $\mathcal{E}$ in the shortest possible time. The answer is clear in the high drift-to-noise regime $\Delta/\sigma \geq \sqrt{\mu/16L^3}$. Indeed, in this case, Theorem 3.2 directly implies that Algorithm 1 with the constant learning rate $\eta^* = 1/2L$ will find a point $x_t$ satisfying $E\|x_t - x^*_t\|^2 \lesssim \mathcal{E}$ in time $t \lesssim (L/\mu) \log(\|x_0 - x^*_0\|^2/\mathcal{E})$. Notice that the efficiency estimate is logarithmic in $1/\mathcal{E}$; intuitively, the reason for the absence of a sublinear component is that the error due to the drift $\Delta$ dominates the error due to the variance $\sigma^2$ in the stochastic gradient.

The low drift-to-noise regime $\Delta/\sigma < \sqrt{\mu/16L^3}$ is more subtle. Namely, the simplest strategy is to execute Algorithm 1 with the constant learning rate $\eta^* = (2\Delta^2/\mu \sigma^2)^{1/3}$. Then a direct application of Theorem 3.2 yields the estimate $E\|x_t - x^*_t\|^2 \lesssim \mathcal{E}$ in time $t \lesssim (\sigma^2/\mu^2 \mathcal{E}) \log(\|x_0 - x^*_0\|^2/\mathcal{E})$. This efficiency estimate can be significantly improved by gradually decaying the learning rate using a “step-decay schedule”, wherein the algorithm is implemented in epochs with the new learning rate chosen to be the midpoint between the current learning rate and $\eta^*$. Such schedules are well known to improve efficiency in the static setting, as was discovered in [14, 15], and can be used here. The end result is the following theorem; see Theorem 5.3 for the formal statement and proof.

Theorem 3.3 (Informal). Suppose that Assumption 3.1 holds. Then there is a learning rate schedule $\{\eta_t\}$ such that Algorithm 1 produces a point $x_t$ satisfying

$$E\|x_t - x^*_t\|^2 \lesssim \mathcal{E} \quad \text{after time} \quad t \lesssim \frac{L}{\mu} \log \left( \frac{\|x_0 - x^*_0\|^2}{\mathcal{E}} \right) + \frac{\sigma^2}{\mu^2 \mathcal{E}}.$$ 

Remarkably, the efficiency estimate in Theorem 3.3 looks identical to the efficiency estimate in the classical static setting [27], with $\mathcal{E}$ playing the role of the target accuracy $\varepsilon$. Theorems 3.2
and \[3.3\] provide useful baseline guarantees for the performance of Algorithm \[1\] Nonetheless, these guarantees are all stated in terms of the expected tracking error \(\mathbb{E}[\|x_t - x_t^*\|^2]\), and are therefore only meaningful if the entire algorithm can be repeated from scratch multiple times. There is no shortage of situations in which a learning algorithm is operating in real time and the time drift is irreversible; in such settings, the algorithm may only be executed once. Such settings call for efficiency estimates that hold with high probability, rather than only in expectation.

### 3.2 High probability guarantees

We next present high probability guarantees on the tracking error \(\|x_t - x_t^*\|^2\). To this end, we make the following standard light tail assumptions on the minimizer drift and gradient noise \[18, 27, 32\].

**Assumption 3.4** (Sub-Gaussian drift and noise). There exist constants \(\Delta, \sigma > 0\) such that the following holds for all \(t \geq 0\).

1. **(Drift)** The square minimizer drift \(\Delta_t^2\) is sub-exponential conditioned on \(\mathcal{F}_t\) with parameter \(\Delta^2\):
   \[
   \mathbb{E}[\exp(\lambda \Delta_t^2) | \mathcal{F}_t] \leq \exp(\lambda \Delta^2) \quad \text{for all} \quad 0 \leq \lambda \leq \Delta^{-2}.
   \]

2. **(Noise)** The gradient noise \(z_t\) is norm sub-Gaussian conditioned on \(\mathcal{F}_t\) with parameter \(\sigma/2\):
   \[
   \mathbb{P}\{\|z_t\| \geq \tau | \mathcal{F}_t\} \leq 2 \exp(-2\tau^2/\sigma^2) \quad \text{for all} \quad \tau > 0.
   \]

Note that the first item of Assumption \[3.4\] is equivalent to asserting that the minimizer drift \(\Delta_t\) is sub-Gaussian conditioned on \(\mathcal{F}_t\). Clearly Assumption \[3.4\] implies Assumption \[3.1\] with the same constants \(\Delta, \sigma\). It is worthwhile to note some common settings in which Assumption \[3.4\] holds; the claims in Remark \[3.5\] follow from known results on sub-Gaussian random variables \[23, 40\].

**Remark 3.5** (Common settings for Assumption \[3.4\]). Fix constants \(\Delta, \sigma > 0\). If \(\Delta_t\) is bounded by \(\Delta\), then clearly \(\Delta_t^2\) is sub-exponential (conditioned on \(\mathcal{F}_t\)) with parameter \(\Delta^2\). Similarly, if \(\|z_t\|\) is bounded by \(\sigma\), then \(z_t\) is norm sub-Gaussian (conditioned on \(\mathcal{F}_t\)) with parameter \(\sigma/2\) (by Markov’s inequality). Alternatively, if the increment \(x_t^* - x_{t+1}^*\) is mean-zero sub-Gaussian conditioned on \(\mathcal{F}_t\) with parameter \(\Delta/\sqrt{d}\), then \(x_t^* - x_{t+1}^*\) is mean-zero norm sub-Gaussian conditioned on \(\mathcal{F}_t\) with parameter \(2\sqrt{2} \cdot \Delta\) and hence \(\Delta_t^2\) is sub-exponential conditioned on \(\mathcal{F}_t\) with parameter \(c \cdot \Delta^2\) for some absolute constant \(c > 0\). Similarly, if \(z_t\) is sub-Gaussian conditioned on \(\mathcal{F}_t\) with parameter \(\sigma/4\sqrt{2d}\), then \(z_t\) is norm sub-Gaussian conditioned on \(\mathcal{F}_t\) with parameter \(\sigma/2\).

The theorem below shows that if Assumption \[3.4\] holds, then the bound on \(\mathbb{E}[\|x_t - x_t^*\|^2]\) derived in Theorem \[3.2\] holds with high probability.

**Theorem 3.6** (High probability distance tracking). Suppose that Assumption \[3.4\] holds and let \(\{x_t\}\) be the iterates produced by Algorithm \[1\] with constant learning rate \(\eta \leq 1/2L\). Then there is an absolute constant \(c > 0\) such that for any specified \(t \in \mathbb{N}\) and \(\delta \in (0, 1)\), the estimate

\[
\|x_t - x_t^*\|^2 \leq \left(1 - \frac{\mu\eta}{2}\right)^t \|x_0 - x_0^*\|^2 + c \left(\frac{\eta\sigma^2}{\mu} + \left(\frac{\Delta}{\mu\eta}\right)^2\right) \log \left(\frac{e}{\delta}\right)
\]

holds with probability at least \(1 - \delta\).

The proof of Theorem \[3.6\] follows a technique utilized in \[18\]. The main idea is to build a careful recursion for the moment generating function of \(\|x_t - x_t^*\|^2\), leading to a sub-exponential tail bound. As a consequence of Theorem \[3.6\] we can again consider a step-decay schedule to obtain the following efficiency estimate with high probability; see Section \[5.2\] for the formal statements and proofs.
Algorithm 2: Averaged Online Proximal Stochastic Gradient \( \text{PSG}(x_0, \{\eta_t\}, T) \)

**Input**: initial \( x_0 =: \hat{x}_0 \) and step-size sequence \( \{\eta_t\}_{t=0}^T \subset (0, \infty) \).

**Step** \( t = 0, \ldots, T \):

1. Set \( g_t = \tilde{\nabla} f_t(x_t) \)
2. Set \( x_{t+1} = \text{prox}_{\eta_t r_t}(x_t - \eta_t g_t) \)
3. Set \( \hat{x}_{t+1} = \left( 1 - \frac{\mu \eta_t}{2 - \mu \eta_t} \right) \hat{x}_t + \frac{\mu \eta_t}{2 - \mu \eta_t} x_{t+1} \)

---

**Theorem 3.7** (Informal). Suppose that Assumption 3.4 holds. Then there is a learning rate schedule \( \{\eta_t\} \) such that for any specified \( \delta \in (0, 1) \), Algorithm 1 produces a point \( x_t \) satisfying

\[
\|x_t - x^*_t\|^2 \lesssim \mathcal{E} \log \left( \frac{\epsilon}{\delta} \right)
\]

with probability at least \( 1 - K \delta \) after time

\[
t \lesssim \frac{L}{\mu} \log \left( \frac{\|x_0 - x^*_0\|^2}{\mathcal{E}} \right) + \frac{\sigma^2}{\mu^2 \mathcal{E}}, \quad \text{where} \quad K \lesssim \log_2 \left( \frac{1}{L} \cdot \left( \frac{\sigma^2 \mu}{\Delta^2} \right)^{1/3} \right).
\]

4 Tracking the minimal value

The results outlined so far have focused on tracking the minimizer \( x^*_t \). In this section, we present results for tracking the minimal value \( \varphi_t^* \). These two goals are fundamentally different. Generally speaking, good bounds on the function gap along with strong convexity imply good bounds on the distance to the minimizer; the reverse implication is false. To this end, we will require a stronger assumption on the variation of the functions \( f_t \) in time \( t \): we will assume control on the gradient variation \( \sup_x \| \nabla f_i(x) - \nabla f_{i+1}(x) \| \) rather than on the minimizer drift \( \Delta_t \), as is common in the online learning literature [19]. We will thus be concerned with the gradient drift

\[
G_{i,t} := \sup_x \| \nabla f_i(x) - \nabla f_t(x) \|.
\]

Our strategy is to track the minimal value along the running average \( \hat{x}_t \) of the iterates \( x_t \) produced by Algorithm 1 defined as

\[
\hat{x}_0 := x_0 \quad \text{and} \quad \hat{x}_{t+1} := \left( 1 - \frac{\mu \eta_t}{2 - \mu \eta_t} \right) \hat{x}_t + \frac{\mu \eta_t}{2 - \mu \eta_t} x_{t+1} \quad \forall t \geq 0.
\]

The reason behind using this particular running average is brought to light in Section 5.3 wherein we apply a standard averaging bound (Lemma A.1) to a one-step improvement along \( x_t \) (Lemma 5.10) to obtain the desired one-step improvement along \( \hat{x}_t \) (Proposition 5.11). We record this average iterate version of Algorithm 1 as Algorithm 2 above.

4.1 Bounds in expectation

We begin with bounding the expected value \( \mathbb{E}[\varphi_t(\hat{x}_t) - \varphi_t^*] \). Analogous to Assumption 3.1 we make the following assumption regarding drift and noise.

**Assumption 4.1** (Bounded second moments). The regularizers \( r_t \equiv r \) are identical for all times \( t \) and there exist constants \( \Delta, \sigma > 0 \) such that the following properties hold for all \( 0 \leq i < t \):

1. **(Drift)** The gradient drift \( G_{i,t} \) satisfies \( \mathbb{E}[G_{i,t}^2] \leq (\mu \Delta |i-t|)^2 \).
2. (Noise) The gradient noise $z_i$ satisfies $\mathbb{E}\|z_i\|^2 \leq \sigma^2$ and $\mathbb{E}\langle z_i, x_i^* \rangle = 0$.

These two assumptions are natural indeed. Taking into account Lemma 2.4 it is clear that Assumption 4.1 implies the earlier Assumption 3.1 with the same constants $\Delta, \sigma$. The assumption on the drift intuitively asserts that gradient drift $G_{i,t}$ can grow only linearly in time $|i-t|$ in expectation. In particular, returning to Example 2.2 suppose that the distribution map $D(\cdot)$ is $\gamma$-Lipschitz continuous in the Wasserstein-1 distance, the loss $\ell(\cdot, w)$ is $C^1$ smooth for all $w$, and the gradient $\nabla \ell(x, \cdot)$ is $\beta$-Lipschitz continuous for all $x$. Then the Kantorovich-Rubinstein duality theorem directly implies $\mathbb{E}\|G_{i,t}\| \leq (\gamma \beta)^2 \mathbb{E}\|u_i - u_t\|^2$. Therefore, as long as the second moment $\mathbb{E}\|u_i - u_t\|^2$ scales quadratically in $|i-t|$, the desired drift assumption holds. The assumption on the noise requires a uniform bound on the second moment $\mathbb{E}\|z_i\|^2$ and for the condition $\mathbb{E}\langle z_i, x_i^* \rangle = 0$ to hold. The latter property confers a weak form of uncorrelatedness between the gradient noise $z_i$ and the future minimizer $x_i^*$, and holds automatically if the gradient noise and the minimizers evolve independently of each other, as would typically be the case for instance in Example 2.2.

The following theorem provides a one-step improvement guarantee for Algorithm 2.

**Theorem 4.2** (Expected function gap). Suppose that Assumption 4.1 holds, and let $\{\hat{x}_t\}$ be the iterates produced by Algorithm 2 with constant learning rate $\eta \leq 1/2L$. Then the following bound holds for all $t \geq 0$:

$$
\mathbb{E}[\varphi_t(\hat{x}_t) - \varphi_0^*] \lesssim \left(1 - \frac{\mu \eta}{2}\right)^t \cdot \mathbb{E}\left[\varphi_t(x_0) - \varphi_t^* + \frac{\mu}{4}\|x_0 - x_t^*\|^2\right] + \frac{\Delta^2}{\mu \eta^2} + \eta \sigma^2 + \frac{\Delta^2}{\mu \eta^2}.
$$

Consequently, we have

$$
\mathbb{E}[\varphi_t(\hat{x}_t) - \varphi_0^*] \lesssim \left(1 - \frac{\mu \eta}{2}\right)^t (\varphi_0(x_0) - \varphi_0^*) + \eta \sigma^2 + \frac{\Delta^2}{\mu \eta^2}
$$

for all $t \geq 0$, and the following asymptotic error bound holds:

$$
\limsup_{t \to \infty} \mathbb{E}[\varphi_t(\hat{x}_t) - \varphi_0^*] \lesssim \eta \sigma^2 + \frac{\Delta^2}{\mu \eta^2}.
$$

A few comments about Theorem 4.2 are in order. The “noise+drift” error term in Theorem 4.2 coincides with $\mu$ times the corresponding error term in Theorem 3.2 as expected. The optimization error in Theorem 4.2 is qualitatively different from the optimization error in Theorem 3.2 in that the term $\mathbb{E}[\varphi_t(x_0) - \varphi_t^* + \frac{\mu}{4}\|x_0 - x_t^*\|^2]$ can grow in time. Notice, however, that this term depends only on the evolution of the functions in time, and not on the iterates $\{x_t\}_{t \geq 1}$ nor the learning rate $\eta$. As a consequence of Assumption 4.1 the quantity $\mathbb{E}[\varphi_t(x_0) - \varphi_t^* + \frac{\mu}{4}\|x_0 - x_t^*\|^2]$ grows at most quadratically in time $t$ and therefore the entire optimization error tends to zero as $t \to \infty$.

Next, with Theorem 4.2 in hand, we are led to define the following asymptotic tracking error of Algorithm 2 corresponding to $\mathbb{E}[\varphi_t(\hat{x}_t) - \varphi_0^*]$:

$$
\mathcal{G} := \mu \mathcal{E} = \min_{\eta \in (0, 1/2L]} \left\{ \eta \sigma^2 + \frac{\Delta^2}{\mu \eta^2} \right\}.
$$

The corresponding asymptotically optimal choice of $\eta$ is again given by

$$
\eta_* = \min \left\{ \frac{1}{2L}, \left( \frac{2\Delta^2}{\mu \sigma^2} \right)^{1/3} \right\}.
$$
and the dichotomy governed by the drift-to-noise ratio $\Delta/\sigma$ remains:

$$G \begin{cases} \frac{\sigma^2}{\mu} + \frac{(L\Delta)^2}{\mu^2} & \text{if } \frac{\Delta}{\sigma} \geq \sqrt{\frac{\mu}{16L^3}} \\ \mu \left( \frac{\Delta^2}{\mu^2} \right)^{2/3} & \text{otherwise.} \end{cases}$$

In the high drift-to-noise regime $\Delta/\sigma \geq \sqrt{\mu/16L^3}$, Theorem 4.2 directly implies that Algorithm 2 with the constant learning rate $\eta_\star = 1/2L$ finds a point $\hat{x}_t$ satisfying $E[\varphi_t(\hat{x}_t) - \varphi^*_t] \lesssim G$ in time $t \lesssim (L/\mu) \log((\varphi_0(x_0) - \varphi^*_0)/G)$. In the low drift-to-noise regime $\Delta/\sigma < \sqrt{\mu/16L^3}$, another direct application of Theorem 4.2 shows that Algorithm 2 with the constant learning rate $\eta_\star = (2\Delta^2/\mu^2)^{1/3}$ finds a point $\hat{x}_t$ satisfying $E[\varphi_t(\hat{x}_t) - \varphi^*_t] \lesssim G$ in time $t \lesssim (\sigma^2/\mu G) \log((\varphi_0(x_0) - \varphi^*_0)/G)$. As before, this efficiency estimate can be significantly improved by implementing a step-decay schedule. The end result is the following theorem; see Section 5.3 for the formal statements and proofs.

**Theorem 4.3** (Informal). Suppose that Assumption 4.1 holds. Then there is a learning rate schedule $\{\eta_t\}$ such that Algorithm 2 produces a point $\hat{x}_t$ satisfying

$$E[\varphi_t(\hat{x}_t) - \varphi^*_t] \lesssim G \quad \text{after time } t \lesssim \frac{L}{\mu} \log \left( \frac{\varphi_0(x_0) - \varphi^*_0}{G} \right) + \frac{\sigma^2}{\mu G}.$$

### 4.2 High probability guarantees

Our next result is an analogue of Theorem 4.2 that holds with high probability. Naturally, such a result should rely on light tail assumptions on the gradient drift $G_{i:t}$ and the norm of the gradient noise $\|z_i\|$. We first state the guarantee under the assumption that $G_{i:t}$ and $\|z_i\|$ are bounded (Assumption 4.4), which yields a better efficiency estimate. We also for the first time require that the gradient noise $z_i$ is mean-zero conditioned on the $\sigma$-algebra

$$\mathcal{F}_{i:t} := \sigma(\mathcal{F}_i, x^*_i)$$

for all $0 \leq i < t$; the property $E[z_i | \mathcal{F}_{i:i}] = 0$ would follow from independence of the gradient noise $z_i$ and the future minimizer $x^*_i$ and is very reasonable in light of Examples 2.1 and 2.2.

**Assumption 4.4** (Bounded drift and noise). The regularizers $r_t \equiv r$ are identical for all times $t$ and there exist constants $\Delta, \sigma > 0$ such that the following properties hold for all $0 \leq i < t$.

1. (Drift) The gradient drift $G_{i:t}$ satisfies $G_{i:t} \leq \mu \Delta |i - t|$.
2. (Noise) The gradient noise $z_i$ satisfies $\|z_i\| \leq \sigma$ and $E[z_i | \mathcal{F}_{i:i}] = 0$.

The proof of Theorem 4.5 is based on combining the generalized Freedman inequality of [18] with a careful control of drift and noise in one-step improvement guarantees for the proximal stochastic gradient method.

**Theorem 4.5** (Function gap with high probability). Suppose that Assumption 4.4 holds, and let $\{\hat{x}_t\}$ be the iterates produced by Algorithm 2 with constant learning rate $\eta \leq 1/2L$. Then there is an absolute constant $c > 0$ such that for any specified $t \in \mathbb{N}$ and $\Delta \in (0, 1/e]$, the estimate

$$\varphi_t(\hat{x}_t) - \varphi^*_t \leq c \left( \left(1 - \frac{\mu \eta}{2}\right) (\varphi_0(x_0) - \varphi^*_0) + \eta \sigma^2 + \frac{\Delta^2}{\mu \eta^2} \right) \log \left( \frac{1}{\Delta} \right),$$

holds with probability at least $1 - \delta$.

With Theorem 4.5 in hand, we may implement a step-decay schedule as before to obtain the following efficiency estimate.
Theorem 4.6 (Informal). Suppose that Assumption 4.4 holds, and fix $\delta \in (0, 1/e]$. Then there is a learning rate schedule $\{\eta_t\}$ such that Algorithm 2 produces a point $\hat{x}_t$ satisfying
\[
\varphi_t(\hat{x}_t) - \varphi^*_t \lesssim \mathcal{G} \log \left( \frac{1}{\delta} \right)
\]
with probability at least $1 - K\delta$ after time
\[
t \lesssim \frac{L}{\mu} \log \left( \frac{\varphi_0(x_0) - \varphi^*_0}{\mathcal{G}} \right) + \frac{\sigma^2}{\mu \mathcal{G}} \log \left( \log \left( \frac{1}{\delta} \right) \right), \quad \text{where } K \lesssim \log_2 \left( \frac{1}{L} \cdot \left( \frac{\sigma^2 \mu}{\Delta^2} \right)^{1/3} \right).
\]

Following a similar line of reasoning as in the proof of Theorem 4.5, we obtain an analogous result in the setting wherein the gradient drift $G_{i,t}$ is only assumed to be sub-Gaussian (equivalently, $G_{i,t}^2$ is sub-exponential) and the gradient noise $z_i$ is only assumed to be mean-zero norm sub-Gaussian conditioned on $\mathcal{F}_{i,t}$. Specifically, we make the following assumption.

Assumption 4.7 (Sub-Gaussian drift and noise). The regularizers $r_i \equiv r$ are identical for all times $t$ and there exist constants $\Delta, \sigma > 0$ such that the following properties hold for all $0 \leq i < t$.

1. (Drift) The square gradient drift $G_{i,t}^2$ is sub-exponential with parameter $(\mu \Delta |i - t|)^2$:
\[
\mathbb{E} \left[ \exp \left( \lambda G_{i,t}^2 \right) \right] \leq \exp \left( \lambda (\mu \Delta |i - t|)^2 \right) \quad \text{for all } 0 \leq \lambda \leq (\mu \Delta |i - t|)^{-2}.
\]

2. (Noise) The gradient noise $z_i$ is mean-zero norm sub-Gaussian conditioned on $\mathcal{F}_{i,t}$ with parameter $\sigma/2$, i.e., $\mathbb{E}[z_i | \mathcal{F}_{i,t}] = 0$ and
\[
\mathbb{P}\left\{ \|z_i\| \geq \tau \mid \mathcal{F}_{i,t} \right\} \leq 2 \exp(-2\tau^2/\sigma^2) \quad \text{for all } \tau \geq 0.
\]

Clearly the chain of implications holds:

Assumption 4.4 $\implies$ Assumption 4.7 $\implies$ Assumption 4.1 $\implies$ Assumption 3.1

Theorem 4.8 (Function gap with high probability). Suppose that Assumption 4.7 holds, and let $\{\hat{x}_t\}$ be the iterates produced by Algorithm 2 with constant learning rate $\eta_t \leq 1/2L$. Then there is an absolute constant $c > 0$ such that for any specified $t \in \mathbb{N}$ and $\delta \in (0, 1/e]$, the estimate
\[
\varphi_t(\hat{x}_t) - \varphi^*_t \leq c \left( 1 - \frac{\mu \eta}{2} \right)^t (\varphi_0(x_0) - \varphi^*_0) + \eta \sigma^2 + \frac{\Delta^2}{\mu \eta^2} \left( \log \left( \frac{1}{\delta} \right) \right)^{3/2}
\]
holds with probability at least $1 - \delta$.

The bound obtained in Theorem 4.8 is worse than that of Theorem 4.5 by a factor of $\sqrt{\log(1/\delta)}$. We leave open the question of whether this extra factor may be removed. We next obtain as before an efficiency estimate from Theorem 4.8 by implementing a step-decay schedule; see Section 5.4 for the formal statements and proofs.

Theorem 4.9 (Informal). Suppose that Assumption 4.7 holds, and fix $\delta \in (0, 1/e]$. Then there is a learning rate schedule $\{\eta_t\}$ such that Algorithm 2 produces a point $\hat{x}_t$ satisfying
\[
\varphi_t(\hat{x}_t) - \varphi^*_t \lesssim \mathcal{G} \left( \log \left( \frac{1}{\delta} \right) \right)^{3/2}
\]
with probability at least $1 - K\delta$ after time
\[
t \lesssim \frac{L}{\mu} \log \left( \frac{\varphi_0(x_0) - \varphi^*_0}{\mathcal{G}} \right) + \frac{\sigma^2}{\mu \mathcal{G}} \log \left( \log \left( \frac{1}{\delta} \right) \right), \quad \text{where } K \lesssim \log_2 \left( \frac{1}{L} \cdot \left( \frac{\sigma^2 \mu}{\Delta^2} \right)^{1/3} \right).
\]
5 Proofs of results in Sections 3 and 4

Roadmap. Throughout this section, we enforce the assumptions and notation of Section 2 and let \( \{x_t\} \) denote the iterates generated by Algorithm 1 with \( \eta_t < 1/L \). Sections 5.1 and 5.2 handle distance tracking under time drift: Section 5.1 derives the results of Section 3.1 while Section 5.2 derives the results of Section 3.2. Then Sections 5.3 and 5.4 handle function gap tracking under time drift: Section 5.3 derives the results of Section 4.1 while Section 5.4 derives the results of Section 4.2.

5.1 Tracking the minimizer: bounds in expectation

The proof of Theorem 3.2 follows a familiar pattern in stochastic optimization. We begin by recalling a standard one-step improvement guarantee [27] for the stochastic gradient method on the fixed problem \( \min \varphi_t \); for completeness, a proof is provided in the appendix (cf. Section A.1).

Lemma 5.1 (One-step improvement). The estimate

\[
2\eta_t (\varphi_t(x_{t+1}) - \varphi_t(x)) \leq (1 - \mu \eta_t)\|x_t - x\|^2 - \|x_{t+1} - x\|^2 + 2\eta_t \langle z_t, x_t - x \rangle + \frac{\eta_t^2}{1 - L\eta_t} \|z_t\|^2
\]

holds for all points \( x \in \mathbb{R}^d \) and for all indices \( t \geq 0 \).

It is critically important that the one-step improvement estimate in Lemma 5.1 holds with respect to any reference point \( x \). In particular, setting \( x = x_t^\star \) yields the following lemma.

Lemma 5.2. The estimate

\[
\|x_{t+1} - x_t^\star\|^2 \leq (1 - \mu \eta_t)\|x_t - x_t^\star\|^2 + 2\eta_t \langle z_t, x_t - x_t^\star \rangle + \frac{\eta_t^2}{1 - L\eta_t} \|z_t\|^2 + \left( 1 + \frac{1}{\mu \eta_t} \right) \Delta_t^2
\]

holds for all indices \( t \geq 0 \).

Proof. Note that the \( \mu \)-strong convexity of \( \varphi_t \) implies \( \frac{\mu}{2} \|x_{t+1} - x_t^\star\|^2 \leq \varphi_t(x_{t+1}) - \varphi_t(x_t^\star) \). Combining this estimate with Lemma 5.1 under the identification \( x = x_t^\star \) yields

\[
(1 + \mu \eta_t)\|x_{t+1} - x_t^\star\|^2 \leq (1 - \mu \eta_t)\|x_t - x_t^\star\|^2 + 2\eta_t \langle z_t, x_t - x_t^\star \rangle + \frac{\eta_t^2}{1 - L\eta_t} \|z_t\|^2.
\]

Next, an application of Young’s inequality reveals

\[
\|x_{t+1} - x_t^\star\|^2 \leq (1 + \mu \eta_t)\|x_{t+1} - x_t^\star\|^2 + (1 + (\mu \eta_t)^{-1})\|x_t^\star - x_{t+1}^\star\|^2,
\]

thereby completing the proof.

Applying Lemma 5.2 recursively yields a bound on \( \|x_t - x_t^\star\|^2 \). When the step size is constant, the next proposition follows immediately.

Proposition 5.3. Suppose \( \eta_t \equiv \eta \). Then the following bound holds for all \( t \geq 0 \):

\[
\|x_t - x_t^\star\|^2 \leq (1 - \mu \eta)^t \|x_0 - x_0^\star\|^2 + 2\eta \sum_{i=0}^{t-1} \langle z_i, x_i - x_i^\star \rangle (1 - \mu \eta)^{t-1-i}
+ \frac{\eta^2}{1 - L\eta} \sum_{i=0}^{t-1} \|z_i\|^2 (1 - \mu \eta)^{t-1-i} + \left( 1 + \frac{1}{\mu \eta} \right) \sum_{i=0}^{t-1} \Delta_i^2 (1 - \mu \eta)^{t-1-i}.
\]

By taking expectations in Proposition 5.3, we obtain the following precise version of Theorem 3.2.
Corollary 5.4 (Expected distance). Suppose that Assumption 3.1 holds. Then the iterates \( \{x_t\} \) generated by Algorithm 1 with constant learning rate \( \eta \leq 1/2L \) satisfy the bound:

\[
\mathbb{E}\|x_t - x_t^*\|^2 \leq (1 - \mu\eta)^t\|x_0 - x_0^*\|^2 + 2\left(\frac{\eta\sigma^2}{\mu} + \left(\frac{\Delta}{\mu\eta}\right)^2\right).
\]

With Corollary 5.4 in hand, we can now prove an expected efficiency estimate for the online proximal stochastic gradient method using a step-decay schedule, wherein the algorithm is implemented in epochs with the new learning rate chosen to be the midpoint between the current learning rate and \( \eta_* \). The following is the formal statement of Theorem 3.3 (as previously noted, in the high drift-to-noise regime \( \Delta/\sigma \geq \sqrt{\mu/16L^3} \), Theorem 3.3 holds trivially with the constant learning rate \( \eta_* = 1/2L \)).

Theorem 5.5 (Time to track in expectation). Suppose that Assumption 3.1 holds and that we are in the low drift-to-noise regime \( \Delta/\sigma < \sqrt{\mu/16L^3} \). Set \( \eta_* = (2\Delta^2/\mu\sigma^2)^{1/3} \) and \( \mathcal{E} = (\Delta\sigma^2/\mu^2)^{2/3} \). Suppose moreover that we have available a positive upper bound on the initial square distance \( D \geq \|x_0 - x_0^*\|^2 \). Consider running Algorithm 1 in \( k = 0, \ldots, K - 1 \) epochs, namely, set \( X_0 = x_0 \) and iterate the process

\[
X_{k+1} = PSG(X_k, \eta_k, T_k) \quad \text{for} \quad k = 0, \ldots, K - 1,
\]

where the number of epochs is

\[
K = 1 + \left\lceil \log_2 \left( \frac{1}{L} \cdot \left( \frac{\sigma^2}{\mu^2} \right)^{1/3} \right) \right\rceil
\]

and we set

\[
\eta_0 = \frac{1}{2L}, \quad T_0 = \left[ \frac{2L}{\mu} \log \left( \frac{\mu L D}{\sigma^2} \right) \right] \quad \text{and} \quad \eta_k = \eta_{k-1} + \eta_*, \quad T_k = \left\lceil \frac{\log(4)}{\mu \eta_k} \right\rceil \quad \forall k \geq 1.
\]

Then the time horizon \( T = T_0 + \cdots + T_{K-1} \) satisfies

\[
T \leq \frac{L}{\mu} \log \left( \frac{\mu L D}{\sigma^2} \right) + \frac{\sigma^2}{\mu^3 \mathcal{E}} < \frac{L}{\mu} \log \left( \frac{D}{\mathcal{E}} \right) + \frac{\sigma^2}{\mu^2 \mathcal{E}},
\]

while the corresponding tracking error satisfies \( \mathbb{E}\|X_K - X_K^*\|^2 \lesssim \mathcal{E} \), where \( X_K^* \) denotes the minimizer of \( \varphi_T \).

Proof. For each index \( k \), let \( t_k := T_0 + \cdots + T_{k-1} \) (with \( t_0 := 0 \), \( X_k^* \) be the minimizer of the corresponding function \( \varphi_{t_k} \), and

\[
E_k := \frac{2\mu}{\mu} \left( \eta_k \sigma^2 + \frac{\Delta^2}{\mu \eta_k^2} \right).
\]

Then taking into account \( \eta_k \geq \eta_* \), Corollary 5.4 directly implies

\[
\mathbb{E}\|X_{k+1} - X_{k+1}^*\|^2 \leq (1 - \mu\eta_k)^{T_k} \mathbb{E}\|X_k - X_k^*\|^2 + \frac{2\mu}{\mu} \left( \eta_k \sigma^2 + \frac{\Delta^2}{\mu \eta_k^2} \right)
\leq e^{-\mu\eta_k T_k} \mathbb{E}\|X_k - X_k^*\|^2 + E_k.
\]

We will verify by induction that the estimate \( \mathbb{E}\|X_{k+1} - X_{k+1}^*\|^2 \leq 2E_k \) holds for all indices \( k \). To see the base case, observe

\[
\mathbb{E}\|X_1 - X_1^*\|^2 \leq e^{-\mu\eta_0 T_0} \mathbb{E}\|X_0 - X_0^*\|^2 + E_0 \leq 2E_0.
\]
Assume next that the claim holds for index \( k - 1 \). We then conclude
\[
\mathbb{E}\|X_{k+1} - X_{k+1}^*\|^2 \leq e^{-\mu_0 T_k} \mathbb{E}\|X_k - X_k^*\|^2 + E_k
\]
\[
\leq \frac{1}{4} \mathbb{E}\|X_k - X_k^*\|^2 + E_k
\]
\[
\leq \frac{E_k}{2E_{k-1}} \mathbb{E}\|X_k - X_k^*\|^2 + E_k \leq 2E_{k-1},
\]
thereby completing the induction. Hence \( \mathbb{E}\|X_K - X_K^*\|^2 \leq 2E_{K-1} \).

Next, observe
\[
E_{K-1} - \sqrt[3]{54} \left( \frac{\Delta \sigma^2}{\mu^2} \right)^{2/3} = \frac{2 \sigma^2}{\mu} (\eta_{K-1} - \eta_*) = \frac{2 \sigma^2}{\mu} (\eta_0 - \eta_*) \leq \left( \frac{\Delta \sigma^2}{\mu^2} \right)^{2/3},
\]
so
\[
\mathbb{E}\|X_K - X_K^*\|^2 \leq 2(1 + \sqrt[3]{54}) \left( \frac{\Delta \sigma^2}{\mu^2} \right)^{2/3} \propto \mathcal{E}.
\]

Finally, note
\[
T \lesssim \frac{L}{\mu} \log \left( \frac{\mu LD}{\sigma^2} \right) + \frac{1}{\mu} \sum_{k=1}^{K-1} \frac{1}{\eta_k}
\]
and
\[
\sum_{k=1}^{K-1} \frac{1}{\eta_k} \leq 2L \sum_{k=1}^{K-1} 2^k \leq 2L \cdot 2^K = 8L \cdot 2^{K-2} \leq 8 \left( \frac{\sigma^2 \mu}{\Delta^2} \right)^{1/3} = \frac{8 \sigma^2}{\mu} \left( \frac{\Delta \sigma^2}{\mu^2} \right)^{-2/3} \propto \frac{\sigma^2}{\mu \mathcal{E}}.
\]
This completes the proof. \( \square \)

### 5.2 Tracking the minimizer: high probability guarantees

The proof strategy of Theorem 3.6 follows a similar argument as in [18, Claim D.1], which recursively controls the moment generating function of \( \|x_t - x_t^*\|^2 \). Namely, Lemma 5.2 in the regime \( \eta_t \leq 1/2L \) directly yields
\[
\|x_{t+1} - x_{t+1}^*\|^2 \leq (1 - \mu \eta_t) \|x_t - x_t^*\|^2 + 2\eta_t \|z_t, u_t\| \|x_t - x_t^*\| + 2\eta_t^2 \|z_t\|^2 + \frac{2 \Delta^2_t}{\mu \eta_t}, \quad (10)
\]
where we set \( u_t := \frac{x_t - x_t^*}{\|x_t - x_t^*\|} \) if \( x_t \) is distinct from \( x_t^* \) and set it to zero otherwise. The right-hand side has the form of a contraction factor, gradient noise, and drift. The goal is now to control the moment generating function \( \mathbb{E}[e^{A \|x_t - x_t^*\|^2}] \) through this recursion. The basic probabilistic tool for similar settings under bounded noise assumptions was developed in [18]. The following proposition is a slight generalization of [18, Claim D.1] to a light tail setting. The proof appears in the appendix for the sake of completeness (cf. Section A.2).

**Proposition 5.6 (Recursive control on MGF).** Consider scalar stochastic processes \((V_t), (D_t), \) and \((X_t)\) on a probability space with filtration \((\mathcal{H}_t)\), which are linked by the inequality
\[
V_{t+1} \leq \alpha_t V_t + D_t \sqrt{V_t} + X_t + \kappa_t
\]
for some deterministic constants \( \alpha_t \in (-\infty, 1] \) and \( \kappa_t \in \mathbb{R} \). Assume that the following properties hold.

- \( V_t \) is nonnegative and \( \mathcal{H}_t \)-measurable.
• $D_t$ is mean-zero sub-Gaussian conditioned on $\mathcal{H}_t$ with deterministic parameter $\sigma_t$:

$$
E[\exp(\lambda D_t) | \mathcal{H}_t] \leq \exp(\lambda^2 \sigma_t^2/2) \quad \text{for all } \lambda \in \mathbb{R}.
$$

• $X_t$ is nonnegative and sub-exponential conditioned on $\mathcal{H}_t$ with deterministic parameter $\nu_t$:

$$
E[\exp(\lambda X_t) | \mathcal{H}_t] \leq \exp(\lambda \nu_t) \quad \text{for all } 0 \leq \lambda \leq 1/\nu_t.
$$

Then the estimate

$$
E[\exp(\lambda V_{t+1})] \leq \exp(\lambda(\nu_t + \kappa_t))\exp\left(\lambda \left(\frac{1 + \alpha_t}{2}\right) V_t\right)
$$

holds for any $\lambda$ satisfying $0 \leq \lambda \leq \min\left\{\frac{1-\alpha_t}{2\nu_t^2}, \frac{1}{2\nu_t}\right\}$.

We may now use Proposition 5.6 to derive the following precise version of Theorem 3.6.

**Theorem 5.7** (High probability distance tracking). Suppose that Assumption 3.4 holds and let $\{x_t\}$ be the iterates produced by Algorithm 1 with constant learning rate $\eta \leq 1/2L$. Then there exists an absolute constant $c > 0$ such that for each $t$, the random variable

$$
\|x_t - x_t^*\|^2 - \left(1 - \frac{\mu \eta}{2}\right) \|x_0 - x_0^*\|^2
$$

is sub-exponential with parameter

$$
\nu := \frac{8\eta(c\sigma)^2}{\mu} + 4\left(\frac{\Delta}{\mu \eta}\right)^2.
$$

Consequently, for any specified $t \in \mathbb{N}$ and $\delta \in (0, 1)$, the estimate

$$
\|x_t - x_t^*\|^2 \leq \left(1 - \frac{\mu \eta}{2}\right) \|x_0 - x_0^*\|^2 + \left(\frac{8\eta(c\sigma)^2}{\mu} + 4\left(\frac{\Delta}{\mu \eta}\right)^2\right) \log \left(\frac{c}{\delta}\right)
$$

holds with probability at least $1 - \delta$.

**Proof.** Note first that under Assumption 3.4, there exists an absolute constant $c \geq 1$ such that $\|z_t\|^2$ is sub-exponential conditioned on $\mathcal{F}_t$ with parameter $c\sigma^2$ and $z_t$ is mean-zero sub-Gaussian conditioned on $\mathcal{F}_t$ with parameter $c\sigma$ for all $t$. Therefore $(z_t, u_t)$ is mean-zero sub-Gaussian conditioned on $\mathcal{F}_t$ with parameter $c\sigma$, while $\Delta_t^2$ is sub-exponential conditioned on $\mathcal{F}_t$ with parameter $\Delta^2$ by assumption. Thus, in light of inequality (10), we may apply Proposition 5.6 with $\mathcal{H}_t = \mathcal{F}_t$, $V_t = \|x_t - x_t^*\|^2$, $D_t = 2\eta \langle z_t, u_t \rangle$, $X_t = 2\eta^2 \|z_t\|^2 + 2\Delta_t^2/\mu \eta$, $\alpha_t = 1 - \mu \eta$, $\kappa_t = 0$, $\sigma_t = 2\eta c \sigma$, and $\nu_t = 2\eta^2 c\sigma^2 + 2\Delta^2/\mu \eta$, yielding the estimate

$$
E\left[\exp(\lambda \|x_{t+1} - x_{t+1}^*\|^2)\right] \leq \exp\left(\lambda \left(2\eta^2 c\sigma^2 + \frac{2\Delta^2}{\mu \eta}\right)\right)\exp\left(\lambda \left(1 - \frac{\mu \eta}{2}\right) \|x_t - x_t^*\|^2\right)
$$

for all $0 \leq \lambda \leq \min\left\{\frac{\mu}{8\eta(c\sigma)^2 + 4\Delta^2/\mu \eta}, \frac{1}{4\eta^2 c\sigma^2 + 4\Delta^2/\mu \eta}\right\}$.

Footnote: Explicitly, one can take any $c \geq 1$ such that $\|z_t\|^2$ is sub-exponential conditioned on $\mathcal{F}_t$ with parameter $c\sigma^2$ and $z_t$ is mean-zero sub-Gaussian conditioned on $\mathcal{F}_t$ with parameter $c\sigma$ for all $t$. 

18
Then the time horizon and we set \( D \geq \| (\Delta \sigma^2/\mu) \| x_0 - x_0^* \|^2 + \frac{2\Delta^2}{\mu \eta} \sum_{i=0}^{t-1} (1 - \frac{\mu \eta}{2})^i \) for all \( 0 \leq \lambda \leq \min \left\{ \frac{\mu}{8\eta(\sigma^2/2)} : \frac{4\eta \sigma^2}{\mu^2} + \frac{4\Delta^2}{\mu \eta} \right\} \). Moreover, taking into account \( c \geq 1 \) and \( \mu \eta \leq 1 \), we deduce
\[
\frac{4\eta \sigma^2}{\mu} + 4 \left( \frac{\Delta}{\mu \eta} \right)^2 \leq \nu
\]
and
\[
\frac{1}{\nu} = \frac{\mu}{8\eta(\sigma^2/2) + 4\Delta^2/\mu \eta} \leq \min \left\{ \frac{\mu}{8\eta(\sigma^2/2)}, \frac{1}{4\eta(\sigma^2/2^2 + 4\Delta^2/\mu \eta)} \right\}.
\]
We thus conclude
\[
\mathbb{E} \left[ \exp \left( \lambda \left( \| x_t - x_t^* \|^2 - \left( 1 - \frac{\mu \eta}{2} \right) \| x_0 - x_0^* \|^2 \right) \right) \right] \leq \exp(\lambda \nu) \quad \text{for all} \quad 0 \leq \lambda \leq 1/\nu.
\]

An application of Markov’s inequality completes the proof.

With Theorem 3.6 in hand, we can now prove a high probability efficiency estimate for the online proximal stochastic gradient method using a step-decay schedule, wherein the algorithm is implemented in epochs with the new learning rate chosen to be the midpoint between the current learning rate and \( \eta^* \). The following theorem is the precise form of the informal Theorem 3.7 (which, as before, holds trivially in the high drift-to-noise regime \( \Delta / \sigma \geq \sqrt{\mu / 16 L^3} \) with the constant learning rate \( \eta^* = 1/2L \)). The argument follows the same reasoning as in the proof of Theorem 5.5, with Theorem 3.6 playing the role of Corollary 5.4 while using a union bound over the epochs. The proof appears in the appendix (cf. Section A.3).

**Theorem 5.8** (Time to track with high probability). Suppose that Assumption 3.4 holds and that we are in the low drift-to-noise regime \( \Delta / \sigma \leq \sqrt{\mu / 16 L^3} \). Set \( \eta^* = (2\Delta^2 / \mu \sigma^2)^{1/3} \) and \( \mathcal{E} = (\Delta \sigma^2 / \mu^2)^{2/3} \). Suppose moreover that we have available an upper bound on the initial square distance \( D \geq \| x_0 - x_0^* \|^2 \). Consider running Algorithm 7 in \( k = 0, \ldots, K - 1 \) epochs, namely, set \( X_0 = x_0 \) and iterate the process

\[
X_{k+1} = PSG(X_k, \eta_k, T_k) \quad \text{for} \quad k = 0, \ldots, K - 1,
\]

where the number of epochs is
\[
K = 1 + \left\lfloor \log_2 \left( \frac{1}{L} \cdot \left( \frac{\sigma^2 \mu}{\Delta^2} \right)^{1/3} \right) \right\rfloor
\]
and we set
\[
\eta_0 = \frac{1}{2L}, \quad T_0 = \left\lfloor \frac{4L}{\mu} \log \left( \frac{\mu LD}{\sigma^2} \right) \right\rfloor \quad \text{and} \quad \eta_k = \frac{\eta_{k-1} + \eta^*}{2}, \quad T_k = \left\lfloor \frac{2\log(4)}{\mu \eta_k} \right\rfloor \quad \forall k \geq 1.
\]

Then the time horizon \( T = T_0 + \cdots + T_{K-1} \) satisfies
\[
T \leq \frac{L}{\mu} \log \left( \frac{\mu LD}{\sigma^2} \right) + \frac{\sigma^2}{\mu^2 \mathcal{E}} < \frac{L}{\mu} \log \left( \frac{L}{\mathcal{E}} \right) + \frac{\sigma^2}{\mu^2 \mathcal{E}},
\]

19
and for any specified $\delta \in (0, 1)$, the corresponding tracking error satisfies
\[ \|X_K - X^*_K\|^2 \lesssim \mathcal{E} \log \left( \frac{e}{\delta} \right) \]
with probability at least $1 - K\delta$, where $X^*_K$ denotes the minimizer of $\varphi_T$.

In both Theorems 5.5 and 5.8 the step-decay schedule occurs over
\[ K \lesssim \log_2 \left( \frac{1}{\mathcal{L}} \left( \frac{\sigma^2 \mu}{\Delta^2} \right)^{1/3} \right) \]
ePOCHS, with the initial epoch taking $T_0 \lesssim \frac{L}{\mu} \log \left( \frac{\mu L D}{\sigma^2} \right)$ steps with step size $\eta_0 = 1/2L$ and, for $k \geq 1$, the $k^{th}$ epoch utilizing step size $\eta_k = \eta_* + \frac{\eta_0 - \eta_*}{2} \text{ for } T_k \lesssim \frac{1}{\mu k} \text{ steps.}$ Thus, if $\eta(t)$ denotes the step size used $t$ steps after the initial epoch, then $\eta(t) \lesssim \eta_* + a \cdot 2^{-bt}$, where $a = \eta_0 - \eta_*$ and $b = \frac{\mu K}{2L^2 \pi}$.

5.3 Tracking the minimal value: bounds in expectation

We turn now to tracking the minimal value. Throughout this section, we suppose $\eta_t \leq 1/2L$ and that the regularizers $\tau_t \equiv r$ are identical for all times $t$. Setting the stage, fix a time horizon $t$. Then Lemma 5.1 directly yields the following one-step improvement guarantee for all indices $i$:
\[ 2\eta_i(x_{i+1} - x_i^*) \leq (1 - \mu \eta_i)\|x_i - x_i^*\|^2 - \|x_{i+1} - x_i^*\|^2 + 2\eta_i(z_i, x_i - x_i^*) + 2\eta_i^2\|z_i\|^2. \]
Notice that this provides an estimate on the “wrong quantity” $\varphi_i(x_{i+1}) - \varphi_i(x_i^*)$, whereas we would like to obtain an estimate on the suboptimality gap $\varphi_i(x_{i+1}) - \varphi_i(x_i^*)$. In words, we would like to replace $\varphi_i$ with $\varphi_t$, while the controlling the incurred error. Lemma 5.9 shows that the incurred error can be controlled by the gradient drift $G_{i,t}$, while Lemma 5.10 deduces the desired one-step improvement guarantee on $\varphi_t$.

**Lemma 5.9** (Gradient drift vs. gap variation). For all indices $i,t \in \mathbb{N}$ and points $x, y \in \text{dom } r$, the estimate holds:
\[ \|[\varphi_i(y) - \varphi_i(x)] - [\varphi_t(y) - \varphi_t(x)]\| \leq G_{i,t}\|y - x\|. \]

**Proof.** Taking into account $\tau_t \equiv r$ and using the fundamental theorem of calculus, we may write
\[ [\varphi_i(y) - \varphi_i(x)] - [\varphi_t(y) - \varphi_t(x)] = \int_0^1 \langle \nabla f_i(x + s(y - x)) - \nabla f_i(x + s(y - x)), y - x \rangle \, ds \]
\[ \leq G_{i,t}\|y - x\|, \]
where the last inequality follows from Cauchy-Schwarz. Switching $x$ and $y$ completes the proof. $lacksquare$

**Lemma 5.10** (One-step improvement). For all indices $i,t \in \mathbb{N}$, points $x \in \text{dom } r$, and arbitrary $\alpha > 0$, we have
\[ 2\eta_i(\varphi_i(x_{i+1}) - \varphi_t(x)) \leq (1 - \mu \eta_i)\|x_i - x\|^2 - (1 - \alpha \eta_i)\|x_{i+1} - x\|^2 + 2\eta_i(z_i, x_i - x) + 2\eta_i^2\|z_i\|^2 + \frac{\eta_i}{\alpha} G_{i,t}^2. \]

**Proof.** This follows immediately from combining Lemmas 5.1 and 5.9 and Young’s inequality, $2G_{i,t}\|x_{i+1} - x\| \leq \alpha^{-1} G_{i,t}^2 + \alpha\|x_{i+1} - x\|^2$. $lacksquare$

Turning the estimate in Lemma 5.10 into an efficiency guarantee on the average iterate is essentially standard and follows for example from the averaging techniques in [13 14 15 25]. The end
result is summarized in the following proposition, while the description of the key averaging lemma is placed in the appendix (cf. Section A.4).

**Proposition 5.11** (One-step improvement along the average). Let \{\hat{x}_t\} be the iterates produced by Algorithm 3 with constant step size \(\eta \leq 1/2L\); thus, setting \(\hat{\rho} := \mu \eta / (2 - \mu \eta)\), we have \(\hat{x}_0 = x_0\) and \(\hat{x}_t = (1 - \hat{\rho}) \hat{x}_{t-1} + \hat{\rho} x_t\) for all \(t \geq 1\). Then the following bound holds for all \(t \geq 0\) and \(x \in \text{dom } r\):

\[
\varphi_t(\hat{x}_t) - \varphi_t(x) \leq (1 - \hat{\rho})^t \left( \varphi_t(x_0) - \varphi_t(x) + \frac{\mu}{4} \|x_0 - x\|^2 \right) + \hat{\rho} \sum_{i=0}^{t-1} \langle z_i, x_i - x \rangle (1 - \hat{\rho})^{t-1-i} + \hat{\rho} \sum_{i=0}^{t-1} \|z_i\|^2 (1 - \hat{\rho})^{t-1-i}.
\]

**Proof.** Setting \(\alpha = \mu / 2\) in Lemma 5.10 we obtain the following recursion for all indices \(k \geq 0\) and points \(x \in \text{dom } r\):

\[
\rho_k(\varphi_k(x_t) - \varphi_k(x)) \leq (1 - c_1 \rho)V_{t-1} - (1 + c_2 \rho)V_t + \omega_t,
\]

where \(\rho = 2\eta, c_1 = \mu / 2, c_2 = -\mu / 4, V_t = \|x_t - x\|^2\), and \(\omega_t = 2\eta \langle z_{t-1}, x_t - x \rangle + 2\eta^2 \|z_{t-1}\|^2 + (2\eta / \mu)G_{t-1,k}\). The result follows by applying the averaging Lemma A.1 with \(h = \varphi_t - \varphi_t(x)\).

Taking expectations in Proposition 5.11 we obtain the following precise version of Theorem 4.2.

**Corollary 5.12** (Expected function gap). Suppose that Assumption 4.1 holds, let \(\{\hat{x}_t\}\) be the iterates produced by Algorithm 3 with constant step size \(\eta \leq 1/2L\), and set \(\varphi := \mu \eta / (2 - \mu \eta)\). Then the following bound holds for all \(t \geq 0\):

\[
\mathbb{E}\left[ \varphi_t(\hat{x}_t) - \varphi^*_t \right] \leq (1 - \hat{\rho})^t \mathbb{E}\left[ \varphi_t(x_0) - \varphi^*_t + \frac{\mu}{4} \|x_0 - x^*_t\|^2 \right] + \eta \sigma^2 + \frac{8\Delta^2}{\mu \eta^2}.
\]

Consequently, we have

\[
\mathbb{E}\left[ \varphi_t(\hat{x}_t) - \varphi^*_t \right] \lesssim (1 - \hat{\rho})^t (\varphi_0(x_0) - \varphi^*_0) + \eta \sigma^2 + \frac{\Delta^2}{\mu \eta^2}
\]

for all \(t \geq 0\), and the following asymptotic error bound holds:

\[
\limsup_{t \to \infty} \mathbb{E}\left[ \varphi_t(\hat{x}_t) - \varphi^*_t \right] \leq \eta \sigma^2 + \frac{8\Delta^2}{\mu \eta^2}.
\]

**Proof.** The bound (12) follows by setting \(x = x^*_t\) in Proposition 5.11 taking expectations, and noting

\[
\sum_{i=0}^{t-1} \mathbb{E}||z_i||^2 (1 - \hat{\rho})^{t-1-i} \leq \frac{\sigma^2}{\hat{\rho}} \quad \text{and} \quad \sum_{i=0}^{t-1} \mathbb{E}\left[ G_{i,t,k}^2 \right] (1 - \hat{\rho})^{t-1-i} \leq \frac{(\mu \Delta)^2 (2 - \hat{\rho})}{\hat{\rho}^3}
\]

by Assumption 4.1. Next, applying Lemma 5.9 and Young’s inequality together with the \(\mu\)-strong convexity of \(\varphi_0\) and Lemma 2.4 yields

\[
\varphi_t(x_0) - \varphi^*_t + \frac{\mu}{4} \|x_0 - x^*_t\|^2 \leq 3(\varphi_0(x_0) - \varphi^*_0) + 2\mu^{-1}G_{0,t}^2,
\]

and then taking expectations and invoking Assumption 4.1 gives

\[
\mathbb{E}\left[ \varphi_t(x_0) - \varphi^*_t + \frac{\mu}{4} \|x_0 - x^*_t\|^2 \right] \leq 3(\varphi_0(x_0) - \varphi^*_0) + 2\mu \Delta^2 \sigma^2.
\]

Further, the inequality

\[
e^{-\mu \eta t/2} \mu^2 \leq 16 / \mu \eta^2 \quad \forall \mu, \eta, t > 0
\]

(15)
combines with inequality \([14]\) to yield
\[
\left(1 - \frac{\mu \eta}{2}\right)^t \cdot \mathbb{E}\left[\varphi_t(x_0) - \varphi_t^* + \frac{\mu}{4}\|x_0 - x_t^*\|^2\right] \leq 3\left(1 - \frac{\mu \eta}{2}\right)^t (\varphi_0(x_0) - \varphi_0^*) + \frac{32\Delta^2}{\mu \eta^2},
\]
whence the remaining assertions of the corollary follow.

We may now apply Corollary \([5.12]\) to obtain the formal version of Theorem \([4.3]\), the proof closely follows that of Theorem \([5.5]\) and is included in the appendix (cf. Section \([A.5]\)).

**Theorem 5.13** (Time to track in expectation). Suppose that Assumption \([I]\) holds and that we are in the low drift-to-noise regime \(\Delta/\sigma < \sqrt{\mu/16L^3}\). Set \(\eta_* = (2\Delta^2/\mu \sigma^2)^{1/3}\) and \(\mathcal{G} = \mu(\Delta \sigma^2/\mu^2)^{2/3}\). Suppose moreover that we have available a positive upper bound on the initial gap \(D = \varphi_0(x_0) - \varphi_0^*\). Consider running Algorithm \([2]\) in \(k = 0, \ldots, K - 1\) epochs, namely, set \(X_0 = x_0\) and iterate the process
\[
X_{k+1} = \frac{\text{PSG}}{X_k, \eta_k, T_k}\quad \text{for } k = 0, \ldots, K - 1,
\]
where the number of epochs is
\[
K = 1 + \left\lceil \log_2 \left(1 - \frac{\mu^2 \mathcal{G}}{L \cdot \left(\frac{\sigma \mu \Delta}{2}\right)^{1/3}}\right) \right\rceil,
\]
and we set
\[
\eta_0 = \frac{1}{2L}, \quad T_0 = \left[\frac{4L}{\mu} \log \left(\frac{LD}{\sigma^2}\right)\right] \quad \text{and} \quad \eta_k = \frac{\eta_{k-1} + \eta_*}{2}, \quad T_k = \left[\frac{2\log(12)}{\mu \eta_k}\right] \quad \forall k \geq 1.
\]
Then the time horizon \(T = T_0 + \cdots + T_{K-1}\) satisfies
\[
T \lesssim \frac{L}{\mu} \log \left(\frac{LD}{\sigma^2}\right) + \frac{\sigma^2}{\mu \mathcal{G}} < \frac{L}{\mu} \log \left(\frac{D}{\mathcal{G}}\right) + \frac{\sigma^2}{\mu \mathcal{G}}
\]
and the corresponding tracking error satisfies \(\mathbb{E}[\varphi_T(X_K) - \varphi_T^*] \lesssim \mathcal{G}\).

### 5.4 Tracking the minimal value: high probability guarantees

In this section, we derive the high probability analogues of the results in Section \([5.3]\). In light of Proposition \([5.11]\) we seek upper bounds on the sums
\[
\sum_{i=0}^{t-1} \langle z_i, x_i - x_t^* \rangle (1 - \hat{\rho})^{t-1-i}, \quad \sum_{i=0}^{t-1} \|z_i\|^2 (1 - \hat{\rho})^{t-1-i}, \quad \sum_{i=0}^{t-1} G_{i,t}^2 (1 - \hat{\rho})^{t-1-i}
\]
that hold with high probability. The last two sums can easily be estimated under boundedness or light tail assumptions on \(\|z_i\|\) and \(G_{i,t}\). Controlling the first sum is more challenging because the error \(\|x_i - x_t^*\|\) may in principle grow large. In order to control this term, we will use a remarkable generalization of Freedman’s inequality, recently proved in \([18]\) for the purpose of analyzing the stochastic gradient method on static nonsmooth problems (without a regularizer).

The main idea is as follows. Fix a horizon \(t\), assume \(\mathbb{E}[z_i | \mathcal{F}_{i,t}] = 0\) for all \(0 \leq i < t\) (recall that \(\mathcal{F}_{i,t} := \sigma(\mathcal{F}_i, x_t)\)), and define the martingale difference sequence
\[
d_i := \langle z_i, x_i - x_t^* \rangle (1 - \hat{\rho})^{t-1-i}
\]
adapted to the filtration \((\mathcal{F}_{i+1,t})_{i=0}^{t-1}\). Roughly speaking, under mild assumptions, the total conditional variance of the corresponding martingale \(\sum_{i=0}^{t-1} d_i\) can be bounded above by an affine transformation of itself, i.e., by an affine combination of the sequence \(\{d_i\}_{i=0}^{t-1}\). In this way, the martingale is self-regulating. This is the content of the following proposition. The proof amounts to algebraic manipulation and is placed in the appendix (cf. Section \([A.6]\)).
Proposition 5.14 (Self-regulation). Let \( \{x_t\} \) be the iterates produced by Algorithm 1 with constant step size \( \eta \leq 1/2L \), and set \( \hat{\rho} := \mu \eta / (2 - \mu \eta) \). Then the following holds for all indices \( t \geq 1 \):

\[
\sum_{i=0}^{t-1} \alpha_j (z_j, x_j - x^*_i)(1 - \hat{\rho})^{t-1-j} + \beta_t,
\]

where we set

\[
\alpha_j := 2\eta \sigma^2 \sum_{i=j+1}^{t-1} (1 - \hat{\rho})^{t-2-i}
\]

for \( j = 0, \ldots, t-1 \) (with \( \alpha_{t-1} = 0 \)) and

\[
\beta_t := (1 - \hat{\rho})^{t-1} \left( \|x_0 - x^*_0\|^2 + \Delta^2 t^2 \right) \frac{2\sigma^2}{\hat{\rho}} + \frac{2\eta^2 \sigma^4}{\hat{\rho}^3} + \frac{3\mu \Delta^2 \eta \sigma^2}{\hat{\rho}^4}.
\]

Proof. By Proposition 5.14, it suffices to note

\[
\|x_0 - x^*_0\|^2 \leq 2\left( \|x_0 - x^*_0\|^2 + \Delta^2 t^2 \right)
\]

(using Lemma 2.4),

\[
\sum_{j=0}^{t-2} \|z_j\|^2 (1 - \hat{\rho})^{t-2-j} \leq \frac{\sigma^2}{\hat{\rho}},
\]

and

\[
\sum_{j=0}^{t-2} G^2_{j,t} (1 - \hat{\rho})^{t-2-j} \leq \frac{(\mu \Delta)^2}{1 - \hat{\rho}} \sum_{j=0}^{t-2} (t - j)^2 (1 - \hat{\rho})^{t-j-1} \leq \frac{(\mu \Delta)^2}{1 - \hat{\rho}} \cdot \frac{2 - \hat{\rho}}{\hat{\rho}^3} \leq \frac{3(\mu \Delta)^2}{\hat{\rho}^3},
\]

where the last inequality holds because \( \hat{\rho} \leq 1/3 \). \( \square \)

In order to bound the self-regulating martingale \( \sum_{i=0}^{t-1} d_i \), we will use the generalized Freedman inequality developed in [13], or rather a direct consequence thereof.

Theorem 5.16 (Consequence of generalized Freedman). Let \( (D_i)_{i=0}^n \) and \( (V_i)_{i=0}^n \) be scalar stochastic processes on a probability space with filtration \( (\mathcal{H}_i)_{i=0}^{n+1} \) satisfying

\[
\mathbb{E}[\exp(\lambda D_i) | \mathcal{H}_i] \leq \exp(\lambda^2 V_i / 2) \quad \forall \lambda \geq 0.
\]

Suppose that \( D_i \) is \( \mathcal{H}_{i+1} \)-measurable with \( \mathbb{E}[D_i] < \infty \) and \( \mathbb{E}[D_i | \mathcal{H}_i] = 0 \), and that \( V_i \) is nonnegative and \( \mathcal{H}_i \)-measurable. Suppose moreover that there are constants \( \alpha_0, \ldots, \alpha_n \geq 0 \), \( \delta \in [0,1] \), and
\( \beta(\delta) \geq 0 \) satisfying
\[
\mathbb{P}\left\{ \sum_{i=0}^{n} V_i \leq \sum_{i=0}^{n} \alpha_i D_i + \beta(\delta) \right\} \geq 1 - \delta.
\]

Then for all \( \tau > 0 \), the following bound holds:
\[
\mathbb{P}\left\{ \sum_{i=0}^{n} D_i \geq \tau \right\} \leq \delta + \exp\left(-\frac{\tau}{4\alpha + 8\beta(\delta)/\tau}\right),
\]
where we set \( \alpha := \max\{\alpha_0, \ldots, \alpha_n\} \).

Combining Corollary 5.15 and Theorem 5.16 yields the following proposition.

**Proposition 5.17** (Noise martingale tail bound). Fix \( t \geq 1 \). Under the assumptions of Corollary 5.15 assume further that we have \( \mathbb{E}[z_i | F_i,t] = 0 \) for all \( 0 \leq i < t \). Then the following holds for all \( \tau > 0 \):
\[
\mathbb{P}\left\{ \sum_{i=0}^{t-1} (z_i, x_i - x^*_i)(1 - \hat{\rho})^{t-1-i} \geq \tau \right\} \leq \exp\left(-\frac{\tau}{4\alpha + 8\beta(\delta)/\tau}\right),
\]
where \( \alpha := 3\eta\sigma^2/\hat{\rho} \) and
\[
\beta_t := (1 - \hat{\rho})^{t-1} \left( ||x_0 - x^*_0||^2 + \Delta^2 t^2 \right) \frac{2\sigma^2}{\hat{\rho}} + \frac{2\eta^2 \sigma^4}{\hat{\rho}^2} + \frac{3\mu \Delta^2 \eta \sigma^2}{\hat{\rho}^4}.
\]

**Proof.** Let \( D_i = (z_i, x_i - x^*_i)(1 - \hat{\rho})^{t-1-i} \) and \( V_i = \sigma^2 ||x_i - x^*_i||^2 (1 - \hat{\rho})^{2(t-1-i)} \) for all \( 0 \leq i < t \), and consider the refinement \( (H_i)_{i \geq 0} \) of \( (F_i)_{i \geq 0} \) given by \( H_i := F_{i,t} \). For each \( 0 \leq i < t \), it follows that \( D_i \) is \( H_{i+1} \)-measurable, \( \mathbb{E}[D_i] < \infty \) (since \( ||z_i|| \leq \sigma \) and \( ||x_i - x^*_i|| \in L^2(\Omega) \)), \( \mathbb{E}[D_i | H_i] = 0 \) (since \( \mathbb{E}[z_i | F_{i,t}] = 0 \)), and \( V_i \) is nonnegative and \( H_i \)-measurable; moreover, by Hoeffding's lemma, we have
\[
\mathbb{E}[\exp(\lambda D_i) | H_i] \leq \exp(\lambda^2 V_i/2) \quad \forall \lambda \in \mathbb{R}.
\]
Furthermore, Corollary 5.15 shows
\[
\sum_{i=0}^{t-1} V_i \leq \sum_{i=0}^{t-1} \alpha_i D_i + \beta_t,
\]
where \( 0 \leq \alpha_i \leq \alpha \) for all \( 0 \leq i < t \). An application of Theorem 5.16 with \( \delta = 0 \) completes the proof.

A quick computation shows that given \( \delta \in (0, 1/e] \), we may take
\[
\tau = (2 + \sqrt{5})\sqrt{8\beta_t \log(1/\delta)}
\]
in Proposition 5.17 to obtain
\[
\mathbb{P}\left\{ \sum_{i=0}^{t-1} (z_i, x_i - x^*_i)(1 - \hat{\rho})^{t-1-i} < (2 + \sqrt{5})\sqrt{8\beta_t \log(1/\delta)} \right\} \geq 1 - \delta.
\]
Together with Proposition 5.11 this establishes the following theorem, which is a sharper version of Theorem 4.5

**Theorem 5.18** (Function gap with high probability). Suppose that Assumption 4.4 holds, and let \( \{\hat{x}_t\} \) be the average iterates produced by Algorithm 3 with constant learning rate \( \eta \in (0, 1/2L] \). Then for any specified \( t \in \mathbb{N} \) and \( \delta \in (0, 1/e] \), the following estimate holds with probability at least \( 1 - \delta \):
\[
\varphi_t(\hat{x}_t) - \varphi^*_t \leq (1 - \hat{\rho})^t \left( \varphi_t(x_0) - \varphi^*_t + \frac{\mu}{4} ||x_0 - x^*_t||^2 \right) + \eta \sigma^2 + \frac{8\Delta^2}{\mu \eta^2} + (2 + \sqrt{5})\hat{\rho} \sqrt{8\beta_t \log \left( \frac{1}{\delta} \right)}.
\]
where $\hat{\rho} := \mu \eta / (2 - \mu \eta)$ and

$$\beta_t := (1 - \hat{\rho})^{t-1} \left( \|x_0 - x_0^*\|^2 + \Delta^2 t^2 \right) \frac{2\sigma^2}{\hat{\rho}^2} + \frac{2\eta^2 \sigma^4}{\hat{\rho}^2} + \frac{3\mu \Delta^2 \eta \sigma^2}{\hat{\rho}^4}.$$

**Remark 5.19.** To see that Theorem 5.18 entails Theorem 4.5, fix $t \in \mathbb{N}$ and observe

$$\hat{\rho} \sqrt{8\beta_t} \leq 4 \left( (1 - \hat{\rho})^t (\|x_0 - x_0^*\|^2 + \Delta^2 t^2) \mu \eta \sigma^2 + \eta \sigma^2 + \sqrt{6} \frac{\Delta \sigma}{\sqrt{\mu \eta}} \right),$$

while the AM-GM inequality implies

$$2 \sqrt{(1 - \hat{\rho})^t (\|x_0 - x_0^*\|^2 + \Delta^2 t^2) \mu \eta \sigma^2} \leq (1 - \hat{\rho})^t (\mu \|x_0 - x_0^*\|^2 + \mu \Delta^2 t^2) + \eta \sigma^2,$$

inequality (15) implies

$$(1 - \hat{\rho})^t (\mu \|x_0 - x_0^*\|^2 + \mu \Delta^2 t^2) \leq 2(1 - \hat{\rho})^t (\varphi_0(x_0) - \varphi_0^*) + \frac{16 \Delta^2}{\mu \eta^2},$$

and Young’s inequality implies

$$\frac{2\Delta \sigma}{\sqrt{\mu \eta}} \leq \eta \sigma^2 + \frac{\Delta^2}{\mu \eta^2}.$$

Hence

$$\hat{\rho} \sqrt{8\beta_t} \lesssim (1 - \hat{\rho})^t (\varphi_0(x_0) - \varphi_0^*) + \eta \sigma^2 + \frac{\Delta^2}{\mu \eta^2}.$$

Further, inequalities (13) and (15) together with Assumption 4.4 imply

$$(1 - \hat{\rho})^t (\varphi_0(x_0) - \varphi_0^*) + \frac{\mu}{4} \|x_0 - x_0^*\|^2 \lesssim 3(1 - \hat{\rho})^t (\varphi_0(x_0) - \varphi_0^*) + \frac{32 \Delta^2}{\mu \eta^2}.$$

Thus, under the assumptions of Theorem 5.18 it follows that for all $t \in \mathbb{N}$ and $\delta \in (0, 1/e]$, the estimate

$$\varphi_t(x_t) - \varphi_t^* \leq (1 - \hat{\rho})^t (\varphi_t(x_0) - \varphi_t^* + \frac{\mu}{4} \|x_0 - x_t^*\|^2) + \eta \sigma^2 + \frac{8 \Delta^2}{\mu \eta^2} + (2 + \sqrt{5}) \hat{\rho} \sqrt{8\beta_t} \log \left( \frac{1}{\delta} \right)$$

$$\lesssim \left( (1 - \hat{\rho})^t (\varphi_0(x_0) - \varphi_0^*) + \eta \sigma^2 + \frac{\Delta^2}{\mu \eta^2} \right) \log \left( \frac{1}{\delta} \right)$$

holds with probability at least $1 - \delta$.

We may now apply Theorem 4.5 to obtain the formal version of Theorem 4.6; the proof closely follows that of Theorem 5.8 and is included in the appendix (cf. Section A.7).

**Theorem 5.20** (Time to track with high probability). Suppose that Assumption 4.4 holds and that we are in the low drift-to-noise regime $\Delta / \sigma < \sqrt{\mu / 16L^3}$. Set $\eta_* = (2\Delta^2 / \mu \sigma^2)^{1/3}$ and $G = \mu (\Delta \sigma^2 / \mu \sigma^4)^{2/3}$. Suppose moreover that we have available a positive upper bound on the initial gap $D \geq \varphi_0(x_0) - \varphi_0^*$. Fix $\delta \in (0, 1/e]$ and consider running Algorithm 4 in $k = 0, \ldots, K - 1$ epochs, namely, set $X_0 = x_0$ and iterate the process

$$X_{k+1} = PSG(X_k, \eta_k, T_k) \quad \text{for} \quad k = 0, \ldots, K - 1,$$

where the number of epochs is

$$K = 1 + \left\lceil \log_2 \left( \frac{1}{L} \cdot \left( \frac{\sigma^2 \mu}{\Delta^2} \right)^{1/3} \right) \right\rceil,$$
and we set
\[ \eta_0 = \frac{1}{2L}, \quad T_0 = \left\lfloor \frac{4L}{\mu} \log \left( \frac{LD}{\sigma^2} \right) \right\rfloor \quad \text{and} \quad \eta_k = \frac{\eta_{k-1} + \eta_*}{2}, \quad T_k = \left\lfloor \frac{2 \log \left( \frac{4c \log(1/\delta)}{\mu \eta_k} \right)}{\eta_k} \right\rfloor \]
for all \( k \geq 1 \), where \( c > 0 \) is the absolute constant furnished by the bound \( \delta \). Then the time horizon \( T = T_0 + \cdots + T_{K-1} \) satisfies
\[ T \lesssim \frac{L}{\mu} \log \left( \frac{LD}{\sigma^2} \right) + \frac{\sigma^2}{\mu G} \log \left( \log \left( \frac{1}{\delta} \right) \right) < \frac{L}{\mu} \log \left( \frac{D}{G} \right) + \frac{\sigma^2}{\mu G} \log \left( \log \left( \frac{1}{\delta} \right) \right) \]
and the corresponding tracking error satisfies
\[ \varphi_T(X_K) - \varphi_T^* \lesssim \mathcal{G} \log \left( \frac{1}{\delta} \right) \]
with probability at least \( 1 - K \delta \).

Using similar proof techniques, we obtain analogues of Theorem 5.18 and Theorem 5.20 under the more general Assumption 4.7. First is the following sharper version of Theorem 4.8.

**Theorem 5.21** (Function gap with high probability). Suppose that Assumption 4.7 holds, and let \( \{\hat{x}_i\} \) be the average iterates produced by Algorithm 4 with constant learning rate \( \eta \in (0, 1/2L] \). Then there is an absolute constant \( c > 0 \) such that for any specified \( t \in \mathbb{N} \) and \( \delta \in (0, 1) \), the following estimate holds with probability at least \( 1 - \delta \):

\[
\varphi_t(\hat{x}_t) - \varphi_t^* \leq (1 - \hat{\rho})^t \left( \varphi_t(x_0) - \varphi_t^* + \frac{\mu}{4} \|x_0 - x_t^*\|^2 \right) + \eta(\sigma) \left[ 2 \Delta^2 \frac{\rho}{\mu} + \frac{2 \eta^2(\sigma)}{\rho^2} + \frac{3 \mu \Delta^2 \eta(\sigma)^2}{\rho^4} \right] \log \left( \frac{12 e}{\delta} \right),
\]

where \( \hat{\rho} := \mu \eta / (2 - \mu \eta) \) and
\[
\beta_t(\delta/4) := \left( (1 - \hat{\rho})^{t-1} \left( \|x_0 - x_0^*\|^2 + \Delta^2 t^2 \right) \right) \frac{2 \eta^2(\sigma)}{\rho^2} + \frac{3 \mu \Delta^2 \eta(\sigma)^2}{\rho^4} \log \left( \frac{12 e}{\delta} \right).
\]

**Proof.** By Assumption 4.7 there exists an absolute constant \( c \geq 1 \) such that \( \|z_i\|^2 \) is sub-exponential conditioned on \( F_{i,t} \) with parameter \( \sigma^2 \) and \( z_i \) is mean-zero sub-Gaussian conditioned on \( F_{i,t} \) with parameter \( \sigma \) for all \( i \leq t \). Then for each \( 0 \leq i < t \), the \( F_{i+t-1,t} \)-measurable random variable \( \langle z_i, x_i - x_t^* \rangle \) is mean-zero sub-Gaussian conditioned on \( F_{i,t} \) with parameter \( \sigma \|x_i - x_t^*\| \), so
\[
\mathbb{E} \left[ \exp \left( \lambda \langle z_i, x_i - x_t^* \rangle (1 - \hat{\rho})^{t-1-i} \right) \mid F_{i,t} \right] \leq \exp \left( \lambda^2 \sigma^2 \|x_i - x_t^*\|^2 (1 - \hat{\rho})^{2(t-1-i)}/2 \right) \quad \forall \lambda \in \mathbb{R}.
\]

Further, Proposition 5.14 yields the total conditional variance bound
\[
\sum_{i=0}^{t-1} (\sigma \sigma)^2 \|x_i - x_t^*\|^2 (1 - \hat{\rho})^{2(t-1-i)} \leq \sum_{j=0}^{t-2} \alpha_j \langle z_j, x_j - x_t^* \rangle (1 - \hat{\rho})^{t-1-j} + R_t,
\]
where \( 0 \leq \alpha_j \leq 3 \eta(\sigma)^2 / \hat{\rho} \) for all \( 0 \leq j \leq t - 2 \) and
\[
R_t = (1 - \hat{\rho})^{t-1} \|x_0 - x_t^*\|^2 \frac{\sigma \sigma}{\hat{\rho}} + \frac{2 \eta^2(\sigma)^2}{\rho^2} \sum_{j=0}^{t-2} \|z_j\|^2 (1 - \hat{\rho})^{t-2-j} + \frac{\eta(\sigma)^2}{\mu \hat{\rho}} \sum_{j=0}^{t-2} C_j (1 - \hat{\rho})^{t-2-j}.
\]

Observe that for all \( n \geq 0 \), the sum \( \sum_{i=0}^{n} \|z_i\|^2 (1 - \hat{\rho})^{n-i} \leq (\sigma \sigma)^2 / \hat{\rho} \), so Markov’s inequality implies
\[
\mathbb{P} \left\{ \sum_{i=0}^{n} \|z_i\|^2 (1 - \hat{\rho})^{n-i} \leq \frac{(\sigma \sigma)^2}{\hat{\rho}} \log \left( \frac{e}{\delta} \right) \right\} \geq 1 - \delta \quad \forall \delta \in (0, 1).
\]
Moreover, for all $0 \leq n < t$, it follows from Assumption 4.7 and Lemma 2.4 that $\|x_0 - x_t^*\|^2$ is sub-exponential with parameter $q(t) := 2(\|x_0 - x_0^*\|^2 + \Delta^2 t^2)$ and $\sum_{i=0}^{n} G^2_{i,t}(1-\hat{\rho})^{n-i}$ is sub-exponential with parameter

$$\sum_{i=0}^{n} (\mu \Delta)^2 (t-i)^2(1-\hat{\rho})^{n-i} = (\mu \Delta)^2 (1-\hat{\rho})^{n+1-t} \sum_{i=0}^{n} (t-i)^2(1-\hat{\rho})^{t-i-1} \leq \frac{2(\mu \Delta)^2}{\hat{\rho}^2(1-\hat{\rho})^{t-1-n}},$$

so Markov’s inequality implies

$$\mathbb{P}\left\{ \|x_0 - x_t^*\|^2 \leq q(t) \log \left( \frac{e}{\delta} \right) \right\} \geq 1 - \delta \quad \forall \delta \in (0, 1)$$

and

$$\mathbb{P}\left\{ \sum_{i=0}^{n} G^2_{i,t}(1-\hat{\rho})^{n-i} \leq \frac{2(\mu \Delta)^2}{\hat{\rho}^2(1-\hat{\rho})^{t-1-n}} \log \left( \frac{e}{\delta} \right) \right\} \geq 1 - \delta \quad \forall \delta \in (0, 1).$$

Thus, for any fixed $t \geq 1$, a union bound reveals

$$\mathbb{P}\left\{ R_t \leq \left( (1-\hat{\rho})^{t-1} q(t) \frac{(c\sigma)^2}{\hat{\rho}^2} + \frac{2\eta^2(c\sigma)^4}{\hat{\rho}^4} + \frac{3\mu \Delta^2 \eta(c\sigma)^2}{\hat{\rho}^4} \right) \log \left( \frac{3\epsilon}{\delta} \right) \right\} \geq 1 - \delta \quad \forall \delta \in (0, 1).$$

Consequently, Theorem 5.16 implies that the following bound holds for all $\delta \in (0, 1)$ and $\tau > 0$:

$$\mathbb{P}\left\{ \sum_{i=0}^{t-1} (z_i, x_i - x_t^*) (1-\hat{\rho})^{t-1-i} \geq \tau \right\} \leq \delta + \exp \left( -\frac{\tau}{4\alpha + 8\beta_t(\delta)/\tau} \right),$$

where $\alpha := 3\eta(c\sigma)^2/\hat{\rho}$ and

$$\beta_t(\delta) := \left( (1-\hat{\rho})^{t-1} q(t) \frac{(c\sigma)^2}{\hat{\rho}^2} + \frac{2\eta^2(c\sigma)^4}{\hat{\rho}^4} + \frac{3\mu \Delta^2 \eta(c\sigma)^2}{\hat{\rho}^4} \right) \log \left( \frac{3\epsilon}{\delta} \right).$$

As before, a quick computation shows that given $\delta \in (0, 1/e]$, we may take

$$\tau = (2 + \sqrt{5}) \sqrt{8\beta_t(\delta)} \log \left( \frac{1}{\delta} \right)$$

in (18) to obtain

$$\mathbb{P}\left\{ \sum_{i=0}^{t-1} (z_i, x_i - x_t^*) (1-\hat{\rho})^{t-1-i} < (2 + \sqrt{5}) \sqrt{8\beta_t(\delta)} \log \left( \frac{1}{\delta} \right) \right\} \geq 1 - 2\delta.$$

We may now combine (16), (17), and (19) together with Proposition 5.11 and a union bound to conclude that for all $\delta \in (0, 1/e]$, the estimate

$$\varphi_t(\tilde{x}_t) - \varphi_t^* \leq (1-\hat{\rho})^t \left( \varphi_t(x_0) - \varphi_t^* + \frac{\mu}{4} \|x_0 - x_t^*\|^2 \right) + \left( \eta(c\sigma)^2 + \frac{2\mu \Delta^2}{\hat{\rho}^2} \right) \log \left( \frac{e}{\delta} \right)$$

$$+ \left( 2 + \sqrt{5} \right) \hat{\rho} \sqrt{8\beta_t(\delta)} \log \left( \frac{1}{\delta} \right)$$

holds with probability at least $1 - 4\delta$; hence

$$\varphi_t(\tilde{x}_t) - \varphi_t^* \leq (1-\hat{\rho})^t \left( \varphi_t(x_0) - \varphi_t^* + \frac{\mu}{4} \|x_0 - x_t^*\|^2 \right) + \eta(c\sigma)^2 + \frac{8\Delta^2}{\mu \eta^2}$$

$$+ \left( \eta(c\sigma)^2 + \frac{8\Delta^2}{\mu \eta^2} + (2 + \sqrt{5}) \hat{\rho} \sqrt{8\beta_t(\delta)} \right) \log \left( \frac{1}{\delta} \right).$$

with probability at least $1 - 4\delta$.

\begin{remark} To see that Theorem 5.21 entails Theorem 4.8 fix $t \in \mathbb{N}$ and $\delta \in (0, 1)$ and observe \end{remark}
as in Remark 5.19 that upon setting $C := \max\{c, 1\}$, we have
\[
\hat{\rho}\sqrt{8\beta t(\delta/4)} \leq 4C^2\left(\sqrt{(1 - \hat{\rho})^t (\|x_0 - x_0^*\|^2 + \Delta^2 t^2 \mu \eta \sigma^2)} + \eta \sigma^2 + \sqrt{6 \frac{\Delta \sigma}{\sqrt{\mu \eta}}} \right) \sqrt{\log \left(\frac{12e}{\delta}\right)}
\]
while the AM-GM inequality implies
\[
2\sqrt{(1 - \hat{\rho})^t (\|x_0 - x_0^*\|^2 + \Delta^2 t^2 \mu \eta \sigma^2)} \leq (1 - \hat{\rho})^t (\mu \|x_0 - x_0^*\|^2 + \mu \Delta^2 t^2) + \eta \sigma^2,
\]

inequality (15) implies
\[
(1 - \hat{\rho})^t (\mu \|x_0 - x_0^*\|^2 + \mu \Delta^2 t^2) \leq 2(1 - \hat{\rho})^t (\varphi_0(x_0) - \varphi_0^*) + \frac{16\Delta^2}{\mu\eta},
\]
and Young’s inequality implies
\[
\frac{2\Delta \sigma}{\sqrt{\mu \eta}} \leq \eta \sigma^2 + \frac{\Delta^2}{\mu \eta^2}.
\]

Hence
\[
\hat{\rho}\sqrt{8\beta t(\delta/4)} \lesssim (1 - \hat{\rho})^t (\varphi_0(x_0) - \varphi_0^*) + \eta \sigma^2 + \frac{\Delta^2}{\mu \eta^2} \sqrt{\log \left(\frac{1}{\delta}\right)}.
\]

Further, inequalities (13) and (15) together with Assumption 4.7 imply that the estimate
\[
(1 - \hat{\rho})^t (\varphi_t(x_0) - \varphi_t^* + \frac{\mu}{4} \|x_0 - x_t^*\|^2) \leq 3(1 - \hat{\rho})^t (\varphi_0(x_0) - \varphi_0^*) + \frac{32\Delta^2}{\mu \eta^2} \log \left(\frac{e}{\delta}\right)
\]
holds with probability at least $1 - \delta$. Thus, under the assumptions of Theorem 5.21, a union bound reveals that for all $t \in \mathbb{N}$ and $\delta \in (0, 1/e]$, the estimate
\[
\varphi_t(\hat{x}_t) - \varphi_t^* \leq (1 - \hat{\rho})^t (\varphi_t(x_0) - \varphi_t^* + \frac{\mu}{4} \|x_0 - x_t^*\|^2) + \eta (c \sigma)^2 + \frac{8\Delta^2}{\mu \eta^2}
\]
\[
+ \left(\eta (c \sigma)^2 + \frac{8\Delta^2}{\mu \eta^2} + (2 + \sqrt{5})\hat{\rho}\sqrt{8\beta t(\delta/4)}\right) \log \left(\frac{4}{\delta}\right)
\]
\[
\lesssim (1 - \hat{\rho})^t (\varphi_0(x_0) - \varphi_0^*) + \eta \sigma^2 + \frac{\Delta^2}{\mu \eta^2} \left(\log \frac{1}{\delta}\right)^{3/2}
\]
holds with probability at least $1 - \delta$.

We may now apply Theorem 4.8 to obtain the formal version of Theorem 4.9; the proof is entirely analogous to that of Theorem 5.20 and is therefore omitted.

**Theorem 5.23** (Time to track with high probability). Suppose that Assumption 4.7 holds and that we are in the low drift-to-noise regime $\Delta/\sigma < \sqrt{\mu/16L^3}$. Set $\eta_* = (2\Delta^2/\mu \sigma^2)^{1/3}$ and $G = \mu(\Delta \sigma^2/\mu)^{2/3}$. Suppose moreover that we have available a positive upper bound on the initial gap $D \geq \varphi_0(x_0) - \varphi_0^*$. Fix $\delta \in (0, 1/e]$ and consider running Algorithm 4 in $k = 0, \ldots, K - 1$ epochs, namely, set $X_0 = x_0$ and iterate the process
\[
X_{k+1} = \text{PSG}(X_k, \eta_k, T_k) \quad \text{for} \quad k = 0, \ldots, K - 1,
\]
where the number of epochs is
\[
K = 1 + \left\lceil \log_2 \left(\frac{1}{L} \cdot \left(\frac{\sigma^2 \mu}{\Delta^2}\right)^{1/3}\right) \right\rceil
\]
and we set
\[ \eta_0 = \frac{1}{2L}, \quad T_0 = \left[ \frac{4L}{\mu} \log \left( \frac{LD}{\sigma^2} \right) \right] \quad \text{and} \quad \eta_k = \eta_{k-1} + \eta_*, \quad T_k = \left[ \frac{2 \log \left( \frac{4c(1/\delta)^{3/2}}{\mu \eta_k} \right)}{\mu \eta_k} \right] \]
for all \( k \geq 1 \), where \( c > 0 \) is the absolute constant furnished by the bound \( \mathcal{G} \). Then the time horizon \( T = T_0 + \cdots + T_{K-1} \) satisfies
\[ T \lesssim \frac{L}{\mu} \log \left( \frac{LD}{\sigma^2} \right) + \frac{\sigma^2}{\mu G} \log \left( \frac{1}{\delta} \right) \]
and the corresponding tracking error satisfies
\[ \varphi_T(X_K) - \varphi^*_T \lesssim \mathcal{G} \left( \frac{1}{\delta} \right)^{3/2} \]
with probability at least \( 1 - K\delta \).

6 Extensions to decision-dependent settings

We now show how the framework and results of the previous sections may be easily adapted to track equilibria in the setting of decision-dependent proximal stochastic gradient descent. Henceforth, we fix a proper, closed regularizer \( r : \mathbb{R}^d \to (-\infty, \infty] \). Our aim is to study a parameterized family of stochastic optimization problems of the form
\[ \min_u f_{t,x}(u) + r(u) \quad (20) \]
along a sequence \( \{x_t\} \) of decisions in \( \mathbb{R}^d \). Here, the family of functions \( \{f_{t,x}\} \) is parameterized by \( (t, x) \in \mathbb{N} \times \mathbb{R}^d \) and may evolve stochastically. Instead of tracking the true minimizers of the problem \( (20) \) — typically a challenging task — we will settle for tracking the equilibrium points \( \bar{x}_t \) of \( (20) \). These are the points satisfying
\[ \bar{x}_t \in \arg \min_u f_{t,x}(u) + r(u). \]
We refer the reader to [33] for a compelling motivation for considering such equilibrium points, which are sure to exist and are unique under certain Lipschitzness and strong convexity assumptions. When the decisions \( \{x_t\} \) are generated by a proximal stochastic gradient method, a natural assumption to make in order to obtain equilibrium tracking error bounds is the following control on gradient variation: there exist random variables \( \Gamma \) and \( \Theta \) such that
\[ \sup_{u \in \mathbb{R}^d} \| \nabla f_{t,x}(u) - \nabla f_{t,x'}(u) \| \leq \Gamma \| x - x' \| + \Theta |t - t'| \quad \forall (t, x), (t', x') \in \mathbb{N} \times \mathbb{R}^d. \quad (21) \]
When \( \Gamma \) is constant and \( \Theta \) is sub-Gaussian, the results of the preceding sections extend naturally to tracking the equilibria of \((20)\) in the appropriate parameter regime. We will illustrate this extension in the special case of interest in which \( f_{t,x}(\cdot) = \mathbb{E}_{w \sim D_t(x)} [\ell(\cdot, w)] \), where \( D : (t, x) \mapsto D_t(x) \) is a Lipschitz distribution mapping with respect to Wasserstein-1 distance and \( \ell \) is a loss function satisfying certain regularity properties; in this case we may take both \( \Gamma \) and \( \Theta \) to be constant. We formulate this distributional framework precisely in the next section, closely following the time-independent version proposed in [33].

6.1 Decision-dependent distributional framework

Fix a nonempty metric space \( M \) equipped with its Borel \( \sigma \)-algebra and let \( P_1(M) \) denote the space of Radon probability measures on \( M \) with finite first moment; equip \( P_1(M) \) with the Wasserstein-1
Lemma 6.4

\[
W_1(\pi, \xi) := \sup_{\phi \in \text{Lip}_1(M)} \left\{ \int_M \phi \, d\pi - \int_M \phi \, d\xi \right\},
\]

where Lip$_1$(M) denotes the set of 1-Lipschitz continuous functions on M. The equivalence of this definition with the description of $W_1(\pi, \xi)$ using couplings is the Kantorovich-Rubinstein duality theorem [24]. We will work with a distribution map $D : \mathbb{N} \times \mathbb{R}^d \to P_1(M)$ that is Lipschitz continuous with respect to $W_1$.

Assumption 6.1 (Distribution map). There exists a map $D : \mathbb{N} \times \mathbb{R}^d \to P_1(M) : (t, x) \mapsto D_t(x)$ admitting joint Lipschitz constants $\gamma, \theta > 0$ satisfying

\[
W_1(D_t(x), D_{t'}(x')) \leq \gamma \|x - x'\| + \theta |t - t'| \quad \forall (t, x), (t', x') \in \mathbb{N} \times \mathbb{R}^d.
\]

The parameters $\gamma$ and $\theta$ control the sensitivity of the distribution $D_t(x)$ to changes in $x$ and $t$. This in turn translates to control on the spatial and temporal sensitivity of expected loss functions of the form $\mathbb{E}_{w \sim D_t(x)}[\ell(\cdot, w)]$. Specifically, we will work with a loss function $\ell : \mathbb{R}^d \times M \to \mathbb{R}$ satisfying the following regularity properties. Throughout, $\nabla \ell(x, w)$ denotes the gradient of the function $\ell(\cdot, w)$ at $x$.

Assumption 6.2 (Loss function). There exists a function $\ell : \mathbb{R}^d \times M \to \mathbb{R}$ satisfying the following three properties:

(i) $\ell(x, \cdot) \in L^1(\pi)$ for all $x \in \mathbb{R}^d$ and $\pi \in P_1(M)$,

(ii) $\ell(\cdot, w)$ is $C^1$-smooth for all $w \in M$,

(iii) there exists a constant $\beta > 0$ such that the map $w \mapsto \nabla \ell(x, w)$ is $\beta$-Lipschitz continuous for all $x \in \mathbb{R}^d$.

By Assumption 6.2 and the dominated convergence theorem, we may define for each $\pi \in P_1(M)$ the expected loss $f_\pi \in C^1(\mathbb{R}^d)$ by setting

\[
f_\pi(x) := \mathbb{E}_{w \sim \pi} \ell(x, w).
\]

As the next two lemmas show, Assumption 6.2 implies that for each $x \in \mathbb{R}^d$, the map $\pi \mapsto \nabla f_\pi(x)$ is $\beta$-Lipschitz continuous, thereby yielding a multiplicative bound on function gap variation.

Lemma 6.3 (Gradient variation). For all $\pi, \xi \in P_1(M)$, we have

\[
\sup_{x \in \mathbb{R}^d} \|\nabla f_\pi(x) - \nabla f_\xi(x)\| \leq \beta \cdot W_1(\pi, \xi).
\]

Proof. Fix $\pi, \xi \in P_1(M)$. Given any unit vector $u \in \mathbb{S}^{d-1}$ and any point $x \in \mathbb{R}^d$, consider the $\beta$-Lipschitz continuous function $\phi : M \to \mathbb{R} : w \mapsto \langle u, \nabla \ell(x, w) \rangle$ and observe

\[
\langle u, \nabla f_\pi(x) - \nabla f_\xi(x) \rangle = \int_M \phi \, d\pi - \int_M \phi \, d\xi \leq \beta \cdot W_1(\pi, \xi).
\]

Taking the supremum over $u \in \mathbb{S}^{d-1}$ and $x \in \mathbb{R}^d$ completes the proof. \qed

Lemma 6.4 (Function gap variation). For all $\pi, \xi \in P_1(M)$ and $x, y \in \mathbb{R}^d$, we have

\[
[f_\pi(x) - f_\pi(y)] - [f_\xi(x) - f_\xi(y)] \leq \beta \cdot W_1(\pi, \xi) \cdot \|x - y\|.
\]
Proof. Fix $\pi, \xi \in P_1(M)$ and $x, y \in \mathbb{R}^d$ and set $x_s := y + s(x - y)$ for all $s \in [0, 1]$. By the fundamental theorem of calculus, Cauchy-Schwarz, and Lemma 6.3, we have
\[
[f_\pi(x) - f_\pi(y)] - [f_\xi(x) - f_\xi(y)] = \int_0^1 \langle \nabla f_\pi(x_s) - \nabla f_\xi(x_s), x - y \rangle \, ds \leq \beta \cdot W_1(\pi, \xi) \cdot \|x - y\|,
\]
as desired. \qed

Note that Assumption 6.1 and Lemma 6.3 imply the bound (21) with $\Gamma \equiv \gamma \beta$ and $\Theta \equiv \theta \beta$ under the identification $f_{t,x} = f_{D_t(x)}$. We are now ready to study the family of stochastic optimization problems
\[
\min_u f_{D_t(x)}(u) + r(u)
\]
along a sequence of decisions $\{x_t\}$ by way of tracking equilibria.

**Definition 6.5** (Equilibrium point). For each index $t$, we say that a point $\bar{x}_t \in \mathbb{R}^d$ is an equilibrium point of (22) if
\[
\bar{x}_t \in \arg\min_u f_{D_t(x)}(u) + r(u).
\]

Under the following strong convexity assumption, the problem (22) always admits an equilibrium point.

**Assumption 6.6** (Strong Convexity). The regularizer $r$ is convex and there exists a parameter $\mu$ such that $\mu > \gamma \beta$ and the expected loss $f_{D_t(x)}(\cdot)$ is $\mu$-strongly convex for all $(t, x) \in \mathbb{N} \times \mathbb{R}^d$.

Throughout, $\nabla f_{D_t(x)}(u)$ denotes the gradient of the expected loss $f_{D_t(x)}(\cdot)$ evaluated at $u$; hence
\[
\nabla f_{D_t(x)}(u) = \mathbb{E}_{w \sim D_t(x)} \nabla \ell(u, w).
\]

For each index $t$, we set
\[
\psi_t := f_{D_t(x_t)} + r \quad \text{and} \quad \psi_t^* := \psi_t(\bar{x}_t).
\]

Thus, the equilibrium point $\bar{x}_t$ is the minimizer of the $\mu$-strongly convex equilibrium function $\psi_t$, and $\psi_t^*$ denotes its minimal value. We will track the equilibria $\{\bar{x}_t\}$ of (22) using a decision-dependent proximal gradient method. Specifically, we make the standing assumption that at every time $t$, and at every query point $x$, the learner may obtain an unbiased estimator $\nabla f_{D_t(x)}(x)$ of $\nabla f_{D_t(x)}(x)$. Then Algorithm 3 in each iteration $t$ simply takes a stochastic gradient step on $f_{D_t(x)}$ at $x_t$ (setting $g_t = \nabla f_{D_t(x_t)}(x_t)$) followed by a proximal operation on $r$:
\[
x_{t+1} := \text{prox}_{\eta r}(x_t - \eta g_t) = \arg\min_{u \in \mathbb{R}^d} \left\{ r(u) + \frac{1}{2 \eta} \|u - (x_t - \eta g_t)\|^2 \right\}.
\]

Our goal is to obtain efficiency estimates for this procedure that hold both in expectation and with high probability.

Setting the stage, given $\{x_t\}$ and $\{g_t\}$ as in Algorithm 3, we let
\[
z_t := \nabla f_{D_t(x_t)}(x_t) - g_t
\]
denote the gradient noise at time $t$ and we impose the following assumption modeling stochasticity in the decision-dependent problem throughout Section 6.

**Assumption 6.7** (Stochastic framework). There exists a filtered probability space $(\Omega, \mathcal{F}, \mathbb{F}, \mathbb{P})$ with filtration $\mathbb{F} = (\mathcal{F}_t)_{t \geq 0}$ such that $\mathcal{F}_0 = \{\emptyset, \Omega\}$ and the following holds for all $t \geq 0$:

(i) $x_t, \bar{x}_t : \Omega \to \mathbb{R}^d$ are $\mathcal{F}_t$-measurable,
Algorithm 3 Decision-Dependent Proximal Stochastic Gradient \( \mathcal{D}-\text{PSG}(x_0, \{\eta_t\}, T) \)

**Input**: initial \( x_0 \) and step-size sequence \( \{\eta_t\}_{t=0}^T \subset (0, \infty) \).

**Step** \( t = 0, \ldots, T \):

1. Set \( g_t = \tilde{\nabla} f_{\mathcal{D}_t}(x_t) \)
2. Set \( x_{t+1} = \text{prox}_{\eta_t r}(x_t - \eta_t g_t) \)

(ii) \( z_t : \Omega \to \mathbb{R}^d \) is \( \mathcal{F}_{t+1} \)-measurable with \( \mathbb{E}[z_t | \mathcal{F}_t] = 0 \).

Note in particular that we allow both the iterates \( x_t \) and the equilibria \( \bar{x}_t \) to evolve stochastically.

We define the *equilibrium drift* at time \( t \) to be the random variable

\[ \Delta_t := \|\bar{x}_t - \bar{x}_{t+1}\| . \]

We also define the positive parameter

\[ \bar{\mu} := \mu - \gamma\beta. \]

The following lemma shows that the equilibrium drift is uniformly bounded by

\[ \bar{\Delta} := \theta \beta / \bar{\mu}. \]

**Lemma 6.8** (Bounded equilibrium drift). For all indices \( i, t \geq 0 \), the following estimate holds:

\[ \|\bar{x}_i - \bar{x}_t\| \leq \bar{\Delta}|i - t|. \]

**Proof.** By Lemma 2.4, Lemma 6.3, and Assumption 6.1 we have

\[
\begin{align*}
\mu \|\bar{x}_i - \bar{x}_t\| &\leq \|\nabla f_{\mathcal{D}_i}(\bar{x}_i) - \nabla f_{\mathcal{D}_t}(\bar{x}_t)\| \\
&\leq \beta \cdot W_1(\mathcal{D}_i(\bar{x}_i), \mathcal{D}_t(\bar{x}_t)) \\
&\leq \gamma \beta \|\bar{x}_i - \bar{x}_t\| + \theta \beta |i - t|. 
\end{align*}
\]

Rearranging completes the proof.

In addition to the strong convexity Assumption 6.6, we will also enforce the following smoothness assumption on the expected loss.

**Assumption 6.9** (Smoothness). There exists a parameter \( L > 0 \) such that the expected loss \( f_{\mathcal{D}_t}(\cdot) \) is \( L \)-smooth for all \( (t, x) \in \mathbb{N} \times \mathbb{R}^d \).

For the remainder of Section 6 we let \( \{x_t\} \) denote the iterates generated by Algorithm 3 with \( \eta_t < 1/L \).

### 6.2 Tracking the equilibrium point

In a nutshell, all the results of Section 3 extend directly to tracking the equilibrium points \( \bar{x}_t \), with \( \Delta \) replaced by \( \bar{\Delta} \) and \( \mu \) replaced by \( \bar{\mu} \). We begin with bounding the expected value \( \mathbb{E}\|x_t - \bar{x}_t\|^2 \), under a bounded second moment assumption on the noise.

**Assumption 6.10** (Bounded second moment). There exists a constant \( \sigma > 0 \) such that \( \mathbb{E}\|z_t\|^2 \leq \sigma^2 \) for all \( t \geq 0 \).

The following theorem is a direct analogue of Theorem 3.2.
Theorem 6.11 (Expected distance). Suppose that Assumption 6.10 holds. Then the iterates produced by Algorithm 3 with constant learning rate $\eta \leq 1/2L$ satisfy the bound:

$$\mathbb{E}\|x_t - \bar{x}_t\|^2 \lesssim (1 - \tilde{\mu}\eta)^t \|x_0 - \bar{x}_0\|^2 + \frac{\eta\sigma^2}{\mu} + \frac{\tilde{\Delta}^2}{\mu\eta^3}.$$ 

With Theorem 6.11 in hand, we are led to define the following asymptotic tracking error of Algorithm 3 corresponding to $\eta$ into the definition of $\bar{\Delta}$, together with the corresponding optimal step size:

$$\bar{\Delta} := \min_{\eta \in [0,1/2L]} \left\{ \frac{\eta\sigma^2}{\mu} + \frac{(\Delta \tilde{\mu})^2}{\mu^2} \right\} \text{ and } \bar{\eta}_* := \min \left\{ \frac{1}{2L}, \left( \frac{2\tilde{\Delta}^2}{\mu^2\sigma^2} \right)^{1/3} \right\}.$$ 

Plugging $\bar{\eta}_*$ into the definition of $\bar{\Delta}$, we see that Algorithm 3 exhibits qualitatively different behaviors in settings corresponding to high or low drift-to-noise ratio $\Delta/\sigma$, explicitly given by

$$\bar{\Delta} \times \begin{cases} \frac{\tilde{\Delta}^2}{\mu^2} + \left( \frac{L\tilde{\mu}}{\mu} \right)^{2/3} & \text{if } \frac{\tilde{\Delta}}{\sigma} \geq \sqrt{\frac{\tilde{\mu}}{16L^3}} \\ \frac{\Delta^2}{\eta^2\mu^2} & \text{otherwise.} \end{cases}$$

As before, the high drift-to-noise regime $\Delta/\sigma \geq \sqrt{\tilde{\mu}/16L^3}$ is uninteresting from the viewpoint of stochastic optimization and we focus on the low drift-to-noise regime $\Delta/\sigma < \sqrt{\tilde{\mu}/16L^3}$. The following theorem is analogous to Theorem 3.3.

Theorem 6.12 (Informal). Suppose that Assumption 6.10 holds. Then there is a learning rate schedule $\{\eta_t\}$ such that Algorithm 3 produces a point $x_t$ satisfying

$$\mathbb{E}\|x_t - \bar{x}_t\|^2 \lesssim \bar{\Delta} \text{ after time } t \lesssim \frac{L}{\tilde{\mu}} \log \left( \frac{\|x_0 - \bar{x}_0\|^2}{\bar{\Delta}} \right) + \frac{\sigma^2}{\tilde{\mu}^2\bar{\Delta}}.$$ 

Next, we present high probability guarantees on the tracking error $\|x_t - \bar{x}_t\|^2$ under the following standard light tail assumption on the gradient noise.

Assumption 6.13 (Norm sub-Gaussian gradient noise). There exists a constant $\sigma > 0$ such that for all $t \geq 0$, the gradient noise $z_t$ is norm sub-Gaussian conditioned on $\mathcal{F}_t$ with parameter $\sigma/2$:

$$\mathbb{P}\left\{ \|z_t\| \geq \tau \mid \mathcal{F}_t \right\} \leq 2 \exp(-2\tau^2/\sigma^2) \text{ for all } \tau > 0.$$ 

The theorem below shows that if Assumption 6.13 holds, then the bound on $\mathbb{E}\|x_t - \bar{x}_t\|^2$ derived in Theorem 6.11 holds with high probability.

Theorem 6.14 (High probability distance tracking). Suppose that Assumption 6.13 holds and let $\{x_t\}$ be the iterates produced by Algorithm 3 with constant learning rate $\eta \leq 1/2L$. Then there is an absolute constant $c > 0$ such that for any specified $t \in \mathbb{N}$ and $\delta \in (0,1)$, the estimate

$$\|x_t - \bar{x}_t\|^2 \leq \left( 1 - \tilde{\mu} \eta \right)^t \|x_0 - \bar{x}_0\|^2 + c \left( \frac{\eta\sigma^2}{\mu} + \frac{\tilde{\Delta}^2}{\mu\eta^3} \right)^2 \log \left( \frac{c}{\delta} \right) \tag{23}$$

holds with probability at least $1 - \delta$.

The proof of Theorem 6.14 mirrors that of Theorem 3.6. As a consequence of Theorem 6.14, we can again consider a step-decay schedule to obtain the following efficiency estimate with high probability; see Theorem 7.8 for the formal statement.
We begin with bounding the expected value \( \mathbb{E} \) of the gradient noise, and the future equilibria. In a nutshell, all the results of Sections 4 extend directly to tracking the equilibrium values \( \psi^*_t \), with \( \Delta \) replaced by \( \hat{\Delta} \) and \( \mu \) replaced by \( \hat{\mu} \).

We will track \( \psi^*_t \) along the running average \( \hat{x}_t \) of the iterates \( x_t \) produced by Algorithm 3, defined as

\[
\hat{x}_0 := x_0 \quad \text{and} \quad \hat{x}_{t+1} := \left( 1 - \frac{\hat{\mu}_t}{2 - \hat{\mu}_t} \right) \hat{x}_t + \frac{\hat{\mu}_t}{2 - \hat{\mu}_t} x_{t+1} \quad \forall t \geq 0.
\]

In a nutshell, all the results of Sections 4 extend directly to tracking the equilibrium values \( \psi^*_t \), with \( \Delta \) replaced by \( \hat{\Delta} \) and \( \mu \) replaced by \( \hat{\mu} \).

We begin with bounding the expected value \( \mathbb{E}[\psi_t(\hat{x}_t) - \psi^*_t] \). This requires a weak form of uncorrelatedness between the gradient noise \( z_i \) and the future equilibrium point \( \hat{x}_t \), which we stipulate in the following strengthening of Assumption 6.10.

**Assumption 6.16** (Gradient noise and future equilibria). There exists a constant \( \sigma > 0 \) such that for all \( 0 \leq i < t \), we have \( \mathbb{E}[\|z_i\|^2] \leq \sigma^2 \) and \( \mathbb{E}[z_i, \hat{x}_t] = 0 \).

The following theorem presents a one-step improvement guarantee for Algorithm 3.

**Theorem 6.17** (Expected function gap). Suppose that Assumption 6.16 holds, and let \( \{\hat{x}_t\} \) be the iterates produced by Algorithm 3 with constant learning rate \( \eta \leq 1/2L \). Then the following bound holds for all \( t \geq 0 \):

\[
\mathbb{E}[\psi_t(\hat{x}_t) - \psi^*_t] \lesssim \left( 1 - \frac{\hat{\mu}t}{2} \right) \cdot \mathbb{E}[\psi_t(x_0) - \psi^*_t + \frac{\hat{\mu}}{4} \|x_0 - \hat{x}_t\|^2] + \frac{\eta \sigma^2}{\hat{\mu}t^2} + \frac{\hat{\Delta}^2}{\hat{\mu}t^2}.
\]
Consequently, we have
\[ E[\psi_t(\hat{x}_t) - \psi_t^*] \lesssim (1 - \frac{\hat{\mu} \eta}{2})^t (\psi_0(x_0) - \psi_0^*) + \eta \sigma^2 + \frac{\hat{\Delta}^2}{\mu \eta^2} \]
for all \( t \geq 0 \), and the following asymptotic error bound holds:
\[ \limsup_{t \to \infty} E[\psi_t(\hat{x}_t) - \psi_t^*] \lesssim \eta \sigma^2 + \frac{\hat{\Delta}^2}{\mu \eta^2}. \]

Next, with Theorem 6.17 in hand, we are led to define the following asymptotic tracking error
of Algorithm 4 corresponding to \( E[\psi_t(\hat{x}_t) - \psi_t^*] \), together with the corresponding optimal step size:
\[ \hat{G} := \min_{\eta \in (0, 1/2L]} \left\{ \eta \sigma^2 + \frac{\hat{\Delta}^2}{\mu \eta^2} \right\} \quad \text{and} \quad \hat{\eta} := \min \left\{ \frac{1}{2L}, \left( \frac{2\hat{\Delta}^2}{\mu \sigma^2} \right)^{1/3} \right\}. \]

A familiar dichotomy governed by the drift-to-noise ratio \( \hat{\Delta}/\sigma \) arises. We again focus on the low
drift-to-noise regime \( \hat{\Delta}/\sigma < \sqrt{\mu}/16L^3 \). The following theorem is analogous to Theorem 4.3

**Theorem 6.18 (Informal).** Suppose that Assumption 6.16 holds. Then there is a learning rate
schedule \( \{\eta_t\} \) such that Algorithm 4 produces a point \( \hat{x}_t \) satisfying
\[ E[\psi_t(\hat{x}_t) - \psi_t^*] \lesssim \hat{G} \quad \text{after time} \quad t \leq \frac{L}{\hat{\mu}} \log \left( \frac{\psi_0(x_0) - \psi_0^*}{\hat{G}} \right) + \frac{\sigma^2}{\mu \hat{G}}. \]

Our next result is an analogue of Theorem 6.17 that holds with high probability. Naturally, such
a result should rely on a light tail assumption on the norm of the gradient noise \( \|z_i\| \). We first state
the guarantee under the assumption that \( \|z_i\| \) is uniformly bounded and require that the gradient
noise \( z_i \) is mean-zero conditioned on the \( \sigma \)-algebra \( \mathcal{F}_{i,t} := \sigma(\mathcal{F}_t, \hat{x}_t) \) for all \( 0 \leq i < t \). The proof of
Theorem 6.20 mirrors that of Theorem 4.5

**Assumption 6.19 (Bounded gradient noise).** There exists a constant \( \sigma > 0 \) such that for all
\( 0 \leq i < t \), the gradient noise satisfies \( \|z_i\| \leq \sigma \) and \( E[z_i | \mathcal{F}_{i,t}] = 0 \).

**Theorem 6.20 (Function gap with high probability).** Suppose that Assumption 6.16 holds, and let
\( \{\hat{x}_t\} \) be the iterates produced by Algorithm 4 with constant learning rate \( \eta \leq 1/2L \). Then there is
an absolute constant \( c > 0 \) such that for any specified \( t \in \mathbb{N} \) and \( \delta \in (0, 1/e] \), the estimate
\[ \psi_t(\hat{x}_t) - \psi_t^* \leq c \left( 1 - \frac{\hat{\mu} \eta}{2} \right)^t (\psi_0(x_0) - \psi_0^*) + \eta \sigma^2 + \frac{\hat{\Delta}^2}{\mu \eta^2} \log \left( \frac{1}{\delta} \right) \]  
holds with probability at least \( 1 - \delta \).

With Theorem 6.20 in hand, we may implement a step-decay schedule as before to obtain the
following efficiency estimate; see Theorem 7.17 for the formal statement.

**Theorem 6.21 (Informal).** Suppose that Assumption 6.16 holds, and fix \( \delta \in (0, 1/e] \). Then there
is a learning rate schedule \( \{\eta_t\} \) such that Algorithm 4 produces a point \( \hat{x}_t \) satisfying
\[ \psi_t(\hat{x}_t) - \psi_t^* \lesssim \hat{G} \log \left( \frac{1}{\delta} \right) \]
with probability at least \( 1 - K \delta \) after time
\[ t \leq \frac{L}{\hat{\mu}} \log \left( \frac{\psi_0(x_0) - \psi_0^*}{\hat{G}} \right) + \frac{\sigma^2}{\mu \hat{G}} \log \left( \frac{1}{\delta} \right), \quad \text{where} \quad K \lesssim \log_2 \left( \frac{1}{L} \cdot \left( \frac{\sigma^2 \hat{\mu}}{\hat{\Delta}^2} \right)^{1/3} \right). \]
Following a similar line of reasoning as in the proof of Theorem 6.20 we obtain an analogous result in the setting wherein the gradient noise \( z_i \) is only assumed to be mean-zero norm sub-Gaussian conditioned on \( F_{i,t} \). Specifically, we make the following assumption.

**Assumption 6.22** (Sub-Gaussian gradient noise). There exists a constant \( \sigma > 0 \) such that for all \( 0 \leq i < t \), the gradient noise \( z_i \) is mean-zero norm sub-Gaussian conditioned on \( F_{i,t} \) with parameter \( \sigma / 2 \), i.e., \( \mathbb{E}[z_i | F_{i,t}] = 0 \) and

\[
\mathbb{P}\{\|z_i\| \geq \tau | F_{i,t}\} \leq 2 \exp(-2\tau^2/\sigma^2) \quad \text{for all} \quad \tau \geq 0.
\]

**Theorem 6.23** (Function gap with high probability). Suppose that Assumption 6.22 holds, and let \( \{\hat{x}_t\} \) be the iterates produced by Algorithm 4 with constant learning rate \( \eta \leq 1/2L \). Then there is an absolute constant \( c > 0 \) such that for any specified \( t \in \mathbb{N} \) and \( \delta \in (0, 1/e) \), the estimate

\[
\psi_t(\hat{x}_t) - \psi_t^* \leq c \left( 1 - \frac{\mu \eta}{2} \right)^t (\psi_0(x_0) - \psi_0^*) + \frac{\bar{\Delta}^2}{\mu \eta^2} \left( \log \left( \frac{1}{\delta} \right) \right)^{3/2}
\]

holds with probability at least \( 1 - \delta \).

The bound obtained in Theorem 6.23 is worse than that of Theorem 6.20 by a factor of \( \sqrt{\log(1/\delta)} \). We leave open the question of whether this extra factor may be removed. In any case, we obtain as before an efficiency estimate from Theorem 6.23 by implementing a step-decay schedule; see Theorem 7.20 for the formal statement.

**Theorem 6.24** (Informal). Suppose that Assumption 6.22 holds, and fix \( \delta \in (0, 1/e) \). Then there is a learning rate schedule \( \{\eta_t\} \) such that Algorithm 4 produces a point \( \hat{x}_t \) satisfying

\[
\psi_t(\hat{x}_t) - \psi_t^* \lesssim \mathcal{G} \left( \log \left( \frac{1}{\delta} \right) \right)^{3/2}
\]

with probability at least \( 1 - K\delta \) after time

\[
t \leq \frac{L}{\mu} \log \left( \frac{\psi_0(x_0) - \psi_0^*}{\mathcal{G}} \right) + \frac{\sigma^2}{\mu \mathcal{G}} \log \left( \log \left( \frac{1}{\delta} \right) \right), \quad \text{where} \quad K \lesssim \log_2 \left( \frac{1}{L} \cdot \frac{\sigma^2}{\bar{\Delta}^2} \right)^{1/3}.
\]

7 Proofs of results in Section 6

**Roadmap.** Throughout this section, we enforce the assumptions and notation of Section 6.1, letting \( \{x_t\} \) denote the iterates generated by Algorithm 3 with \( \eta < 1/L \) and setting

\[
\varphi_t := f_{D_t(x_t)} + r \quad \text{and} \quad \psi_t := f_{D_t(\bar{x}_t)} + r,
\]

where the equilibrium point \( \bar{x}_t \) is the minimizer of \( \psi_t \) and \( \psi_t(\bar{x}_t) =: \psi_t^* \). The arguments in this section very closely parallel those of Section 6.1 and we omit the proofs that are essentially identical. Section 7.1 derives the results of Section 6.2 while Section 7.2 derives the results of Section 6.3.

To begin, note that because the expected loss \( f_{D_t(x_t)} \) is \( \mu \)-strongly convex and \( L \)-smooth, we have the same one-step improvement guarantee as in Lemma 5.1.

**Lemma 7.1** (One-step improvement). The estimate

\[
2\eta_t (\varphi_t(x_{t+1}) - \varphi_t(x)) \leq (1 - \mu \eta_t)\|x_t - x\|^2 - \|x_{t+1} - x\|^2 + 2\eta_t \langle z_t, x_t - x \rangle + \frac{\eta_t^2}{1 - L\eta_t} ||z_t||^2
\]

holds for all points \( x \in \mathbb{R}^d \) and all indices \( t \geq 0 \).
Using the function gap variation Lemma 6.4, this one-step improvement guarantee for $\varphi_t$ implies the following one-step improvement guarantee for $\psi_t$ (analogous to Lemma 5.10).

**Lemma 7.2** (Equilibrium one-step improvement). For all indices $i, t \geq 0$ and arbitrary $\alpha > 0$, we have

$$2\eta_i(\psi_t(x_{i+1}) - \psi_t^*) \leq (1 - \bar{\mu}\eta_i)\|x_i - \bar{x}_t\|^2 - (1 - (\gamma + \alpha\theta)\beta\eta_i)\|x_{i+1} - \bar{x}_t\|^2$$

$$+ 2\eta_i(z_i, x_i - \bar{x}_t) + \frac{\eta_i^2}{1 - L\eta_i}\|z_i\|^2 + \frac{\theta\beta\eta_i}{\alpha}\|t - i\|^2.$$

**Proof.** By Lemma 6.4 and Assumption 6.1, we have

$$[\psi_t(x_{i+1}) - \psi_t(\bar{x}_t)] - [\varphi_t(x_{i+1}) - \varphi_t(\bar{x}_t)]$$

$$= [f_{D_t}(x_t)(x_{i+1}) - f_{D_t}(\bar{x}_t)] - [f_{D_t}(x_t)(x_{i+1}) - f_{D_t}(\bar{x}_t)]$$

$$\leq \beta \cdot W_1(D_t(\bar{x}_t), D_t(x_t)) \cdot \|x_{i+1} - \bar{x}_t\|$$

$$\leq \beta(\gamma\|x_i - \bar{x}_t\| + \theta|t - i|)\|x_{i+1} - \bar{x}_t\|.$$

Hence

$$\psi_t(x_{i+1}) - \psi_t^* \leq \varphi_t(x_{i+1}) - \varphi_t(\bar{x}_t) + \beta(\gamma\|x_i - \bar{x}_t\| + \theta|t - i|)\|x_{i+1} - \bar{x}_t\|.$$ 

Now observe that Young’s inequality implies

$$\beta(\gamma\|x_i - \bar{x}_t\| + \theta|t - i|)\|x_{i+1} - \bar{x}_t\| \leq \frac{\gamma\beta}{2}\|x_i - \bar{x}_t\|^2 + \frac{(\gamma - \alpha\theta)\beta}{2}\|x_{i+1} - \bar{x}_t\|^2 + \frac{\theta\beta}{2\alpha}\|t - i\|^2.$$

Multiplying through by $2\eta_i$ and applying Lemma 7.1 completes the proof.

We proceed now to derive bounds on $\|x_t - \bar{x}_t\|^2$ and $\psi_t(\hat{x}_t) - \psi_t^*$ using Lemma 7.2 as our starting point, where $\hat{x}_t$ is the averaged sequence of iterates given by Algorithm 4.

### 7.1 Tracking the equilibrium point

Lemma 7.2 and the $\mu$-strong convexity of $\psi_t$ imply the following recursion on $\|x_t - \bar{x}_t\|^2$.

**Lemma 7.3.** The estimate

$$\|x_{t+1} - \bar{x}_{t+1}\|^2 \leq (1 - \bar{\mu}\eta_i)\|x_t - \bar{x}_t\|^2 + 2\eta_i\langle z_t, x_t - \bar{x}_t \rangle + \frac{\eta_i^2}{1 - L\eta_i}\|z_t\|^2 + \left(1 + \frac{2}{\bar{\mu}\eta_i}\right)\Delta_t^2$$

holds for all $t \geq 0$.

**Proof.** Taking $\alpha = \bar{\mu}/2\beta$ in Lemma 7.2 and applying the $\mu$-strong convexity of $\psi_t$ reveals that for all indices $i, t \geq 0$, we have

$$\left(1 + \frac{\bar{\mu}\eta_i}{2}\right)\|x_{i+1} - \bar{x}_t\|^2 \leq (1 - \bar{\mu}\eta_i)\|x_i - \bar{x}_t\|^2 + 2\eta_i\langle z_i, x_i - \bar{x}_t \rangle$$

$$+ \frac{\eta_i^2}{1 - L\eta_i}\|z_i\|^2 + \frac{2(\theta\beta)^2\eta_i}{\bar{\mu}}|t - i|^2. \quad (27)$$

Now fix $t$ and observe that Young’s inequality implies

$$\|x_{t+1} - \bar{x}_{t+1}\|^2 \leq (1 + c_t)\|x_{t+1} - \bar{x}_t\|^2 + (1 + c_t^{-1})\Delta_t^2$$

for all $c_t > 0$; taking $c_t = \bar{\mu}\eta_i/2$ and applying (27) with $i = t$ completes the proof.

Applying Lemma 7.3 recursively yields a bound on $\|x_t - \bar{x}_t\|^2$. When the step size is constant, the next proposition follows immediately.
Proposition 7.4. The following bound holds for all $t \geq 0$:

$$\|x_t - \bar{x}_t\|^2 \leq (1 - \bar{\mu} \eta)^t \|x_0 - \bar{x}_0\|^2 + 2\eta \sum_{i=0}^{t-1} \langle z_i, x_i - \bar{x}_i \rangle (1 - \bar{\mu} \eta)^{t-1-i}$$

$$+ \frac{\eta^2}{1 - L\eta} \sum_{i=0}^{t-1} \|z_i\|^2 (1 - \bar{\mu} \eta)^{t-1-i} + \left( 1 + \frac{2}{\bar{\mu} \eta} \right) \sum_{i=0}^{t-1} \Delta^2_i (1 - \bar{\mu} \eta)^{t-1-i}.$$  

By taking expectations in Proposition 7.4 and applying Lemma 6.8, we obtain the following precise version of Theorem 6.11.

Corollary 7.5. Suppose that Assumption 6.10 holds. Then the iterates $\{x_t\}$ produced by Algorithm 3 with constant learning rate $\eta \leq 1/2L$ satisfy the bound:

$$\mathbb{E}\|x_t - \bar{x}_t\|^2 \leq (1 - \bar{\mu} \eta)^t \|x_0 - \bar{x}_0\|^2 + 2\eta \sigma^2 \mu^{-1} + 3 \left( \frac{\bar{\Delta}}{\bar{\mu} \eta} \right)^2.$$  

With Corollary 7.5 in hand, we obtain the formal version of Theorem 6.12. The proof is essentially identical to that of Theorem 5.5 and so is omitted.

Theorem 7.6 (Time to track in expectation). Suppose that Assumption 6.10 holds and that we are in the low drift-to-noise regime $\bar{\Delta}/\sigma < \sqrt{\bar{\mu}/16L^2}$. Set $\bar{\eta}_* = (2\bar{\Delta}^2/\bar{\mu} \sigma^2)^{1/3}$ and $\bar{\mathcal{E}} = (\bar{\Delta} \sigma^2/\bar{\mu}^2)^{2/3}$. Suppose moreover that we have available a positive upper bound on the initial square distance $D \geq \|x_0 - \bar{x}_0\|^2$. Consider running Algorithm 3 in $k = 0, \ldots, K - 1$ epochs, namely, set $X_0 = x_0$ and iterate the process $X_{k+1} = \mathcal{D} \cdot \text{PSG}(X_k, \eta_k, T_k)$ for $k = 0, \ldots, K - 1$, where the number of epochs is

$$K = 1 + \left\lfloor \log_2 \left( \frac{1}{L} \cdot \left( \frac{\sigma^2 \mu}{\bar{\Delta}^2} \right)^{1/3} \right) \right\rfloor$$

and we set

$$\eta_0 = \frac{1}{2L}, \quad T_0 = \left\lceil \frac{2L}{\bar{\mu}} \log \left( \frac{\bar{\mu}LD}{\sigma^2} \right) \right\rceil \quad \text{and} \quad \eta_k = \frac{\eta_{k-1} + \bar{\eta}_*}{2}, \quad T_k = \left\lceil \log_2 \left( \frac{4}{\bar{\mu} \eta_k} \right) \right\rceil \quad \forall k \geq 1.$$  

Then the time horizon $T = T_0 + \cdots + T_{K-1}$ satisfies

$$T \lesssim \frac{L}{\bar{\mu}} \log \left( \frac{\bar{\mu}LD}{\sigma^2} \right) + \frac{\sigma^2}{\bar{\mu}^2 \bar{\mathcal{E}}} < \frac{L}{\bar{\mu}} \log \left( \frac{D}{\bar{\mathcal{E}}} \right) + \frac{\sigma^2}{\bar{\mu}^2 \bar{\mathcal{E}}},$$

while the corresponding tracking error satisfies $\mathbb{E}\|X_K - \bar{X}_K\|^2 \lesssim \bar{\mathcal{E}}$, where $\bar{X}_K$ denotes the minimizer of $\psi_T$.

Next, we obtain a high-probability analogue of Corollary 7.5 in the setting of norm sub-Gaussian gradient noise. Note first that Lemmas 6.8 and 7.3 show that in the regime $\eta_t \leq 1/2L$, we have

$$\|x_{t+1} - \bar{x}_{t+1}\|^2 \leq (1 - \bar{\mu} \eta_t) \|x_t - \bar{x}_t\|^2 + 2\eta_t \langle z_t, u_t \rangle \|x_t - \bar{x}_t\|^2 + 2\eta_t^2 \|z_t\|^2 + \frac{3\Delta^2}{\bar{\mu} \eta_t},$$

where we set $u_t := \frac{x_t - \bar{x}_t}{\|x_t - \bar{x}_t\|}$ if $x_t$ is distinct from $\bar{x}_t$ and set it to zero otherwise. The inequality (28) facilitates an application of Proposition 5.6, resulting in the following precise version of Theorem 6.14. The proof is essentially identical to that of Theorem 5.7 and so is omitted.

38
Theorem 7.7. Suppose that Assumption 6.13 holds and let \( \{x_t\} \) be the iterates produced by Algorithm 5 with constant learning rate \( \eta \leq 1/2L \). Then there exists an absolute constant \( c > 0 \) such that for each \( t \), the random variable
\[
\|x_t - \bar{x}_t\|^2 - \left(1 - \frac{\bar{\mu}\eta}{2}\right) \|x_0 - \bar{x}_0\|^2
\]
is sub-exponential with parameter
\[
\nu := \frac{8\eta(c\sigma)^2}{\bar{\mu}} + 6\left(\frac{\bar{\Delta}}{\bar{\mu}\eta}\right)^2.
\]
Consequently, for any specified \( t \in \mathbb{N} \) and \( \delta \in (0, 1) \), the estimate
\[
\|x_t - \bar{x}_t\|^2 \leq \left(1 - \frac{\bar{\mu}\eta}{2}\right) \|x_0 - \bar{x}_0\|^2 + \left(\frac{8\eta(c\sigma)^2}{\bar{\mu}} + 6\left(\frac{\bar{\Delta}}{\bar{\mu}\eta}\right)^2\right) \log\left(\frac{e}{\delta}\right)
\]
holds with probability at least \( 1 - \delta \).

With Theorem 6.14 in hand, we can now deduce the formal version of Theorem 6.15. The proof is essentially identical to that of Theorem 5.8 and is therefore omitted.

Theorem 7.8 (Time to track with high probability). Suppose that Assumption 6.13 holds and that we are in the low drift-to-noise regime \( \bar{\Delta}/\sigma < \sqrt{\bar{\mu}/16L} \). Set \( \bar{\eta}_* = (2\bar{\Delta}^2/\bar{\mu}\sigma^2)^{1/3} \) and \( \bar{\varepsilon} = (\bar{\Delta}^2/\bar{\mu}^2)^{2/3} \). Suppose moreover that we have available an upper bound on the initial square distance \( D \geq \|x_0 - \bar{x}_0\|^2 \). Consider running Algorithm 5 in \( k = 0, \ldots, K - 1 \) epochs, namely, set \( X_0 = x_0 \) and iterate the process
\[
X_{k+1} = D-PSG(X_k, \eta_k, T_k) \quad \text{for} \quad k = 0, \ldots, K - 1,
\]
where the number of epochs is
\[
k = 1 + \left\lceil \log_2 \left(\frac{1}{L} \cdot \left(\frac{\sigma^2}{\bar{\mu}^2\bar{\varepsilon}}\right)^{1/3}\right) \right\rceil
\]
and we set
\[
\eta_0 = \frac{1}{2L}, \quad T_0 = \left\lceil \frac{4L}{\bar{\mu}} \log\left(\frac{\bar{\mu}LD}{\sigma^2}\right) \right\rceil \quad \text{and} \quad \eta_k = \frac{\eta_{k-1} + \bar{\eta}_*}{2}, \quad T_k = \left\lceil \frac{2\log(4)}{\bar{\mu}\eta_k} \right\rceil \quad \forall k \geq 1.
\]
Then the time horizon \( T = T_0 + \cdots + T_{K-1} \) satisfies
\[
T \leq \frac{L}{\bar{\mu}} \log\left(\frac{\bar{\mu}LD}{\sigma^2}\right) + \frac{\sigma^2}{\bar{\mu}^2\bar{\varepsilon}} < \frac{L}{\bar{\mu}} \log\left(\frac{D}{\bar{\varepsilon}}\right) + \frac{\sigma^2}{\bar{\mu}^2\bar{\varepsilon}},
\]
and for any specified \( \delta \in (0, 1) \), the corresponding tracking error satisfies
\[
\|X_K - \bar{X}_K\|^2 \lesssim \bar{\varepsilon} \log\left(\frac{e}{\delta}\right)
\]
with probability at least \( 1 - K\delta \), where \( \bar{X}_K \) denotes the minimizer of \( \psi_T \).

7.2 Tracking the equilibrium value

Throughout this section, we suppose that we are in the regime (24): \( \bar{\mu} > \gamma \beta \). Recall that we set \( \hat{\mu} := \bar{\mu} - \gamma \beta \) and \( \hat{\Delta} := \theta \beta / \bar{\mu} \). We begin by deducing from Lemma 7.2 an equilibrium one-step improvement along the average iterate \( \bar{x}_t \).

\[
\text{Explicitly, one can take any } c \geq 1 \text{ such that } \|z_t\|^2 \text{ is sub-exponential conditioned on } F_t \text{ with parameter } c\sigma^2 \text{ and } z_t \text{ is mean-zero sub-Gaussian conditioned on } F_t \text{ with parameter } c\sigma \text{ for all } t.
\]
Proposition 7.9 (Equilibrium one-step improvement along the average). Let \{\hat{x}_t\} be the iterates produced by Algorithm 4 with constant step size \(\eta \leq 1/2L\); thus, setting \(\hat{\rho} := \hat{\mu} \eta / (2 - \mu \eta)\), we have \(\hat{x}_0 = x_0\) and \(\hat{x}_t = (1 - \hat{\rho}) \hat{x}_{t-1} + \hat{\rho} x_t\) for all \(t \geq 1\). Then the following bound holds for all \(t \geq 0\):

\[
\psi_t(\hat{x}_t) - \psi_t^* \leq (1 - \hat{\rho})^t \left( \psi_t(x_0) - \psi_t^* + \frac{\hat{\mu}}{4} \|x_0 - \bar{x}_t\|^2 \right) + \hat{\rho} \sum_{i=0}^{t-1} \langle z_i, x_i - \bar{x}_t \rangle (1 - \hat{\rho})^{t-1-i} + \hat{\rho} n \sum_{i=0}^{t-1} \|z_i\|^2 (1 - \hat{\rho})^{t-1-i} + \frac{2\hat{\mu}\hat{\Delta}^2}{\hat{\rho}^2}.
\]

Proof. Setting \(\alpha = \hat{\mu}/2\theta\beta\) in Lemma 7.2 we obtain the following recursion for all indices \(k \geq 0\) and \(t \geq 1\):

\[
\rho(\psi_k(x_t) - \psi_k^* \leq (1 - c_1 \rho) V_{t-1} - (1 + c_2 \rho) V_t + \omega_t,
\]

where \(\rho = 2\eta\), \(c_1 = \bar{\rho}/2\), \(c_2 = -\mu/4\), \(V_i = \|x_i - \bar{x}_k\|^2\), and \(\omega_t = 2\eta(z_{t-1} - x_{t-1} - \bar{x}_k) + 2\eta^2 \|z_{t-1}\|^2 + 2\eta\hat{\Delta}^2 |k - t + 1|^2\). The result follows by applying the averaging Lemma A.1 with \(h = \psi_t - \psi_t^*\).

Observe that the quantity \(\psi_t(x_0) - \psi_t^* + \frac{\hat{\mu}}{4} \|x_0 - \bar{x}_t\|^2\) appearing in Proposition 7.9 satisfies the bound

\[
\psi_t(x_0) - \psi_t^* + \frac{\hat{\mu}}{4} \|x_0 - \bar{x}_t\|^2 \leq 3(\psi_0(x_0) - \psi_0^*) + 5\hat{\mu}\hat{\Delta}^2 t^2
\]

as a consequence of Lemma 6.4 Assumption 6.1 inequality (24) and Young's inequality together with the \(\hat{\mu}\)-strong convexity of \(\psi_0\). Further, the inequality (15) combines with inequality (29) to yield

\[
(1 - \frac{\hat{\mu} \eta}{2})^t \left( \psi_t(x_0) - \psi_t^* + \frac{\hat{\mu}}{4} \|x_0 - \bar{x}_t\|^2 \right) \leq 3 \left(1 - \frac{\hat{\mu} \eta}{2}\right)^t (\psi_0(x_0) - \psi_0^*) + \frac{80\hat{\Delta}^2}{\hat{\mu}^2}.
\]

Therefore taking expectations in Proposition 7.9 yields the following precise version of Theorem 6.17.

Corollary 7.10 (Expected function gap). Suppose that Assumption 6.16 holds, and let \{\hat{x}_t\} be the iterates produced by Algorithm 4 with constant learning rate \(\eta \leq 1/2L\). Then the following bound holds for all \(t \geq 0\):

\[
E[\psi_t(\hat{x}_t) - \psi_t^*] \leq (1 - \hat{\rho})^t E[\psi_t(x_0) - \psi_t^* + \frac{\hat{\mu}}{4} \|x_0 - \bar{x}_t\|^2] + \eta \sigma^2 + \frac{8\hat{\Delta}^2}{\hat{\mu}}.
\]

Consequently, we have

\[
E[\psi_t(\hat{x}_t) - \psi_t^*] \leq (1 - \hat{\rho})^t (\psi_0(x_0) - \psi_0^*) + \eta \sigma^2 + \frac{\hat{\Delta}^2}{\hat{\mu}}
\]

for all \(t \geq 0\), and the following asymptotic error bound holds:

\[
\limsup_{t \to \infty} E[\psi_t(\hat{x}_t) - \psi_t^*] \lesssim \eta \sigma^2 + \frac{\hat{\Delta}^2}{\hat{\mu}}.
\]

We may now apply Corollary 7.10 to obtain the formal version of Theorem 6.18, the proof is essentially identical to that of Theorem 5.13 and is therefore omitted.

Theorem 7.11 (Time to track in expectation). Suppose that Assumption 6.16 holds and that we are in the low drift-to-noise regime \(\hat{\Delta}/\sigma < \sqrt{\hat{\mu}/16L^3}\). Set \(\hat{\eta}_* = (2\hat{\Delta}^2/\hat{\mu}^2)^{1/3}\) and \(\hat{\mu} = \hat{\mu}(\Delta^2/\hat{\mu})^{2/3}\). Suppose moreover that we have available a positive upper bound on the initial gap \(D = \psi_0(x_0) - \psi_0^\dagger\). Consider running Algorithm 4 in \(k = 0, \ldots, K - 1\) epochs, namely, set \(X_0 = x_0\) and iterate the process

\[
X_{k+1} = D \cdot \nabla G(x_k, \eta_k, T_k) \quad \text{for} \quad k = 0, \ldots, K - 1,
\]

40
where the number of epochs is
\[ K = 1 + \left\lfloor \log_2 \left( \frac{1}{L} \cdot \left( \frac{\sigma^2 \tilde{\mu}}{\Delta^2} \right)^{1/3} \right) \right\rfloor \]
and we set
\[ \eta_0 = \frac{1}{2L}, \quad T_0 = \left\lfloor \frac{4L}{\tilde{\mu}} \log \left( \frac{LD}{\sigma^2} \right) \right\rfloor \quad \text{and} \quad \eta_k = \frac{\eta_{k-1} + \eta_*}{2}, \quad T_k = \left\lfloor \frac{2 \log(12)}{\tilde{\mu} \eta_k} \right\rfloor \quad \forall k \geq 1. \]

Then the time horizon \( T = T_0 + \cdots + T_{K-1} \) satisfies
\[ T \lesssim \frac{L}{\tilde{\mu}} \log \left( \frac{LD}{\sigma^2} \right) + \frac{\sigma^2}{\tilde{G}} < \frac{L}{\tilde{\mu}} \log \left( \frac{D}{\tilde{G}} \right) + \frac{\sigma^2}{\tilde{G}} \]
and the corresponding tracking error satisfies \( \mathbb{E}[\psi_T(X_K) - \psi_T^*] \lesssim \tilde{G}. \)

Next, we obtain high probability analogues of Corollary 7.10 and Theorem 7.11. The approach mirrors that of Section 5.4 and the proofs are essentially identical and are therefore omitted. We begin with an analogue of Proposition 5.14 which follows from Lemma 7.2.

**Proposition 7.12 (Self-regulation).** Let \( \{x_t\} \) be the iterates produced by Algorithm 3 with constant step size \( \eta \leq 1/2L \), and set \( \tilde{\rho} := \tilde{\mu} \eta/(2 - \mu \eta) \). Then the following holds for all indices \( t \geq 1 \):
\[
\sum_{i=0}^{t-1} \|x_i - \bar{x}_t\|^2 (1 - \tilde{\rho})^{2(t-1-i)} \leq \sum_{j=0}^{t-2} 2\eta \sum_{i=j+1}^{t-1} (1 - \tilde{\rho})^{t-2-i} \langle z_j, x_j - \bar{x}_t \rangle (1 - \tilde{\rho})^{t-1-j} 
\]
\[
+ (1 - \tilde{\rho})^{t-1} \frac{\|x_0 - \bar{x}_t\|^2}{\tilde{\rho}} + \frac{2\eta^2}{\tilde{\rho}} \sum_{j=0}^{t-2} \|z_j\|^2 (1 - \tilde{\rho})^{t-2-j} + \frac{3\eta \tilde{\mu} \Delta^2}{\tilde{\rho}^4}. 
\]

Proposition 7.12 simplifies as follows when the gradient noise is uniformly bounded.

**Corollary 7.13 (Self-regulation).** Under the assumptions of Proposition 7.12, assume further that there exists \( \sigma \geq 0 \) such that \( \|z_t\| \leq \sigma \) for all \( t \geq 0 \). Then for any \( t \geq 1 \), the estimate holds:
\[
\sum_{i=0}^{t-1} \sigma^2 \|x_i - \bar{x}_t\|^2 (1 - \tilde{\rho})^{2(t-1-i)} \leq \sum_{j=0}^{t-1} \alpha_j \langle z_j, x_j - \bar{x}_t \rangle (1 - \tilde{\rho})^{t-1-j} + \beta_t, 
\]
where we set
\[ \alpha_j := 2\eta \sigma^2 \sum_{i=j+1}^{t-1} (1 - \tilde{\rho})^{t-2-i} \]
for \( j = 0, \ldots, t-1 \) (with \( \alpha_{t-1} = 0 \)) and
\[ \beta_t := (1 - \tilde{\rho})^{t-1} \left( \|x_0 - \bar{x}_0\|^2 + \Delta^2 t^2 \right) \frac{2\sigma^2}{\tilde{\rho}} + \frac{2\eta^2 \sigma^4}{\tilde{\rho}^2} + \frac{3\tilde{\mu} \Delta^2 \eta \sigma^2}{\tilde{\rho}^4}. \]

Combining Corollary 7.13 and Theorem 5.16 yields the following proposition.

**Proposition 7.14 (Noise martingale tail bound).** Fix \( t \geq 1 \). Under the assumptions of Corollary 7.13, assume further that we have \( \mathbb{E}[z_i | \mathcal{F}_{i,t}] = 0 \) for all \( 0 \leq i < t \). Then the following holds for all \( \tau > 0 \):
\[
\mathbb{P} \left\{ \sum_{i=0}^{t-1} \langle z_i, x_i - \bar{x}_t \rangle (1 - \tilde{\rho})^{t-1-i} \geq \tau \right\} \leq \exp \left( -\frac{\tau}{4\alpha + 8\beta_t/\tau} \right), 
\]

41
where $\alpha := 3\eta^2/\check{\rho}$ and

$$\beta_t := (1 - \check{\rho})^{t-1} \left( \|x_0 - \bar{x}_0\|^2 + \Delta^2 t^2 \right) \frac{2\sigma^2}{\check{\rho}} + \frac{2\eta^2 \sigma^4}{\rho^2} + \frac{3\check{\mu} \Delta^2 \eta \sigma^2}{\rho^4}.$$ 

A quick computation shows that given $\delta \in (0, 1/e]$, we may take

$$\tau = (2 + \sqrt{5}) \sqrt{8\beta_t \log(1/\delta)}$$

in Proposition 7.14 to obtain

$$\mathbb{P} \left\{ \sum_{i=0}^{t-1} \langle z_i, x_i - \bar{x}_t \rangle (1 - \check{\rho})^{t-1-i} < (2 + \sqrt{5}) \sqrt{8\beta_t \log(1/\delta)} \right\} \geq 1 - \delta.$$

Together with Proposition 7.9 this establishes the following theorem, which is a sharper version of Theorem 6.20.

**Theorem 7.15** (Function gap with high probability). Suppose that Assumption 6.19 holds, and let $\{\hat{x}_t\}$ be the iterates produced by Algorithm 4 with constant learning rate $\eta \in (0, 1/2L]$. Then for any specified $t \in \mathbb{N}$ and $\delta \in (0, 1/e]$, the following estimate holds with probability at least $1 - \delta$:

$$\psi_t(\hat{x}_t) - \psi^* \leq (1 - \check{\rho})^t \left( \psi_t(x_0) - \psi^* + \frac{\hat{\rho}}{4} \|x_0 - \bar{x}_t\|^2 \right) + \eta \sigma^2 + \frac{8\check{\Delta}^2}{\mu \eta^2} (2 + \sqrt{5}) \hat{\rho} \sqrt{8\beta_t \log \left( \frac{1}{\delta} \right)},$$

where $\check{\rho} := \hat{\mu} \eta / (2 - \mu)$ and

$$\beta_t := (1 - \check{\rho})^{t-1} \left( \|x_0 - \bar{x}_0\|^2 + \Delta^2 t^2 \right) \frac{2\sigma^2}{\check{\rho}} + \frac{2\eta^2 \sigma^4}{\rho^2} + \frac{3\check{\mu} \Delta^2 \eta \sigma^2}{\rho^4}.$$

**Remark 7.16.** Upon noting the inequalities $\check{\Delta} \leq \check{\Delta}$, $\hat{\mu} \Delta^2 \leq \hat{\mu} \Delta^2$, and (29), it follows as in Remark 5.19 that Theorem 7.15 entails Theorem 6.20.

We may now apply Theorem 7.15 to obtain the formal version of Theorem 5.21.

**Theorem 7.17** (Time to track with high probability). Suppose that Assumption 6.19 holds and that we are in the low drift-to-noise regime $\Delta / \sigma < \sqrt{\mu / 16L^3}$. Set $\zeta_* = (2\Delta^2 / \mu \sigma^2)^{1/3} \hat{\overline{G}} = \hat{\mu}(\Delta^2 / \mu \sigma^2)^{2/3}$. Suppose moreover that we have available a positive upper bound on the initial gap $D \geq \psi_0(x_0) - \psi^*$. Fix $\delta \in (0, 1/e]$ and consider running Algorithm 4 in $k = 0, \ldots, K - 1$ epochs, namely, set $X_0 = x_0$ and iterate the process

$$X_{k+1} = D \cdot PSG(X_k, \eta_k, T_k) \quad \text{for} \quad k = 0, \ldots, K - 1,$$

where the number of epochs is

$$K = 1 + \left\lceil \log_2 \left( \frac{L}{2} \cdot \left( \frac{\sigma^2 \hat{\mu}}{\Delta^2} \right)^{1/3} \right) \right\rceil$$

and we set

$$\eta_0 = \frac{1}{2L}, \quad T_0 = \left\lceil \frac{4L}{\hat{\mu}} \log \left( \frac{LD}{\sigma^2} \right) \right\rceil \quad \text{and} \quad \eta_k = \frac{\eta_{k-1} + \eta_*}{2}, \quad T_k = \left\lceil \frac{2 \log \left( 4c \log(1/\delta) \right)}{\hat{\mu} \eta_k} \right\rceil$$

for all $k \geq 1$, where $c > 0$ is the absolute constant furnished by the bound (25). Then the time horizon $T = T_0 + \cdots + T_{K-1}$ satisfies

$$T \leq \frac{L}{\hat{\mu}} \left( \log \left( \frac{LD}{\sigma^2} \right) + \frac{\sigma^2}{\hat{\mu} \overline{G}} \log \left( \frac{1}{\delta} \right) \right) < \frac{L}{\hat{\mu}} \left( \log \left( \frac{D}{\overline{G}} \right) + \frac{\sigma^2}{\hat{\mu} \overline{G}} \log \left( \frac{1}{\delta} \right) \right)$$

42
and the corresponding tracking error satisfies

\[ \psi_T(X_K) - \psi^*_T \lesssim \hat{\mathcal{G}} \log \left( \frac{1}{\delta} \right) \]

with probability at least \( 1 - K\delta \).

Using similar proof techniques, we obtain analogues of Theorem 7.15 and Theorem 7.17 under the more general Assumption 6.22. First is the following sharper version of Theorem 6.23.

**Theorem 7.18** (Function gap with high probability). Suppose that Assumption 6.22 holds, and let \( \{\hat{x}_t\} \) be the average iterates produced by Algorithm 4 with constant learning rate \( \eta \in (0, 1/2L] \). Then there is an absolute constant \( c > 0 \) such that for any specified \( t \in \mathbb{N} \) and \( \delta \in (0, 1) \), the following estimate holds with probability at least \( 1 - \delta \):

\[
\psi_t(\hat{x}_t) - \psi_t^* \leq (1 - \hat{\rho})^t \left( \psi_t(x_0) - \psi_t^* + \frac{\mu_l}{4} \|x_0 - \bar{x}_t\|^2 \right) + \eta(\sigma^2) + \frac{8\Delta^2}{\mu \eta^2} + \left( \eta(\sigma^2) + (2 + \sqrt{5})\hat{\rho} \sqrt{8\beta_t(\delta/3)}\right) \log \left( \frac{3}{\delta} \right),
\]

where \( \hat{\rho} := \hat{\mu} \eta / (2 - \mu \eta) \) and

\[
\beta_t(\delta/3) := (1 - \hat{\rho})^{t-1} \left( \|x_0 - \bar{x}_0\|^2 + \Delta^2 t^2 \right) \frac{2(\sigma^2) \rho^4}{2 + \sigma^2} + \frac{\eta^2(\sigma^2) \rho^4}{2} \log \left( \frac{3e}{\delta} \right) + \frac{3\delta}{\rho^4} \eta(\sigma^2)^2.
\]

**Remark 7.19.** Upon noting the inequalities \( \Delta \leq \hat{\Delta}, \mu \hat{\Delta}^2 \leq \hat{\mu} \Delta^2 \), and (29), it follows as in Remark 5.22 that Theorem 7.18 entails Theorem 6.23.

We may now apply Theorem 6.23 to obtain the formal version of Theorem 6.24.

**Theorem 7.20** (Time to track with high probability). Suppose that Assumption 6.22 holds and that we are in the low drift-to-noise regime \( \Delta / \sigma < \sqrt{\hat{\mu} / 16L^3} \). Set \( \eta_* = (2\Delta^2 / \hat{\mu} \sigma^2)^{1/3} \) and \( \hat{\mathcal{G}} = \hat{\mu}(\hat{\Delta} \sigma^2 / \hat{\mu} \sigma^2)^{2/3} \). Suppose moreover that we have available a positive upper bound on the initial gap \( D \geq \psi_0(x_0) - \psi^*_0 \). Fix \( \delta \in (0, 1/e) \) and consider running Algorithm 4 in \( k = 0, \ldots, K - 1 \) epochs, namely, set \( X_0 = 0 \) and iterate the process

\[ X_{k+1} = D \cdot \text{PSG}(X_k, \eta_k, T_k) \quad \text{for} \quad k = 0, \ldots, K - 1, \]

where the number of epochs is

\[ K = 1 + \left\lceil \log_2 \left( \frac{1}{L} \cdot \left( \frac{\sigma^2 \hat{\mu}}{\Delta^2} \right)^{1/3} \right) \right\rceil \]

and we set

\[ \eta_0 = \frac{1}{2L}, \quad T_0 = \left\lfloor \frac{4L}{\hat{\mu}} \log \left( \frac{LD}{\sigma^2} \right) \right\rfloor \quad \text{and} \quad \eta_k = \frac{\eta_{k-1} + \eta_*}{2}, \quad T_k = \left\lfloor \frac{2 \log \left( 4c(\log(1/\delta))^{3/2} \right)}{\hat{\mu} \eta_k} \right\rfloor \]

for all \( k \geq 1 \), where \( c > 0 \) is the absolute constant furnished by the bound (26). Then the time horizon \( T = T_0 + \cdots + T_{K-1} \) satisfies

\[ T \lesssim \frac{L}{\hat{\mu}} \log \left( \frac{LD}{\sigma^2} \right) + \frac{\sigma^2}{\hat{\mu} \hat{\mathcal{G}}} \log \left( \log \left( \frac{1}{\delta} \right) \right) < \frac{L}{\hat{\mu}} \log \left( \frac{D}{\hat{\mathcal{G}}} \right) + \frac{\sigma^2}{\hat{\mu} \hat{\mathcal{G}}} \log \left( \log \left( \frac{1}{\delta} \right) \right) \]

and the corresponding tracking error satisfies

\[ \psi_T(X_K) - \psi^*_T \lesssim \hat{\mathcal{G}} \left( \log \left( \frac{1}{\delta} \right) \right)^{3/2} \]

with probability at least \( 1 - K\delta \).
References

A Additional proofs

A.1 Proof of Lemma 5.1

Since $f_t$ is $L$-smooth, we have
\[
\varphi_t(x_{t+1}) = f_t(x_{t+1}) + r_t(x_{t+1}) \\
\leq f_t(x_t) + \langle \nabla f_t(x_t), x_{t+1} - x_t \rangle + \frac{L}{2} \|x_{t+1} - x_t\|^2 + r_t(x_{t+1}) \\
= f_t(x_t) + r_t(x_{t+1}) + \langle g_t, x_{t+1} - x_t \rangle + \frac{L}{2} \|x_{t+1} - x_t\|^2 + \langle z_t, x_{t+1} - x_t \rangle.
\]

Next, given any $\delta_t > 0$, Young’s inequality yields
\[
\langle z_t, x_{t+1} - x_t \rangle \leq \frac{\delta_t}{2} \|z_t\|^2 + \frac{1}{2\delta_t} \|x_{t+1} - x_t\|^2.
\]

Therefore, given any $x \in \mathbb{R}^d$, we have
\[
\varphi_t(x_{t+1}) \leq f_t(x_t) + r_t(x_{t+1}) + \langle g_t, x_{t+1} - x_t \rangle + \frac{\delta_t^{-1} + L}{2} \|x_{t+1} - x_t\|^2 + \frac{\delta_t}{2} \|z_t\|^2 \\
\leq f_t(x_t) + r_t(x) + \langle g_t, x - x_t \rangle + \frac{1}{2\eta_t} \|x - x_t\|^2 - \frac{1}{2\eta_t} \|x - x_{t+1}\|^2 \\
\leq f_t(x_t) + r_t(x) + \langle g_t, x - x_t \rangle + \frac{1}{2\eta_t} \|x - x_t\|^2 - \frac{1}{2\eta_t} \|x - x_{t+1}\|^2
\]

where the last inequality holds because $x_{t+1} = \text{prox}_{\eta_t r_t}(x_t - \eta_t g_t)$ is the minimizer of the $\eta_t^{-1}$-strongly convex function $r_t + \langle g_t, \cdot - x_t \rangle + \frac{1}{2\eta_t} \|\cdot - x_t\|^2$. Now we estimate
\[
f_t(x_t) + r_t(x) + \langle g_t, x - x_t \rangle = f_t(x_t) + \langle \nabla f_t(x_t), x - x_t \rangle + r_t(x) + \langle z_t, x_t - x \rangle \\
\leq f_t(x_t) - \frac{\mu}{2} \|x - x_t\|^2 + r_t(x) + \langle z_t, x_t - x \rangle \\
= \varphi_t(x) - \frac{\mu}{2} \|x - x_t\|^2 + \langle z_t, x_t - x \rangle
\]

using the $\mu$-strong convexity of $f_t$. Thus,
\[
\varphi_t(x_{t+1}) \leq \varphi_t(x) - \frac{\mu}{2} \|x - x_t\|^2 + \langle z_t, x_t - x \rangle + \frac{1}{2\eta_t} \|x - x_t\|^2 - \frac{1}{2\eta_t} \|x - x_{t+1}\|^2 \\
+ \frac{\delta_t^{-1} + L - \eta_t^{-1}}{2} \|x_{t+1} - x_t\|^2 + \frac{\delta_t}{2} \|z_t\|^2.
\]

Finally, taking $\delta_t = \eta_t / (1 - L\eta_t)$ and rearranging (note that $\varphi_t(x_{t+1})$ is finite) yields
\[
2\eta_t(\varphi_t(x_{t+1}) - \varphi_t(x)) \leq (1 - \mu\eta_t)\|x_t - x\|^2 - \|x_{t+1} - x\|^2 + 2\eta_t \langle z_t, x_t - x \rangle + \frac{\eta_t^2}{1 - L\eta_t} \|z_t\|^2,
\]
as claimed.
A.2 Proof of Proposition 5.6

For any index $t$ and any scalar $\lambda \geq 0$, the tower rule implies
\[
\mathbb{E}[\exp(\lambda V_{t+1})] \leq \mathbb{E}\left[ \exp \left( \lambda (\alpha_t V_t + D_t \sqrt{V_t} + X_t + \kappa_t) \right) \right]
\]
\[
= \exp(\lambda \kappa_t) \mathbb{E}\left[ \exp(\lambda \alpha_t V_t) \mathbb{E}\left[ \exp \left( \lambda D_t \sqrt{V_t} \right) \right] \right] \mathbb{E}\left[ \exp(\lambda X_t) \mathbb{I}_{H_t} \right].
\]
Hölder’s inequality in turn yields
\[
\mathbb{E}\left[ \exp \left( \lambda D_t \sqrt{V_t} \right) \mathbb{E}(\lambda X_t) | H_t \right] \leq \sqrt{\mathbb{E}\left[ \exp \left( 2\lambda \sqrt{V_t} D_t \right) | H_t \right] \cdot \mathbb{E}\left[ \exp \left( 2\lambda X_t \right) | H_t \right]}
\]
\[
\leq \sqrt{\exp(2\lambda^2 \sigma_t^2 V_t) \exp(2\lambda \nu_t)}
\]
\[
= \exp(\lambda^2 \sigma_t^2 V_t) \exp(\lambda \nu_t)
\]
provided $0 \leq \lambda \leq \frac{1}{2\sigma_t}$. Therefore, provided $0 \leq \lambda \leq \min \left\{ \frac{1-\alpha_t}{2\sigma_t^2}, \frac{\sqrt{\tau \nu_t}}{2\sigma_t} \right\}$, the following estimate holds:
\[
\mathbb{E}[\exp(\lambda V_{t+1})] \leq \exp(\lambda \kappa_t) \mathbb{E}\left[ \exp(\lambda \alpha_t V_t) \exp(\lambda^2 \sigma_t^2 V_t) \exp(\lambda \nu_t) \right]
\]
\[
= \exp(\lambda \nu_t + \kappa_t) \mathbb{E}\left[ \exp(\lambda \alpha_t + \lambda \sigma_t^2 V_t) \right]
\]
\[
\leq \exp(\lambda \nu_t + \kappa_t) \mathbb{E}\left[ \exp \left( \frac{\lambda}{2} \left( 1 + \alpha_t \right) \right) \right]
\]
The proof is complete.

A.3 Proof of Theorem 5.8

For each index $k$, let $t_k := T_0 + \cdots + T_{k-1}$ (with $t_0 := 0$), $X^*_k$ be the minimizer of the corresponding function $\varphi_{t_k}$, and
\[
E_k := c \left( \frac{\eta_k \sigma^2}{\mu} + \left( \frac{\Delta}{\mu \eta_k} \right)^2 \right),
\]
where $c \geq 1$ is an absolute constant satisfying the bound (7) in Theorem 3.6. Taking into account $\eta_k \geq \eta_*$ and our selection of $c$, Theorem 3.6 implies that for any specified $k \geq 0$ and $\delta \in (0, 1)$ the following estimate holds with probability at least $1 - \delta$:
\[
\|X_{k+1} - X^*_k\|^2 \leq \left( 1 - \frac{\mu \eta_k}{2} \right)^{T_k} \|X_k - X^*_k\|^2 + c \left( \frac{\eta_k \sigma^2}{\mu} + \left( \frac{\Delta}{\mu \eta_k} \right)^2 \right) \log \left( \frac{e}{\delta} \right)
\]
\[
\leq e^{-\mu \eta_k T_k/2} \|X_k - X^*_k\|^2 + E_k \log \left( \frac{e}{\delta} \right).
\]

We will verify by induction that for all indices $k \geq 1$, the estimate $\|X_k - X^*_k\|^2 \leq 3E_{k-1} \log(e/\delta)$ holds with probability at least $1 - k\delta$ for all $\delta \in (0, 1)$. To see the base case, observe that the estimate
\[
\|X_1 - X^*_1\|^2 \leq e^{-\mu \eta_0 T_0/2} \|X_0 - X^*_0\|^2 + E_0 \log \left( \frac{e}{\delta} \right) \leq 3E_0 \log \left( \frac{e}{\delta} \right)
\]
holds with probability at least $1 - \delta$ for all $\delta \in (0, 1)$. Now assume the claim holds for some index $k \geq 1$, and let $\delta \in (0, 1)$; then $\|X_k - X^*_k\|^2 \leq 3E_{k-1} (e/\delta)$ with probability at least $1 - k\delta$. Thus,
for each

for all

\{h_\infty\}

We will use a small variation of the averaging lemma in [14]. To this end, consider a convex

A.4 The averaging lemma

This completes the proof.

with probability at least $1-\delta$, a union bound reveals $\|X_{k+1}-X^*_k\|^2 \leq 3E_k \log(e/\delta)$ with probability at least $1-(k+1)\delta$, thereby completing the induction. Hence, upon fixing $\delta \in (0,1)$, we have $\|X_K-X^*_k\|^2 \leq 3E_{K-1} \log(e/\delta)$ with probability at least $1-K\delta$.

Next, observe

$$\frac{2}{e}E_{K-1} - \sqrt{54} \left(\frac{\Delta \sigma^2}{\mu^2}\right)^{2/3} = \frac{2\sigma^2}{\mu} (\eta_{K-1} - \eta_*) = \frac{2\sigma^2}{\mu} \cdot \frac{\eta_\infty - \eta_*}{2^{K-1}} \leq \left(\frac{\Delta \sigma^2}{\mu^2}\right)^{2/3} = \mathcal{E},$$

so

$$\|X_K-X^*_k\|^2 \leq \frac{3c}{2} \left(1 + \sqrt{54}\right) \mathcal{E} \log \left(\frac{e}{\delta}\right) \leq \mathcal{E} \log \left(\frac{e}{\delta}\right)$$

with probability at least $1-K\delta$. Finally, note

$$T \preceq \frac{L}{\mu} \log \left(\frac{\mu LD}{\sigma^2}\right) + \frac{1}{\mu} \sum_{k=1}^{K-1} \frac{1}{\eta_k}$$

and

$$\sum_{k=1}^{K-1} \frac{1}{\eta_k} \leq 2L \sum_{k=1}^{K-1} 2^k \leq 2L \cdot 2^K = 8L \cdot 2^{K-2} \leq 8 \left(\frac{\sigma^2 \mu}{\Delta \sigma^2}\right)^{1/3} \leq \frac{8\sigma^2}{\mu} \cdot \left(\frac{\Delta \sigma^2}{\mu^2}\right)^{-2/3} \preceq \frac{\sigma^2}{\mu \mathcal{E}}.$$ 

This completes the proof.

A.4 The averaging lemma

We will use a small variation of the averaging lemma in [14]. To this end, consider a convex function $h: \mathbb{R}^d \to \mathbb{R} \cup \{\infty\}$ and let $\{x_t\}_{t \geq 0}$ be a sequence of vectors in dom $h$. Suppose that there are constants $c_1, c_2 \in \mathbb{R}$, a nonnegative sequence of weights $\{\rho_t\}_{t \geq 1}$, and scalar sequences $\{V_t\}_{t \geq 0}$ and $\{\omega_t\}_{t \geq 1}$ satisfying the recursion

$$\rho_th(x_t) \leq (1-c_1\rho_t)V_{t-1} - (1+c_2\rho_t)V_t + \omega_t \quad (30)$$

for all $t \geq 1$. The goal is to bound the function value $h(\hat{x}_t)$ evaluated along an “average iterate” $\hat{x}_t$.

Suppose that the relations $c_1 + c_2 > 0$, $1-c_1\rho_t > 0$, and $1+c_2\rho_t > 0$ hold for all $t \geq 1$. Define the augmented weights and products

$$\hat{\rho}_t = \frac{\rho_t(c_1 + c_2)}{1 + c_2\rho_t} \quad \text{and} \quad \hat{\Gamma}_t = \prod_{i=1}^{t}(1 - \hat{\rho}_i)$$

for each $t \geq 1$, while setting $\hat{\Gamma}_0 = 1$. A straightforward induction yields the relation

$$1 + \sum_{i=1}^{t} \frac{\hat{\rho}_i}{\hat{\Gamma}_i} = \frac{1}{\hat{\Gamma}_t}.$$

Now set $\hat{x}_0 = x_0$ and recursively define the average iterates

$$\hat{x}_t = (1 - \hat{\rho}_t)\hat{x}_{t-1} + \hat{\rho}_tx_t$$
for all \( t \geq 1 \). Unrolling this recursion, we may equivalently write
\[
\hat{x}_t = \hat{\Gamma}_t \left( x_0 + \sum_{i=1}^t \frac{\hat{\rho}_i}{\hat{\Gamma}_i} x_i \right) .
\] (31)

The following is the key estimate we will need.

**Lemma A.1 (Averaging).** The following estimate holds for all \( t \geq 0 \):
\[
\frac{h(\hat{x}_t)}{c_1 + c_2} + V_t \leq \hat{\Gamma}_t \left( \frac{h(x_0)}{c_1 + c_2} + V_0 + \sum_{i=1}^t \frac{\omega_i}{\Gamma_i(1 + c_2 \rho_i)} \right).
\]

**Proof.** Observe that (31) expresses \( \hat{x}_t \) as a convex combination of \( x_0, \ldots, x_t \). Therefore, by the convexity of \( h \) we may apply Jensen’s inequality to obtain
\[
h(\hat{x}_t) \leq \hat{\Gamma}_t h(x_0) + \sum_{i=1}^t \frac{\hat{\rho}_i}{\hat{\Gamma}_i} h(x_i).
\]

On the other hand, for each \( i \geq 1 \), we may divide the recursion (30) by \( \hat{\Gamma}_i(1 + c_2 \rho_i) \) to obtain
\[
\frac{\hat{\rho}_i}{\hat{\Gamma}_i(c_1 + c_2)} h(x_i) \leq \frac{V_{i-1}}{\Gamma_{i-1}} - \frac{V_i}{\hat{\Gamma}_i} + \frac{\omega_i}{\Gamma_i(1 + c_2 \rho_i)},
\]
which telescopes to yield
\[
\frac{1}{c_1 + c_2} \sum_{i=1}^t \frac{\hat{\rho}_i}{\hat{\Gamma}_i} h(x_i) \leq V_0 - \frac{V_t}{\hat{\Gamma}_t} + \sum_{i=1}^t \frac{\omega_i}{\Gamma_i(1 + c_2 \rho_i)}.
\]
Hence
\[
\frac{h(\hat{x}_t)}{c_1 + c_2} \leq \hat{\Gamma}_t \left( \frac{h(x_0)}{c_1 + c_2} + V_0 - \frac{V_t}{\hat{\Gamma}_t} + \sum_{i=1}^t \frac{\omega_i}{\Gamma_i(1 + c_2 \rho_i)} \right),
\]
as claimed. \( \square \)

A.5 **Proof of Theorem 5.13**

For each index \( k \), let \( t_k := T_0 + \ldots + T_{k-1} \) (with \( t_0 := 0 \)) and \( G_k := \eta_k \sigma^2 + 8 \Delta^2 / \mu \eta_k^2 \). Then taking into account \( \eta_k \geq \eta_* \), Corollary 5.12 and inequality (14) directly imply
\[
\mathbb{E} \left[ \varphi_{t_{k+1}}(X_{k+1}) - \varphi_{t_k}^* \right] \leq \left( 1 - \frac{\mu \eta_k}{2} \right) T_k \mathbb{E} \left[ \varphi_{t_k}(X_k) - \varphi_{t_k}^* \right] + 2 \mu \Delta^2 T_k^2 + \eta_k \sigma^2 + \frac{8 \Delta^2}{\mu \eta_k}
\leq 3 e^{-\mu \eta T_k/2} \mathbb{E} \left[ \varphi_{t_k}(X_k) - \varphi_{t_k}^* \right] + 2 e^{-\mu \eta T_k/2} \Delta^2 T_k^2 + G_k.
\]

We will verify by induction that the estimate \( \mathbb{E} \left[ \varphi_{t_{k+1}}(X_{k+1}) - \varphi_{t_k}^* \right] \leq 7G_k \) holds for all indices \( k \). To see the base case, observe that inequality (15) facilitates the estimation
\[
\mathbb{E} \left[ \varphi_{t_1}(X_1) - \varphi_{t_1}^* \right] \leq 3 e^{-\mu \eta T_0/2} \mathbb{E} \left[ \varphi_{t_0}(X_0) - \varphi_{t_0}^* \right] + 2 e^{-\mu \eta T_0/2} \Delta^2 T_0^2 + G_0 \leq 7G_0.
\]
Assume next that the claim holds for index \( k - 1 \). We then conclude
\[
\mathbb{E} \left[ \varphi_{t_{k+1}}(X_{k+1}) - \varphi_{t_k}^* \right] \leq 3 e^{-\mu \eta T_k/2} \mathbb{E} \left[ \varphi_{t_k}(X_k) - \varphi_{t_k}^* \right] + 2 e^{-\mu \eta T_k/2} \Delta^2 T_k^2 + G_k
\leq \frac{1}{4} \mathbb{E} \left[ \varphi_{t_k}(X_k) - \varphi_{t_k}^* \right] + \frac{16 \Delta^2}{\mu \eta_k^2} + G_k
\leq \frac{G_k}{2G_{k-1}} \mathbb{E} \left[ \varphi_{t_k}(X_k) - \varphi_{t_k}^* \right] + \frac{16 \Delta^2}{\mu \eta_k^2} + G_k < 7G_k.
\]

50
completing the induction. Hence \( \mathbb{E}[\varphi_T(X_K) - \varphi_T^*] \leq 7G_{K-1} \).

Next, observe
\[
G_{K-1} - \frac{\sqrt{2}25}{250} \cdot \mu \left( \frac{\Delta \sigma^2}{\mu^2} \right)^{2/3} = \sigma^2(\eta_{K-1} - \eta_*) = \sigma^2 \cdot \frac{\eta_0 - \eta_*}{2K-1} \leq \frac{\mu}{2} \left( \frac{\Delta \sigma^2}{\mu^2} \right)^{2/3} = \frac{1}{2} G,
\]
so
\[
\mathbb{E}[\varphi_T(X_K) - \varphi_T^*] \leq 7 \left( \frac{1}{2} + \frac{\sqrt{2}250}{250} \right) \cdot \mu \left( \frac{\Delta \sigma^2}{\mu^2} \right)^{2/3} \leq \mathcal{O}.
\]
Finally, note
\[
T \leq \frac{L}{\mu} \log \left( \frac{LD}{\sigma^2} \right) + \frac{1}{\mu} \sum_{k=1}^{K-1} \frac{1}{\eta_k}
\]
and
\[
\sum_{k=1}^{K-1} \frac{1}{\eta_k} \leq 2L \sum_{k=1}^{K-1} 2^k \leq 2L \cdot 2^{K-2} \leq 8 \left( \frac{\sigma^2 \mu}{\Delta^2} \right)^{1/3} = 8 \sigma^2 \cdot \mu^{-1} \left( \frac{\Delta \sigma^2}{\mu^2} \right)^{-2/3} \leq \frac{\sigma^2}{\mathcal{G}}.
\]
This completes the proof.

A.6 Proof of Proposition 5.14

Fix \( t \geq 1 \). Given \( i \geq 1 \) and \( \alpha > 0 \), the \( \mu \)-strong convexity of \( \varphi_t \) and Lemma 5.10 imply
\[
\mu \eta \| x_i - x_t^* \|^2 \leq 2 \eta (\varphi_t(x_i) - \varphi_t^*) \leq (1 - \mu \eta) \| x_{i-1} - x_t^* \|^2 - (1 - \alpha \eta) \| x_i - x_t^* \|^2
\]
\[
+ 2 \eta \langle z_{i-1}, x_{i-1} - x_t^* \rangle + 2 \eta^2 \| z_i - 1 \|^2 + \alpha^{-1} \eta G_{i-1,t}^2,
\]
\[
(1 + (\mu - \alpha) \eta) \| x_i - x_t^* \|^2 \leq (1 - \mu \eta) \| x_{i-1} - x_t^* \|^2 + 2 \eta \langle z_{i-1}, x_{i-1} - x_t^* \rangle + 2 \eta^2 \| z_i - 1 \|^2 + \alpha^{-1} \eta G_{i-1,t}^2.
\]
Taking \( \alpha = \mu \), we obtain
\[
\| x_i - x_t^* \|^2 \leq (1 - \mu \eta) \| x_{i-1} - x_t^* \|^2 + 2 \eta \langle z_{i-1}, x_{i-1} - x_t^* \rangle + 2 \eta^2 \| z_i - 1 \|^2 + \frac{\eta}{\mu} G_{i-1,t}^2
\]
\[
\leq (1 - \hat{\rho}) \| x_{i-1} - x_t^* \|^2 + 2 \eta \langle z_{i-1}, x_{i-1} - x_t^* \rangle + 2 \eta^2 \| z_i - 1 \|^2 + \frac{\eta}{\mu} G_{i-1,t}^2,
\]
(note \( \hat{\rho} = \mu \eta / (2 - \mu \eta) < \mu \eta \) because \( \mu \eta < 1 \)). Thus, by induction, we conclude
\[
\| x_i - x_t^* \|^2 \leq (1 - \hat{\rho})^i \| x_0 - x_t^* \|^2 + 2 \eta \sum_{j=0}^{i-1} \langle z_j, x_j - x_t^* \rangle (1 - \hat{\rho})^{i-j} \]
\[
+ 2 \eta^2 \sum_{j=0}^{i-1} \| z_j \|^2 (1 - \hat{\rho})^{i-j} + \frac{\eta}{\mu} \sum_{j=0}^{i-1} G_{j,t}(1 - \hat{\rho})^{i-j}
\]
for all \( i \geq 1 \). Therefore
\[
\sum_{i=0}^{t-1} \| x_i - x_t^* \|^2 (1 - \hat{\rho})^{2(t-1-i)} \leq \| x_0 - x_t^* \|^2 \sum_{i=0}^{t-1} (1 - \hat{\rho})^{2(t-1-i)} + 2 \eta \sum_{i=1}^{t-1} \sum_{j=0}^{i-1} \langle z_j, x_j - x_t^* \rangle (1 - \hat{\rho})^{2t-3-j-i}
\]
\[
+ 2 \eta^2 \sum_{i=1}^{t-1} \sum_{j=0}^{i-1} \| z_j \|^2 (1 - \hat{\rho})^{2t-3-j-i} + \frac{\eta}{\mu} \sum_{i=1}^{t-1} \sum_{j=0}^{i-1} G_{j,t}(1 - \hat{\rho})^{2t-3-j-i}.
\]
Further, if \( k \eta \) into account holds with probability at least \( \frac{1}{\hat{\rho}} \), we have
\[
\sum_{i=1}^{t-1} \sum_{j=0}^{t-1} X_j (1 - \hat{\rho})^{t-3-j-i} = \sum_{j=0}^{t-2} \left( \sum_{i=j+1}^{t-1} (1 - \hat{\rho})^{t-2-i} \right) X_j (1 - \hat{\rho})^{t-1-j}.
\]
and observe that for any scalar sequence \((X_j)_{j=0}^{t-2}\), we have
\[
\sum_{i=1}^{t-1} \sum_{j=0}^{t-1} X_j (1 - \hat{\rho})^{2t-3-j-i} = \sum_{j=0}^{t-2} \left( \sum_{i=j+1}^{t-1} (1 - \hat{\rho})^{t-2-i} \right) X_j (1 - \hat{\rho})^{t-2-j}.
\]
Further, if \( X_j \geq 0 \) for all \( j = 0, \ldots, t-2 \), then we have
\[
\sum_{i=1}^{t-1} \sum_{j=0}^{t-1} X_j (1 - \hat{\rho})^{2t-3-j-i} = \sum_{j=0}^{t-2} \left( \sum_{i=j+1}^{t-1} (1 - \hat{\rho})^{t-2-i} \right) X_j (1 - \hat{\rho})^{t-2-j} \leq \frac{1}{\hat{\rho}} \sum_{j=0}^{t-2} X_j (1 - \hat{\rho})^{t-2-j}.
\]
Hence the following estimation holds:
\[
\sum_{i=0}^{t-1} \| x_i - x_i^* \|^2 (1 - \hat{\rho})^{2(t-1-i)} \leq \sum_{j=0}^{t-2} \left( \sum_{i=j+1}^{t-1} (1 - \hat{\rho})^{t-2-i} \right) \langle z_j, x_j - x_j^* \rangle (1 - \hat{\rho})^{t-1-j} + (1 - \hat{\rho})^{t-1} \frac{\| x_0 - x_0^* \|^2}{\hat{\rho}} + \frac{2\eta^2}{\mu \hat{\rho}} \sum_{j=0}^{t-2} \| z_j \|^2 (1 - \hat{\rho})^{t-2-j} + \frac{\eta}{\mu \hat{\rho}} \sum_{j=0}^{t-2} G_j^2 (1 - \hat{\rho})^{t-2-j}.
\]
This completes the proof.

### A.7 Proof of Theorem 5.20

For each index \( k \), let \( t_k := T_0 + \cdots + T_{k-1} \) (with \( t_0 := 0 \)) and \( G_k := \eta_k \sigma^2 + \Delta^2 / \mu \eta_k^2 \). Then taking into account \( \eta_k \geq \eta^* \) and our selection of the absolute constant \( c \) via (8), it follows that for all indices \( k \) the estimate
\[
\varphi_{t_{k+1}}(X_{k+1}) - \varphi^*_{t_{k+1}} \leq c \left( \left( 1 - \frac{\mu \eta_k}{2} \right) T_k (\varphi_{t_k}(X_k) - \varphi^*_{t_k}) + \eta_k \sigma^2 + \frac{\Delta^2}{\mu \eta_k^2} \right) \log \left( \frac{1}{\delta} \right)
\]
holds with probability at least \( 1 - \delta \).

We will verify by induction that for all indices \( k \geq 1 \), the estimate
\[
\varphi_{t_k}(X_k) - \varphi^*_{t_k} \leq 3c G_{k-1} \log \left( \frac{1}{\delta} \right)
\]
holds with probability at least \( 1 - k \delta \). To see the base case, observe that the estimate
\[
\varphi_{t_1}(X_1) - \varphi^*_{t_1} \leq c \left( e^{-\mu \eta_0 T_0 / 2} (\varphi_0(x_0) - \varphi^*_0) + G_0 \right) \log \left( \frac{1}{\delta} \right) \leq 3c G_0 \log \left( \frac{1}{\delta} \right)
\]
holds with probability at least \( 1 - \delta \). Now assume the claim holds for some index \( k \geq 1 \). Then
The goal is to recover using least-squares the vectors $x_{k+1}$ and $(\varphi_{tk})^*_{k+1}$ with probability at least $1 - \delta$, so

$$\varphi_{tk+1}(X_{k+1}) - \varphi^*_{tk+1} \leq c(e^{-\mu \log(1/\delta)(\varphi_{tk}(X_k) - \varphi^*_{tk}) + G_k}) \log \left( \frac{1}{\delta} \right)$$

with probability at least $1 - \delta$, a union bound reveals that the estimate

$$\varphi_{tk+1}(X_{k+1}) - \varphi^*_{tk+1} \leq 3cG_k \log \left( \frac{1}{\delta} \right)$$

holds with probability at least $1 - (k + 1)\delta$, thereby completing the induction. In particular, $\varphi_T(X_K) - \varphi^*_T \leq 3cG_{K-1} \log(1/\delta)$ with probability at least $1 - K\delta$.

Next, observe

$$G_{K-1} - \sqrt{\frac{2}{4}} \cdot \mu \left( \frac{\Delta \sigma^2}{\mu^2} \right)^{2/3} = \sigma^2(\eta_{K-1} - \eta_k) = \sigma^2 \cdot \eta_{k-1} \cdot \eta_k \leq \frac{\mu}{2} \left( \frac{\Delta \sigma^2}{\mu^2} \right)^{2/3},$$

so

$$\varphi_T(X_K) - \varphi^*_T \leq 3c \left( \frac{1}{2} + \sqrt{\frac{2}{4}} \right) \cdot \mu \left( \frac{\Delta \sigma^2}{\mu^2} \right)^{2/3 \log \left( \frac{1}{\delta} \right)} \times G \log \left( \frac{1}{\delta} \right)$$

with probability at least $1 - K\delta$. Finally, note

$$T \leq \frac{L}{\mu} \log \left( \frac{LD}{\sigma^2} \right) + \frac{1}{\mu} \log \left( \log \left( \frac{1}{\delta} \right) \right)\sum_{k=1}^{K-1} \frac{1}{\eta_k},$$

and

$$\sum_{k=1}^{K-1} \frac{1}{\eta_k} \leq 2L \sum_{k=1}^{K-1} 2^k \leq 2L \cdot 2^K - 2L \cdot 2^K = 8L \cdot 2^K - 8 \left( \frac{\sigma^2 \mu}{\Delta^2} \right)^{1/3} = 8\sigma^2 \cdot \mu^{-1} \left( \frac{\Delta \sigma^2}{\mu^2} \right)^{-2/3} \times \frac{\sigma^2}{G}.$$
orthogonal projection onto $B_1$. We implement Algorithm 1 using gradient proxy $g_t = x_t - z_{t,i}$ at step $t$, where $i$ is sampled uniformly from $\{1, \ldots, n\}$. We uniformly sample a vector in $B_1$ to fix as the initial $x_0$ in our simulations, and we take $n = 100$, $d = 70$, $\sigma = 1/4$, and $\Delta = 1/20$. Since $f_t$ is 1-strongly convex and 1-smooth, this puts us in the low drift/noise regime $\Delta/\sigma < \sqrt{\mu/16L^2}$. To estimate $\mathbb{E}[\|x_t - x_\star\|^2]$ and $\mathbb{E}[\varphi_t(\hat{x}_t) - \varphi_\star^T]$ as well as confidence intervals for $\|x_T - x_\star^T\|^2$ and $\varphi_T(\hat{x}_T) - \varphi_\star^T$, we run 500 trials of Algorithm 1 with horizon $T = 25$, initiating the random walk $(x_t^i)$ at the origin for each trial. The numerical results in Fig. 1-2 verify our bounds and show that they capture the correct scalings with respect to $\eta$, $\sigma$, and $\Delta$ both in distance to minimum and in

Figure 1: Tracking error for least-squares recovery of sparse vectors (left: distance to minimum; right: function gap).

Figure 2: Theoretical vs. empirical scaling of tracking errors with respect to $\eta$, $\sigma$, and $\Delta$ for least-squares recovery of sparse vectors (top row: distance to minimum; bottom row: function gap).
function gap.

**Least-squares recovery of dense vectors.** We work here with an unconstrained formulation and without a regularization penalty. Let \((x^*_t)\) be a random walk in \(\mathbb{R}^d\), initialized at the origin, satisfying \(\|x^*_t - x^*_{t+1}\| = \Delta\) for all \(t\). Let \(A \in \mathbb{R}^{n \times d}\), \(C = \frac{\sigma^2_n}{\|A\|_{\text{op}}} I_n\), and \(\mathcal{P}_t = \mathcal{N}(Ax^*_t, C)\). The goal is to recover using least-squares the vectors \((x^*_t)\):

\[
\min_{x \in \mathbb{R}^d} \mathbb{E}_{z \sim \mathcal{P}_t} \frac{1}{2} \|Ax - z\|^2,
\]
which amounts to the target problem (5) under the identifications
\[ f_t(x) = \mathbb{E}_{z \sim P_t} \frac{1}{2} \|Ax - z\|^2 \]
and \( r_t = 0 \). At step \( t \) we use gradient proxy \( g_t = A^T(Ax_t - z) \), where \( z \sim P_t \). We uniformly sample a vector in the unit \( \ell_2 \)-ball to fix as the initial \( x_0 \) in our simulations. We randomly generate \( A \) via its singular value decomposition so that the minimal singular value of \( A \) is \( \sqrt{\mu} = \sqrt{1/2} \) and the maximal singular value of \( A \) is \( \sqrt{\ell} = 1 \), and we take \( n = 100, d = 70, \sigma = 1 \), and \( \Delta = 1/6 \). Since \( f_t \) is \( \mu \)-strongly convex and \( \ell \)-smooth, this puts us in the low drift/noise regime \( \Delta/\sigma < \sqrt{\mu/16\ell^3} \).

To estimate \( \mathbb{E}\|x_t - x^*_t\|^2 \) and \( \mathbb{E}[\varphi_t(\hat{x}_t) - \varphi^*_t] \) as well as confidence intervals for \( \|x_T - x^*_T\|^2 \) and \( \varphi_T(\hat{x}_T) - \varphi^*_T \), we run 250 trials of Algorithm 1 with horizon \( T = 40 \), initiating the random walk \( (x_t^*) \) at the origin for each trial. Here again the numerical results in Fig. 3-4 verify our bounds and show that they capture the correct scalings with respect to \( \eta, \sigma, \) and \( \Delta \) both in distance to minimum and in function gap.

**\( \ell_2 \)-regularized logistic regression.** We consider the time-varying \( \ell_2 \)-regularized logistic regression problem

\[
\min_{x \in \mathbb{R}^d} \sum_{i=1}^{n} \log(1 + \exp(a_i, x)) - \langle Ax, b_t \rangle + \frac{1}{2} \|x\|^2,
\]

where the matrix \( A \in \mathbb{R}^{n \times d} \) has rows \( a_1, ..., a_n \in \mathbb{R}^d, \|A\|_{\text{op}} = \Delta \), and \( (b_t) \) is a random sequence of label vectors in \( \{0, 1\}^n \) such that \( b_t \) and \( b_{t+1} \) differ in precisely one coordinate for each \( t \). This amounts to the target problem (5) under the identifications
\[ f_t(x) = \sum_{i=1}^{n} \log(1 + \exp(a_i, x)) - \langle Ax, b_t \rangle + \frac{1}{2} \|x\|^2 \]
and \( r_t = 0 \), and it follows that \( \sup_x \|\nabla f_t(x) - \nabla f_{t+1}(x)\| \leq \Delta \) for all \( t \). We implement Algorithm 1 using a noisy gradient \( g_t \) satisfying \( \|g_t - \nabla f_t(x_t)\| \leq \sigma \) for each step \( t \), we fix \( x_0 \) to be the origin, and we uniformly sample a vector in \( \{0, 1\}^n \) to fix as the initial label vector \( b_0 \) in our simulations. We take \( n = 100, d = 70, \sigma = 1 \), and \( \Delta = 1/5 \). Since \( f_t \) is \( 1 \)-strongly convex and \((1 + \Delta^2/4)\)-smooth, this puts us in the low drift/noise regime \( \Delta/\sigma < \sqrt{\mu/16\ell^3} \). To estimate \( \mathbb{E}\|x_t - x^*_t\|^2 \) and \( \mathbb{E}[\varphi_t(\hat{x}_t) - \varphi^*_t] \) as well as confidence intervals for \( \|x_T - x^*_T\|^2 \) and \( \varphi_T(\hat{x}_T) - \varphi^*_T \), we run 250 trials of Algorithm 1 with horizon \( T = 25 \). The numerical results in Fig. 5-6 verify our bounds and show that they capture the correct scalings with respect to \( \eta, \sigma, \) and \( \Delta \) both in distance to minimum and in function gap.
Figure 6: Theoretical vs. empirical scaling of tracking errors with respect to $\eta$, $\sigma$, and $\Delta$ for $\ell_2$-regularized logistic regression (top row: distance to minimum; bottom row: function gap).
