Abstract

A well-known theorem of Whitney states that a 3-connected planar graph admits an essentially unique embedding into the 2-sphere. We prove a 3-dimensional analogue: a simply-connected 2-complex every link graph of which is 3-connected admits an essentially unique locally flat embedding into the 3-sphere, if it admits one at all. This can be thought of as a generalisation of the 3-dimensional Schoenflies theorem.

Keywords: 2-complex, unique embedding, Whitney theorem, Schoenflies theorem.

MSC 2020 Classification: 05C10, 57M15, 57M99, 57N35, 54C25.

1 Introduction

The following classical theorem of Whitney states that a 3-connected planar graph admits an essentially unique embedding into the plane or the 2-sphere. A graph is *k-connected*, if it remains connected after removing any set of $k - 1$ vertices.

Theorem 1.1 (Whitney’s theorem [15, Theorem 11], [6, Theorem 4.3.2]). *Let G be a 3-connected, finite, planar graph. Then for every two embeddings $\phi, \psi : G \rightarrow \mathbb{S}^2$, there is a homeomorphism $\alpha : \mathbb{S}^2 \rightarrow \mathbb{S}^2$ such that $\psi = \alpha \circ \phi$.*

This can be thought of as a generalisation of the Schoenflies theorem, which can be phrased as saying that any two embeddings of \mathbb{S}^1 in \mathbb{S}^2 differ by an automorphism of \mathbb{S}^2 . The Schoenflies theorem has been generalised to higher dimensions [2, 13], and its 3-dimensional version reads as follows

Theorem 1.2 (Generalised Schoenflies theorem [2, 13]). *If $K \subset \mathbb{S}^3$ is homeomorphic to \mathbb{S}^2 and locally flat, then there is an automorphism of \mathbb{S}^3 mapping its equator (which is homeomorphic to \mathbb{S}^2) to K .*

The local flatness condition here is a weakening of piecewise linearity; see Section 2.4. Its necessity became clear after Alexander famously introduced his horned sphere, a subset of \mathbb{S}^3 homeomorphic to \mathbb{S}^2 , the exterior of which is not simply connected [1], [10, p. 169].

In this paper we prove a 3-dimensional version of Whitney’s Theorem 1.1, generalising Theorem 1.2 (which is used in our proof):

Theorem 1.3. *Let X be a finite, simply-connected, 2-complex every link graph of which is 3-connected. Then, for every two locally flat embeddings $\phi, \psi : X \rightarrow \mathbb{S}^3$, there exists a homeomorphism $\alpha : \mathbb{S}^3 \rightarrow \mathbb{S}^3$ such that $\psi = \alpha \circ \phi$.*

Our notion of local flatness for 2-complexes generalises the standard one for 2-manifolds, and is introduced in Section 2.4. The reader will lose nothing by replacing it with piecewise linearity.

In fact we will prove a stronger statement than Theorem 1.3, by relaxing the 3-connectedness requirement on the link graphs to a much weaker one. See Section 3 for details.

Simple connectedness is clearly an indispensable condition in Theorem 1.3: if X is a triangulation of a torus, for example, then we can embed it in \mathbb{S}^3 in at least two ways, either knotted or unknotted. This example can be easily modified to make all link graphs 3-connected, by adding 2-cells inside the torus. In Section 3 we also provide further examples showing that our main result is tight in the sense that none of its conditions can be dropped.

The finiteness of X is also easily seen to be necessary. For example, let X be the standard Cayley complex of \mathbb{Z}^3 . Its link graphs are all isomorphic to the 1-skeleton of the octahedron, which is 3-connected. But there are various ways to embed it into \mathbb{S}^3 : we could embed it with a unique accumulation point of images of vertices, or we could embed it inside half of \mathbb{S}^3 , with every point of the equator being an accumulation point. Yet, we can allow X to be infinite in Theorem 1.3 by imposing additional conditions on the embeddings:

Theorem 1.4. *Let X be a locally finite, simply-connected, Whitney, 2-complex, every link graph of which is 3-connected. Let $\phi, \psi : X \rightarrow \mathbb{R}^3$ be locally flat, accumulation-free embeddings with bounded chambers. Then there exists a homeomorphism $\alpha : \mathbb{R}^3 \rightarrow \mathbb{R}^3$ such that $\psi = \alpha \circ \phi$.*

Whitney’s Theorem 1.1 has many applications, one of which is understanding group actions on \mathbb{S}^2 or other 2-manifolds. For example, it is known that a finite group Γ admits a faithful action by homeomorphisms on \mathbb{S}^2 if and only if Γ has a planar Cayley graph. To prove the backward direction of this statement, one can use Theorem 1.1 to extend the canonical action of Γ on a Cayley graph embedded in \mathbb{S}^2 to an action on \mathbb{S}^2 . See [8] for more. This paper was motivated by the quest (currently in progress) to extend such results to groups acting on \mathbb{S}^3 or other 3-manifolds. In parallel work in progress, George Kontogeorgiou (private communication) has used Theorem 1.3 to deduce that if a finite group Γ has a Cayley complex embeddable in \mathbb{S}^3 , then Γ admits a faithful action by isometries on \mathbb{S}^3 .

In a recent series of papers, Carmesin [3] obtained a characterization of the 2-complexes admitting an embedding in \mathbb{S}^3 in terms of forbidden minors, in the spirit of Kuratowski's characterization of the planar graphs. Carmesin's work provided additional motivation, and tools, for the current work. More generally, there is currently an interest for topological extensions of graph-theoretic results to 2-complexes, see e.g. [5, 9, 12], and this paper adds to this trend.

Many of the concepts and results of this paper can be easily extended to higher dimensions, but for others, in particular the results of Section 5, this seems more difficult. We would be interested to see extensions of Theorem 1.3 to higher dimensions:

Problem 1.1. *Let X be a finite, n -dimensional cell complex. Under what conditions is it true that for every two locally flat embeddings $\phi, \psi : X \rightarrow \mathbb{S}^{n+1}$, there exists a homeomorphism $\alpha : \mathbb{S}^{n+1} \rightarrow \mathbb{S}^{n+1}$ such that $\psi = \alpha \circ \phi$?*

For example, it is natural to assume that X is $(n - 1)$ -connected, and its links satisfy a recursive condition ensuring their unique embeddability in \mathbb{S}^n .

The proof of Theorem 1.3 can be summarized as follows. The images $\phi(X), \psi(X)$ of X separate \mathbb{S}^3 into chambers, and we want to apply Theorem 1.2 on each chamber of ϕ to map it to a chamber of ψ , after which we can combine these maps with $\psi^{-1} \circ \phi : X \rightarrow X$ to obtain α . In order to carry out this plan, we need that A) each chamber is bounded by a copy of \mathbb{S}^2 , and B) the subcomplexes of X bounding chambers of ϕ or ψ coincide. To check B), we show that ϕ, ψ give rise to the same rotation system on X , i.e. the same cyclic ordering of 2-cells around each 1-cell of X (Section 4.1). Rotation systems give rise to *local surfaces*, introduced by Carmesin [3] as a combinatorial description of boundaries of chambers (Section 4), which are helpful in establishing (B). It is possible however that (A) is violated, e.g. because the boundary of some chamber contains two copies of \mathbb{R}^2 intersecting at a point or line segment. To amend this issue, we fatten X into a larger complex $\text{fat}(X)$, and show that $\text{fat}(X)$ satisfies (A) (Section 6). Section 7 gives a more accurate implementation of this plan.

2 Preliminaries

2.1 Graphs

A (simple) *graph* G is a pair (V, E) of sets, where V is called the set of *vertex* and E is a set of two-element subsets of V , called the set of *edges*. We will write uv instead of $\{u, v\}$ to denote an edge. A *multi-graph* is defined similarly, except E is a multi-set, and it can have elements consisting of just one vertex.

We let $V(G)$ denote the set of vertices of a graph G and $E(G)$ denote the set of edges of G .

The *degree* of a vertex $v \in V(G)$ in G is the number of edges in $E(G)$ containing v .

Every (multi-)graph $G = (V, E)$ gives rise to an 1-complex, by letting V be the set of 0-cells, and for each $uv \in E$ introducing an arc with its endpoints identified with u and v . Thus we will sometimes interpret the word *graph* as an 1-complex. In particular, when discussing *embeddings* of graphs in \mathbb{S}^2 we will mean topological embeddings of 1-complexes.

A *subdivision* of $G = (V, E)$ is obtained by replacing an edge uv by a pair of edges uw, vw , where $w \notin V$ is a new vertex. Note that subdivisions results in homeomorphic 1-complexes.

2.2 2-complexes

A *2-complex* is a topological space X obtained as follows. We start with an 1-complex X^1 as defined above, called the *1-skeleton* of X . We then introduce a set X^2 of copies of the closed unit disc $\mathbb{D} \subseteq \mathbb{R}^2$, called the *2-cells* or *faces* of X , and for each $f \in X^2$ we *attach* f to X^1 via a map $\phi_f : \mathbb{S}^1 \rightarrow X^1$, where we think of \mathbb{S}^1 as the boundary of \mathbb{D} . Attaching here means that we consider the quotient space where each point x of $\mathbb{S}^1 \subset f$ is identified with $\phi_f(x)$. We let $X^0 := V(X^1)$ be the set of *vertices*, or 0-cells, of X .

We say that X is *regular*, if ϕ_f is a homeomorphism onto its image for every $f \in X^2$.

For $f \in X^2$, we write $f = [x_1, \dots, x_k]$ if x_1, \dots, x_k is the cyclic sequence of vertices appearing in the image of ϕ_f . We only use this notation for regular X . We say that u, v, w are *consecutive* vertices in f , if u, v, w is a consecutive subsequence of a sequence x_1, \dots, x_k as above.

To each face $f = [x_1, \dots, x_k] \in X^2$, we associate two distinct *directed faces* f_1, f_2 , also denoted by $\langle x_1, \dots, x_t \rangle$ and $\langle x_t, \dots, x_1 \rangle$ respectively. Their *reverses* are defined as $f_1^{-1} := f_2$ and $f_2^{-1} := f_1$.

We sometimes abuse the notion and consider faces or edges as sets and write $f \cap g$ to denote the set of vertices belonging to both faces. If the set of vertices belonging to both faces forms either a vertex or an edge, we sometimes write $f \cap g$ to denote the vertex or the edge. For example, if $f = [x_1, x_2, x_3]$ and $g = [x_2, x_3, y]$, then $f \cap g = x_2x_3 \in X^1$.

If X is not regular then it is always possible to produce a regular complex X' homeomorphic to X using the *barycentric subdivision* defined as follows. For each edge $e = uv \in X^1$, we subdivide e by adding a new vertex m at its midpoint. For each occurrence of e in a 2-cell f of X , we replace that occurrence by the pair um, mv or vm, mu as appropriate. We then triangulate each face $h = [x_1, \dots, x_k]$ of the resulting 2-complex by adding a new vertex c in its interior, adding the edges cx_1, \dots, cx_k to the 1-skeleton, and replacing h by the 2-cells $[c, x_1, x_2], [c, x_2, x_3], \dots, [c, x_k, x_1]$.

Note that the barycentric subdivision X' of X is a simplicial complex, in particular a regular one, and its 1-skeleton is a simple graph.

For each $v \in X^0$, the *link graph* $L_X(v)$ is the graph on the neighbourhood of v in X^1 with $uw \in E(L_X(v))$ if and only if u, v, w are consecutive in a face of X . Alternatively, we can define $L_X(v)$ so that its vertices are the edges incident with v , and two edges vu, vw are joined by an edge of $L_X(v)$ whenever u, v, w are consecutive in a face of X . These two definitions yield isomorphic graphs when X^1 is a simple graph, and it is a matter of convenience to use the one or the other. If X is not regular then link graphs are more naturally defined as multigraphs, but we will restrict their use to regular complexes, with simple 1-skeleton, in this paper.

We say that X is *locally- k -connected*, if each of its link graphs is k -connected. Here a graph is *k -connected*, if it has at least k vertices, and remains connected after removing any set of at most $k - 1$ vertices.

A 2-complex X is *locally finite*, if each vertex of X is contained in finitely many edges and faces. **All 2-complexes in this paper are locally finite.**

2.3 Chambers

For an embedding $\phi : X \rightarrow \mathbb{S}^3$ of a 2-complex X , we call each connected component of $\mathbb{S}^3 \setminus \phi(X)$ a ϕ -chamber or simply a chamber. The boundary ∂C of a chamber C is the set of points $x \in \phi(X)$ in the closure of C that are not in C .

It follows from elementary topological arguments that, when X is finite, every chamber C is open, and if ∂C intersects the interior of a face f , then $f \subseteq C$. We deduce

Proposition 2.1. *Let $\phi : X \rightarrow \mathbb{S}^3$ be an embedding of a finite, locally 1-connected, 2-complex X . Then ∂C is a union of faces of X for every ϕ -chamber C .*

An embedding $\phi : X \rightarrow \mathbb{R}^3$ is *accumulation-free*, if $\phi(X^0)$ has no accumulation points in \mathbb{R}^3 . It can be proved by straightforward topological arguments that, under mild conditions, the boundary of each chamber is connected. We provide a proof for completeness.

Proposition 2.2. *Let $\phi : X \rightarrow M$ be either an embedding of a finite 2-complex X in $M = \mathbb{S}^3$, or an accumulation-free embedding of a locally finite 2-complex X in $M = \mathbb{R}^3$. Then ∂C is connected.*

Proof. Suppose $S := \partial C$ is disconnected, and let $K \subset S$ be one of its components. Let $U \supset K$ be an open subset of \mathbb{S}^3 containing K , the closure \bar{U} of which avoids $S \setminus K$; our conditions on ϕ easily imply the existence of such a U . Note that ∂U disconnects U from its complement U^c by elementary topological arguments, hence ∂U disconnects K from $S \setminus K$. Since C connects K to $S \setminus K$, this implies that $\partial U \cap C \neq \emptyset$. Since $Z = C^c$ is a connected set containing both K and $S \setminus K$, this implies that $\partial U \cap C^c \neq \emptyset$. Since ∂C disconnects C from C^c , and ∂U is connected, we deduce that $\partial U \cap \partial C \neq \emptyset$. This contradicts the choice of U . \square

2.4 Local flatness

Let us recall the standard notion of local flatness for 2-manifolds. An embedding $\phi : \mathbb{S}^2 \rightarrow \mathbb{S}^3$ is *locally flat*, if for each $x \in \phi(\mathbb{S}^2)$ there exists a neighbourhood U_x of x such that the topological pair $(U_x, U_x \cap \phi(X))$ is homeomorphic to $(\mathbb{R}^3, \mathbb{R}^2)$, by which we mean that there is a homeomorphism from U_x to \mathbb{R}^3 mapping $U_x \cap \phi(X)$ to $\mathbb{R}^2 \subset \mathbb{R}^3$. (A *topological pair* (X, A) consists of a topological space X and a subspace $A \subseteq X$.)

We now extend the notion of local flatness to embeddings of 2-complexes instead of 2-manifolds. Before doing so we need to introduce some notation. For a given planar multigraph G , consider a planar embedding ψ of G into the boundary of an open unit ball B_1 around the origin in \mathbb{R}^3 . Let $\text{Shadow}(G)$ be the collection of points y lying on a straight line segment between the origin and some point $x \in \psi(G)$, where the origin is included but x is not.

For a face f of X , we write $\text{int}(\phi(f))$ to denote the *interior* of $\phi(f)$, i.e. the set of points of $\phi(f)$ which do not belong to $\phi(e)$ for any $e \in X^1$. Here,

we consider the face as a topological disk, and any edge as a topological curve. Similarly, for $e = uv \in X^1$, we write $\text{int}(\phi(e))$ to denote the *interior* of $\phi(E)$, i.e. the set of points of $\phi(e)$ other than $\phi(v)$ and $\phi(u)$.

We say that an embedding ϕ of a 2-complex X in \mathbb{R}^3 or \mathbb{S}^3 is *locally flat*, if for each $x \in \phi(X)$ there exists a neighbourhood U_x of x satisfying the following:

- (L1) if $x \in \text{int}(\phi(f))$ for some face $f \in X^2$, then $(U_x, U_x \cap \phi(X))$ is homeomorphic to $(\mathbb{R}^3, \mathbb{R}^2)$.
- (L2) If $x \in \text{int}(\phi(e))$ for some edge $e \in X^1$, then $(U_x, U_x \cap \phi(X))$ is homeomorphic to $(B_1, \text{Shadow}(G))$ where G is a multigraph on two vertices with a number of edges equal to the number of 2-cells incident with e .
- (L3) If $x = \phi(v)$ for some $v \in X^0$, then $(U_x, U_x \cap \phi(X))$ is homeomorphic to $(B_1, \text{Shadow}(G))$ where $G = L_X(v)$ is the link graph of v .

3 Definition of Whitney complexes and statement of the main result

In Theorem 1.3 we assumed X to be locally 3-connected. In this section we will re-state our main theorem in a way that significantly relaxes this condition. Before doing so, let us go one dimension down, and revisit planar graphs. Whitney's Theorem 1.1 assumes the graph to be 3-connected, but this condition can be relaxed to yield the following characterisation of graphs with essentially unique planar embeddings

Theorem 3.1 (Fleischner [7]). *A connected graph G has a unique, up to automorphism of \mathbb{S}^2 , embedding in \mathbb{S}^2 , if and only if G is a subdivision of either*

- A) a 3-connected planar simple graph, or*
- B) a connected multigraph with at most three edges.*

We remark that Theorem 3.1 is not needed for the proof of our main result (Theorem 3.3 below), it is provided to motivate the statement of the later. The multigraphs that item (B) allows are the following: an isolated vertex, an edge with multiplicity one, two or three, $K_{1,3}$, and $C_2 \vee K_2$, i.e. a path of length two with one edge having multiplicity two.

A *theta graph* is a subdivision of the multi-graph with 2 vertices and 3 edges between them.

We now return to embeddings of 2-complexes into \mathbb{S}^3 . Assuming 3-connectedness of link graphs in Theorem 1.3 is a natural way to determine the embedding of X locally at each vertex v , by applying Theorem 1.1 to the surface of a small ball centered at v . As we have just seen, it is possible to relax the 3-connectedness condition in Theorem 1.1, and this will allow us to relax our condition on the link graphs of X accordingly. However we cannot do so too naively, and the following definition answers the question of how much we can relax the 3-connectedness condition.

Let \mathcal{F} be the set of all 2-connected graphs with an essentially unique planar embedding. By Theorem 3.1, these are exactly the theta graphs and the subdivisions of 3-connected planar graphs. For a given 2-complex X , let $G(X)$ be the subgraph of the 1-skeleton X^1 consisting of edges belonging to at least three faces.

Definition 3.2. *We say that a regular 2-complex X is Whitney, if every link graph $L_X(v)$ of X is in \mathcal{F} and $G(X)$ is connected.*

The assumption that X be regular here is imposed for simplicity only. We can extend the definition verbatim to a non-regular X , by allowing $L_X(v)$ to be a multigraph. Alternatively, we can define X to be Whitney in the general case, if its barycentric subdivision (see Section 2.2) is Whitney.

Let $Y(X)$ be the set of vertices $u \in X^0$ such that $L_X(u)$ has a vertex of degree at least three. For any edge $uv \in X^1$ in a Whitney complex, if $u \notin Y(X)$, then the link graph $L_X(u)$ is a cycle, so uv belongs to exactly two faces. Hence if X is Whitney, then $G(X)$ is a connected graph with vertex set $Y(X)$, and $Y(X)$ coincides with the set of vertices $u \in X^0$ such that $L_X(u)$ is a subdivision of 3-connected simple graph or a theta graph. We allow $G(X)$ to be empty, e.g. when X is a triangulation of \mathbb{S}^2 .

We can now state the main result of this paper, which strengthens Theorem 1.3:

Theorem 3.3. *Let X be a finite, simply-connected, Whitney, 2-complex, which is embeddable into \mathbb{S}^3 . Then, for every two locally flat embeddings $\phi, \psi : X \rightarrow \mathbb{S}^3$, there exists a homeomorphism $\alpha : \mathbb{S}^3 \rightarrow \mathbb{S}^3$ such that $\psi = \alpha \circ \phi$.*

As remarked in the introduction, both the simple connectedness of X and the local flatness conditions are indispensable here. To see that the connectedness of $G(X)$ (in Definition 3.2) cannot be dropped either, consider the disjoint union $X \cup Z$ of any two simplicial 2-complexes X and Z (uniquely) embeddable in \mathbb{S}^3 , and join X to Z by adding a triangulated cylinder C so that one boundary cycle of C is identified with the boundary of a face f of X and the other boundary cycle is identified with the boundary of a face g of Z . The resulting 2-complex can be embedded in \mathbb{S}^3 in more than one ways: either with both X, Z embedded outside $C \cup \{f, g\}$, or with one of X, Z inside and the other outside $C \cup \{f, g\}$.

The fact that all graphs we allow in \mathcal{F} are planar is not a restriction: if X admits an embedding ϕ in \mathbb{S}^3 , then it is easy to see that each of its link graphs $L_X(v)$ is planar by restricting ϕ to the boundary of a small ball around v . The 2-connectedness of the graphs we allow in \mathcal{F} is also indispensable. To see this, start with a triangulation of \mathbb{S}^2 with about 50 vertices embedded in \mathbb{S}^3 , and add a few cells so as to create one more chamber. It is easy to do this in such a way that the boundaries of the three resulting chambers C_1, C_2, C_3 have about 10, 30, and 60 vertices, respectively. Now pick an edge $e = uv$ lying in the middle of the boundaries of C_2 and C_3 , add one new vertex w to this complex, and add a 2-cell uvw . It is possible to embed the resulting complex X with w either inside C_2 or inside C_3 , and so X violates the conclusion of Theorem 3.3. But X is not Whitney, because the links of u, v, w are not in \mathcal{F} , although they are uniquely embeddable by Theorem 3.1 (the link of w is an edge, while the links of u, v are subdivisions of $C_2 \vee K_2$). It is easy to produce a similar example where the link of w is a $K_{1,3}$. Thus we have to restrict \mathcal{F} to the 2-connected graphs of Theorem 3.3.

3.1 Infinite complexes

Recall the example of the Cayley complex of \mathbb{Z}^3 from the introduction, which shows that we cannot just drop the finiteness condition in Theorem 3.3. However, we can do so under additional restrictions on the embeddings. Recall that an embedding $\phi : X \rightarrow \mathbb{R}^3$ is *accumulation-free*, if $\phi(X^0)$ has no accumulation points in \mathbb{R}^3 . Note that when ϕ is accumulation-free, then a ϕ -chamber C is bounded if and only if ∂C contains finitely many faces of X . Here we used Proposition 2.1, which easily extends to this setup. We now state our variant of Theorem 3.3 for infinite complexes, generalising Theorem 1.4:

Theorem 3.4. *Let X be a locally finite, simply-connected, Whitney, 2-complex. Let $\phi, \psi : X \rightarrow \mathbb{R}^3$ be locally flat, accumulation-free embeddings with bounded chambers. Then there exists a homeomorphism $\alpha : \mathbb{R}^3 \rightarrow \mathbb{R}^3$ such that $\psi = \alpha \circ \phi$.*

We remark that infinite versions of Theorem 1.1 have been obtained by Imrich [11] and Thomassen & Richter [14]. The latter was used by the first author [8] in order to understand discrete group actions on non-compact surfaces. Theorem 3.4 may find similar applications on discrete group actions on \mathbb{R}^3 .

3.2 Proof of Theorem 3.1

Fleischner [7] proved Theorem 3.1 using somewhat different terminology. We provide the following proof that is shorter than Fleischner's.

Proof of Theorem 3.1. We begin by noticing that whether G has a unique, up to automorphism of \mathbb{S}^2 , embedding in \mathbb{S}^2 , is a topological property depending only on the homeomorphism type of G . Thus this property is preserved when subdividing edges (or suppressing subdivisions).

It is thus natural to consider the multigraph G' obtained from G by suppressing vertices of degree 2, i.e. by replacing each maximal path all of whose internal vertices have degree 2 by an edge. If G' is 3-connected, then we are done by Whitney's Theorem 1.1. Otherwise, we consider various cases. If G' is a connected multigraph with at most three edges, it is clear that it has an essentially unique embedding in \mathbb{S}^2 . Thus in the following cases we will assume that G' has an essentially unique embedding, and will show that it has at most three edges.

If G' has at most two vertices, and at least 4 parallel edges between them, then we can embed these edges in different cyclic orderings, and automorphisms of \mathbb{S}^2 cannot map any such cyclic ordering to any other.

Thus we may assume from now on that G' contains at least three vertices, and a cut-set of size at most 2.

If G' contains both a cut-vertex and a cycle C , let K be the maximal 2-connected subgraph of G' containing C . Then K contains a cut-vertex v of G' . As K is 2-connected, it must contain a cycle containing v , and we may assume without loss of generality that $C \ni v$ is this cycle. Let A be a component of $G' - v$ which is disjoint from C , and B be the component intersecting C . When we embed G' , we can embed A either inside C or outside C . If $G'[G' - A] \neq C$, then these two embeddings are not homeomorphic. If $G'[B \cup \{v\}] = C$, and if $G'[A \cup \{v\}]$ is not just an edge, then $G'[A \cup \{v\}]$ contains a vertex of degree 3 other than v . Thus 'flipping' A while fixing B gives two non-homeomorphic

embeddings of G' . This proves that G' consists of a 2-cycle C attached to an edge, i.e. it coincides with $C_2 \vee K_2$.

If G' has a cut-vertex v but no cycles at all, then all neighbors of v lie in different components of $G' - v$. In this case, v must have degree at most three if G' has an essentially unique embedding, because otherwise embedding the components of $G - \{v\}$ in two different cyclic ordering where one is not obtained from the other by flipping yields two non-homeomorphic embeddings. If G' has another cut-vertex u of degree at least three, then let P be a path from u to v . Then $G - P$ has at least four components, and again embedding them in different cyclic ordering yields non-homeomorphic embeddings. It follows that G' must coincide with $K_{1,3}$.

Finally, if G' has no cut-vertex but a cut set $\{u, v\}$ of size two, then let A be a component of $G' - \{u, v\}$, and let $B := G' - \{u, v\} - A$. Find two paths from u to v , one path P through A and another path Q through B . Thus $P \cup Q$ is a cycle C . As all vertices in G' has degree at least three, $G'[A \cup \{u, v\}]$ contains an edge e not in C and $G'[B \cup \{u, v\}]$ also contains an edge e' not in C . We can ‘flip’ the embedding of A while keeping P fixed, to obtain two non-homeomorphic embeddings: one where e and e' both lie inside C , and another where exactly one of e, e' lies inside C . To make this more precise, pick an embedding $\phi : G' \rightarrow \mathbb{S}^2$, and notice that u, v must lie on the boundary of a face of $G'[A \cup \{u, v\}]$ because they are connected by a path in B . Therefore, we can find a closed disc $D \subset \mathbb{S}^2$ containing the image of $G'[A \cup \{u, v\}]$, with u, v lying on the boundary of D . We can reflect D along P to obtain the second embedding. Hence this case is not possible. \square

4 Rotation systems

A *rotation system* of a graph G is a family $(\sigma_v)_{v \in V(G)}$ of cyclic orderings of the edges incident with each vertex $v \in V(G)$. Every embedding of G on an orientable surface defines a rotation system, by taking σ_v to be the clockwise cyclic ordering in which the edges incident to v appear in the embedding. The rotation system $(\sigma_v)_{v \in V(G)}$ is said to be *planar*, if it can be defined by an embedding of G in the sphere \mathbb{S}^2 .

Let X be a regular 2-complex, and let $\overleftrightarrow{E}(X)$ denote the set of *directions* of its 1-cells, that is, the set of directed pairs $\overrightarrow{xy} := \langle x, y \rangle$ such that $xy \in X^1$. Thus every 1-cell gives rise to two elements of $\overleftrightarrow{E}(X)$. A *rotation system* of X is a family $(\sigma_e)_{e \in \overleftrightarrow{E}(X)}$ of cyclic orderings σ_e of the faces incident with each $e = \overrightarrow{xy} \in \overleftrightarrow{E}(X)$, such that if $e' = \overrightarrow{yx}$, then $\sigma_{e'}$ is the reverse of σ_e . A rotation system $(\sigma_e)_{e \in \overleftrightarrow{E}(X)}$ of X induces a rotation system σ^v at each of its link graphs $L_X(v)$ by restricting to the directions of 1-cells emanating from v : for every $u \in V(L_X(v))$ we let σ_u^v be the cyclic order obtained from $\sigma_{\overrightarrow{vu}}$ by replacing each face f appearing in the latter by the unique neighbour w of u in $V(L_X(v))$ such that w, u, v appear consecutively in f .

A rotation system of a regular 2-complex X is *planar*, if it induces a planar rotation system on each of its link graphs. Note that every locally flat embedding ϕ of X into a 3-manifold defines a planar rotation system, by letting σ_e be the cyclic order in which the images of the faces incident with e appear in U_x , where x is any interior point of $\phi(e)$, and U_x is as in the definition of local flatness

(Section 2.4).

The following theorem of Carmesin [4] characterises all 2-complex embeddable onto \mathbb{R}^3 . This theorem is stated for simplicial complexes in [4], but it is easy to extend to general 2-complexes by considering the barycentric subdivision, noting that a rotation system for the triangulated simplicial 2-complex is canonically determined from the rotation system of the original 2-complex.

Theorem 4.1 ([4]). *A simply connected simplicial complex admits an embedding in \mathbb{R}^3 if and only if it admits a planar rotation system.*

We will only use the easy forward direction of Theorem 4.1; the backward direction relies on Perelman's theorem.

4.1 Uniqueness of rotation systems

The following lemma will help us show that for any two embeddings ϕ, ψ of a Whitney complex, there is a bijection between the ϕ -chambers and the ψ -chambers.

Lemma 4.2. *Let X be a simply-connected, Whitney, 2-complex. Suppose that $\phi, \psi : X \rightarrow \mathbb{S}^3$ are two embeddings, and let σ and ρ denote the planar rotation systems induced by ϕ and ψ . Then σ and ρ coincide up to reversion.*

Proof. Recall, from Section 3, that $Y(X)$ is the set of vertices $v \in X^0$ such that $L_X(v)$ contains a vertex of degree at least 3, in other words, an edge of $G(X)$, and that $G(X)$ forms a connected graph with vertex set $Y(X)$.

If an edge $e \in X^1$ is not in $G(X)$, then it is incident with only two faces, hence σ_e and ρ_e is the unique cyclic ordering on two elements. In particular σ and ρ coincide on the complement of $G(X)$.

To see that σ and ρ coincide on $G(X)$ as well, fix a vertex $v \in Y(X)$ (if $Y(X)$ is empty, then so is $G(X)$, and we are done by the above remark). Then Theorem 1.1 says that the rotation systems ρ^v, σ^v on $L_X(v)$ induced by ϕ and ψ , respectively, coincide up to reversion. Pick $vw \in E(G(X))$, and recall that $\rho_{\overline{vw}} = \rho_{\overline{wb}}^{-1}$. Moreover, as vw belongs to at least three cells of X , we have $(\rho_{\overline{wb}})^{-1} \neq \rho_{\overline{wb}}$. Recall that ρ_v^w is determined by $\rho_{\overline{wb}}$. As vw belongs to at least three cells of X , if we know which of the two possible rotation systems on $L_X(v)$ is induced by ψ , then we can deduce which of the two possible rotation systems ψ induces on $L_X(w)$. As $G(X)$ is a connected graph with vertex set $Y(X)$, by recursively repeating this argument we can determine the rotation system ρ^u for all vertices $u \in Y(X)$ as well as the rotation system ρ_e for all edges $e \in X^1$ with $e \subseteq Y(X)$ starting with ρ^v , and the same applies to σ_e and σ^v .

For all edges $e \in X^1$ incident to a vertex not in $Y(X)$, only two faces are incident to e , hence the choice $\rho_e = \sigma_e$ is unique as already mentioned. To summarize, we have shown that ρ^v determines the full rotation system $(\rho_e)_{e \in X^1}$. Moreover, as ρ^v is either σ^v or its reversion, we deduce that the rotation system $(\rho_e)_{e \in X^1}$ coincides with either $(\sigma_e)_{e \in X^1}$ or its reversion. \square

4.2 Local surfaces

Assume a rotation system $\sigma = (\sigma_e)_{e \in \overleftrightarrow{E}(X)}$ of a 2-complex X is induced from an embedding $\phi : X \rightarrow \mathbb{S}^3$. Then two faces f, f' adjacent in σ_e must lie on the

boundary of the same chamber. This information can be encoded by using the notion of local surfaces defined in [4].

Recall that each face of X gives rise to two directed faces. We say that two directed faces f, f' of X are *locally related* via an edge $e = uv \in X^1$, with respect to the given planar rotation system σ , if f appears right before f' in $\sigma_{\overrightarrow{uv}}$, and u appears right before v in f , and v appears right before u in f' . A *local surface* of X with respect to σ is an equivalence class of the transitive reflexive closure of the relation of being locally related.

For a local surface S , a directed face $f \in S$, and a vertex $v \in f$, we define the *S -local-disk* at v containing f , to be the set of directed faces $(f =) f_1, \dots, f_s$ each of which contains v , such that f_i and $f_{i+1 \pmod{s}}$ are locally related via an edge containing v for each $i \in [s]$. For a directed face $f \in S$, we define *the S -local-disk at f* to be the union of all S -local-disks (at the vertices of f) containing f . Note that the faces of a local-disk do not always form a topological disk —although they do so in many cases. To see this, consider two copies of the tetrahedron in \mathbb{R}^3 , glue them along an edge, and let S be the collection of exterior directed faces. Then it is easy to see that the local disk at a glued vertex or at any face is not a topological disk.

Suppose that ϕ is a locally flat embedding of X into \mathbb{S}^3 , and consider a face f . Then any small enough neighbourhood $U_{\phi(y)}$ of any $y \in \phi(f)$ is separated into two components W, W' by $\phi(f)$. We would like to associate one of these components to each of the two possible directions f_1, f_2 of f in a consistent way. This is not hard to do, e.g. by applying the ‘rule of thumb’. We then say that f_1 *touches* W and f_2 *touches* W' . We can then generalise the notion to define what it means for a directed face to touch a chamber or other region as follows. Given a connected open set $U \subset \mathbb{S}^3$ (e.g. a chamber), we say that the directed face f_1 *touches* U , if $\phi(f) \cap \partial U \neq \emptyset$ and for any $y \in \phi(f) \cap \partial U$ which is an interior point of $\phi(f)$, f_1 touches a component W of $U_{\phi(y)} \setminus \phi(f)$ contained in U .

Note that any directed face touches a unique chamber, and it is easy to see that two locally related directed faces touch the same chamber, hence the faces in a local surface touch a unique chamber.

5 Boundaries of chambers

The rough idea of our proof of Theorem 3.3 is as follows. For two given locally flat embeddings $\phi, \psi : X \rightarrow \mathbb{S}^3$, we define a 2-dimensional (simplicial) complex $\text{fat}(X)$ containing X and embeddings $\phi', \psi' : \text{fat}(X) \rightarrow \mathbb{S}^3$ which induces ϕ, ψ when restricted to X . We will show that any two embeddings ϕ', ψ' induce the same rotation systems on $\text{fat}(X)$ (up to inversion) and this will define local surfaces of $\text{fat}(X)$. Moreover, we will define $\text{fat}(X)$ in a way that the closure of all chambers of $\text{fat}(X)$ are homeomorphic to closed balls. By establishing bijections between chambers and local surfaces of $\text{fat}(X)$, we find bijections between ϕ' -chambers and ψ' -chambers. As any closure of such a chamber is homeomorphic to a closed ball, we can find homeomorphisms between closures of corresponding chambers which will yield the desired homeomorphism α once restricted to X .

The following three lemmas will help us to show that the ϕ' -images and ψ' -images of local surfaces will be homeomorphic to \mathbb{S}^2 , and the closures of chambers are homeomorphic to closed balls. A *surface* is a 2-dimensional man-

ifold (without boundary).

Lemma 5.1. *Let X be a locally finite, simply-connected, 2-complex. Let $\phi : X \rightarrow M$ be an accumulation-free embedding in $M = \mathbb{S}^3$ or $M = \mathbb{R}^3$ with bounded chambers, and let C be a ϕ -chamber. If ∂C is a surface, then ∂C is homeomorphic to \mathbb{S}^2 .*

Proof. Let $Z \subset M$ be the union of X with all chambers of ϕ except C . Then Z is homeomorphic to a solid surface embedded in M with boundary homeomorphic to $S := \partial C$. It is easy to see that Z is simply-connected, because any loop in Z is homotopic to a loop in X . Moreover, S is connected by Proposition 2.2. Thus S is homeomorphic with \mathbb{S}^2 . □

In order to use Lemma 5.1, one has to show that the boundary of each chamber is a surface. The boundary of a chamber will be the image of a local surface. Hence, we need to ensure that any local surface S is a 2-dimensional manifold. For this, we need to show that it is locally a disk, i.e. any S -local-disk at a vertex v is homeomorphic to a closed disk and there is only one S -local-disk at v . The following lemma ensures the former. The uniqueness of the S -local-disk at v is not always satisfied, and this is the reason we introduce the fattening $\text{fat}(X)$ in the next section.

Lemma 5.2. *Let X be a locally 2-connected simplicial 2-complex, let σ be a planar rotation system on X , and S a local surface of X with respect to σ . Then for each vertex $v \in S^0$, any S -local-disk D at v is homeomorphic to a closed disk.*

Proof. Assume that we have a S -local-disk D which consists of directed faces f_1, \dots, f_{s+1} and for each $i \in [s]$, the face f_i is locally related to f_{i+1} via the edge vu_i . We claim that u_1, \dots, u_s are all distinct.

Suppose they are not all distinct. By shifting indices, we may assume that $u_1 = u_t$ and u_1, \dots, u_{t-1} are all distinct with $t \leq s$. Then in the link graph $L_X(v)$, the vertices u_1, \dots, u_{t-1} form a cycle C . Furthermore, the rotation system σ^v induced by σ is planar, so $L_X(v)$ has a planar embedding ϕ which induces σ^v . We may assume that u_{t+1} lies outside C in the planar embedding ϕ and $u_i u_{i+1}$ is right after $u_{i-1} u_i$ in the cyclic ordering $\sigma_{u_i}^v$ for each $i \in [t-1]$.

Hence for each $i \in [t-1] \setminus \{1\}$, all neighbors of u_i lie inside C in the planar embedding ϕ . However, this implies that $u_1 = u_t$ is a cut vertex for $L_X(v)$, a contradiction as X is locally 2-connected. Hence u_1, \dots, u_s are all distinct and $f_{s+1} = f_1$. As every face consists of three vertices, $\phi(D)$ is homeomorphic to a closed disk. □

6 Fattenings

We are trying to prove that for every two locally flat embeddings $\phi, \psi : X \rightarrow \mathbb{S}^3$, there exists a homeomorphism $\alpha : \mathbb{S}^3 \rightarrow \mathbb{S}^3$ such that $\psi = \alpha \circ \phi$. Our strategy is to build α as a combination of homeomorphisms, each mapping a chamber of ϕ to one of ψ . Since chambers are bounded by local surfaces, our task would be easier if we knew that each local surface is homeomorphic to a sphere. This is however not always the case, as a local surface may intersect itself along some

edges or vertices of X as remarked after its definition, see Figure 6. To avoid this difficulty we will now extend X into a super-complex $\text{fat}(X)$ called a *fattening*. The idea is to glue a layer of prism-shaped ‘bricks’ along the boundary of each chamber C of X , with one brick being attached onto each directed face of ∂C . The sides of the bricks that are not contained in ∂C or in another brick will then always form a surface, bounding a chamber lying inside C . The interior of each such brick will also form a new chamber inside C .

Figure 1: A chamber C may fail to be bounded by a surface, because e.g. its intersection with a plane in \mathbb{S}^3 may look like the bold curve in the figure. But after glueing some prism-shaped bricks onto ∂C (shaded area), we will ensure that the new chamber mirroring C is bounded by a surface (Lemma 6.1).

The actual construction of $\text{fat}(X)$ is however more technical than the above picture suggests, because rather than being given an embedding of X defining its chambers, we will only be given a planar rotation system σ on X , and we will construct $\text{fat}(X) = \text{fat}(X, \sigma)$ abstractly. Instead of chambers, we will have to work with the local surfaces and local disks of X with respect to σ .

6.1 Construction

Now we formally define the fattening. Let X be a locally 2-connected simplicial 2-complex, let σ be a planar rotation system, and S a local surface with respect to σ . For each S -local-disk D of X with respect to σ (at some vertex w), we introduce a new vertex v_D . For each directed face $f = \langle v_1, v_2, v_3 \rangle \in S$, we introduce a new face $h_f = \{v_{D_1}, v_{D_2}, v_{D_3}\}$ where D_i is the S -local-disk at v_i containing f . The 0-skeleton of $\text{fat}(X)$ will be the union of X^0 with all the new vertices of the form v_D . Note that each vertex w of X gives rise to a number of new vertices of $\text{fat}(X)$ equal to the number of S -local-disks containing w , which is at least one for each local surface containing w .

The new vertices and faces of $\text{fat}(X)$ that we just introduced are not yet connected to X ; they can be imagined as hovering inside the chambers of X , mirroring the boundaries thereof. However, it is important to remember that $\text{fat}(X)$ is being defined with respect to an abstract rotation system rather than with respect to an embedding in \mathbb{S}^3 , and so the chambers of X have to be imagined for now.

We now connect the new vertices to X by introducing new ‘rectangular’ faces, each containing two new and two old vertices, so that each such rectangle has one side on an old face f and the opposite side on h_f . We do so in such

a way that the space between each local surface of X and its imagined mirror image is tiled by ‘bricks’, with each brick having the shape of a prism between faces f and h_f (this picture will become more meaningful later when we define the embedding of $\text{fat}(X)$). These new faces are defined as follows. For each two directed faces f and h locally related via an edge uw , we consider the S -local-disk D at u containing f and the S -local-disk D' at w containing h , so that $\{f, h\} \subseteq D \cap D'$. We introduce a new ‘rectangular’ face $R_{f,h} := [u, w, v_{D'}, v_D]$.

The resulting 2-complex after all the above additions to X is called a *fat-tening* of X with respect to σ , and we denote it by $\text{fat}(X) = \text{fat}(X, \sigma)$.

6.2 Embedability of $\text{fat}(X)$

Our next aim is to prove that any locally flat embedding of X can be extended to a locally flat embedding of $\text{fat}(X)$. Notice that every Whitney complex is locally 2-connected by the definitions.

Lemma 6.1. *Let $\phi : X \rightarrow \mathbb{S}^3$ be a locally flat embedding of a locally 2-connected, simplicial, 2-complex X , and let σ be the planar rotation system induced by ϕ . Then there is a locally flat embedding $\phi' : \text{fat}(X, \sigma) \rightarrow \mathbb{S}^3$ that extends ϕ .*

Moreover, letting σ' be the planar rotation system induced by ϕ' , every local surface of $\text{fat}(X, \sigma)$ with respect to σ' is a surface.

The proof is not difficult, and purely topological. Some readers will find it easy to prove Lemma 6.1 by themselves, and such a reader can skip to Section 6.3. For all others we include the following proof.

In order to prove Lemma 6.1 we will first show that there is enough space around the images of vertices, edges, and faces of X where we can embed the newly introduced vertices, edges and faces of $\text{fat}(X, \sigma)$. This is the purpose of the following technical lemma, which ensures that we can find some open balls disjoint from $\phi(X)$ where we can embed those new cells.

Lemma 6.2. *Let X be a locally 2-connected, simplicial, 2-complex, and ϕ a locally flat embedding of X into \mathbb{S}^3 . Then for each $h \in X^0 \cup X^1 \cup X^2$, there is a neighbourhood N_h of $\phi(h)$ which is homeomorphic to an open ball and satisfies the following conditions. For a local surface S , a vertex v , an edge e containing v , two directed faces f, g locally related via the edge e , and an S -local-disk D at f , we have:*

- (i) $N_v \subseteq N_e \subseteq N_f$;
- (ii) for $h, h' \in X \cup X^1 \cup X^2$ with $h \cap h' = \emptyset$, we have $N_h \cap N_{h'} = \emptyset$. If $h \cap h' = h''$ with $h'' \in X^0 \cup X^1$, then $N_h \cap N_{h'} = N_{h''}$;
- (iii) $\phi(D) \cap N_v$ divides N_v into two regions. The region $W(v, f)$ that f touches is homeomorphic to an open ball and disjoint from $\phi(X)$, and $W(v, f) = W(v, g)$;
- (iv) $\phi(D) \cap N_e$ divides N_e into two regions. The region $W(e, f)$ that f touches is homeomorphic to an open ball and disjoint from $\phi(X)$, and $W(v, f) \subseteq W(e, f)$ and $W(e, f) = W(e, g)$; and
- (v) $\phi(D) \cap N_f$ divides N_f into two regions. The region $W(f)$ that f touches is homeomorphic to an open ball disjoint from $\phi(X)$ and $W(e, f) \subseteq W(f)$.

Proof. As ϕ is a locally flat embedding, for each $x \in \phi(X)$, there exists an open neighbourhood U_x satisfying (L1)–(L3) as in the definition of local flatness. We can shrink each U_x if necessary to ensure that the open neighbourhood $N_f := \bigcup_{x \in \phi(f)} U_x$ of $\phi(f)$ is homeomorphic to an open ball, and so is $N_e := \bigcup_{x \in \phi(e)} U_x$. We just let $N_v = U_{\phi(v)}$. Then (i) is satisfied.

By shrinking the U_x further if necessary, we can easily also achieve that any non-empty intersection $N_h \cap N_{h'}$ is due to an intersection of h and h' , establishing (ii).

As N_v is an open ball satisfying (L3), the pair $(N_v, N_v \cap \phi(X))$ is homeomorphic to $(B_1, U_{L_X(v)})$ as in the definition of local flatness. In $(B_1, U_{L_X(v)})$, imagine the link graph $L_X(v)$ is drawn on the boundary of the open ball B_1 to induce $U_{L_X(v)}$. By Lemma 5.2, the S -local-disk D' at v corresponds to a cycle in this planar drawing, which separates ∂B_1 into two regions. As the faces f_1, \dots, f_s on D' are locally related and $L_X(v)$ is 2-connected, the region that f touches contains no other points of $\phi(X)$ and is homeomorphic to an open ball. As f, g are locally related, this is the region that g touches as well. Thus we have (iii).

Suppose $e = uv$. Recall that N_e is the union of U_x for each $x \in \phi(e)$, and each U_x satisfies (L2) and (L3). As (L2) and (iii) implies that $(U_x, U_x \cap \phi(D))$ is homeomorphic to $(\mathbb{R}^3, \mathbb{R}^2)$ for all $x \in \phi(e)$, we conclude that $N_e \cap \phi(D)$ divides N_e into two regions. The region $W(e, f)$ that f touches contains both $W(v, f)$ and $W(u, f)$. By our choice of U_x for each $x \in \text{int}(\phi(e))$, $W(e, f)$ does not intersect with $\phi(X)$ outside $W(v, f) \cup W(u, f)$. However, (iii) ensures each of $W(v, f)$ and $W(u, f)$ is homeomorphic to an open ball, hence we conclude that $W(e, f)$ is also homeomorphic to an open ball. As f and g are locally related via e , $W(e, f)$ is also the region which g touches. By (L2), we know that $W(e, f)$ does not intersect with $\phi(X)$. Hence (iv) holds.

Finally, for each $x \in \text{int}(\phi(f))$, the pair $(N_x, N_x \cap \phi(D))$ is homeomorphic to $(\mathbb{R}^3, \mathbb{R}^2)$. Hence, $N_x \cap \phi(D)$ divides N_x into two regions, and the region $W(x, f)$ which f touches is homeomorphic to an open ball. Thus $W(f) = \bigcup_{x \in \phi(f)} W(x, f)$ contains $W(e, f)$. Moreover, $N_f \cap \phi(D)$ is obtained from gluing $N_e \cap \phi(D)$ with $\phi(f)$ along with $\phi(f) \cap N_e$. As $\phi(f) \cap N_e$ is a disk, by the Seifert-van Kampen theorem, $N_f \cap \phi(D)$ is a disk. Hence $N_f \cap \phi(D)$ divides N_f into two regions and $W(f)$ is the region that f touches. By (iii)–(iv) and (L1), $W(f)$ does not intersect with $\phi(X)$. Hence (v) holds. \square

We can now prove the main result of this section.

Proof of Lemma 6.1. Let σ be the planar rotation system induced by the embedding ϕ . Consider a local surface S and directed face $f = \langle v_1, v_2, v_3 \rangle$ in S . For each $i \in [3]$, let g_i be the directed face locally related to f via the edge $v_i v_{i+1}$, where here and below all subscripts are taken modulo three. Let D_i be the the S -local-disk at v_i containing f .

By Lemma 6.2, we obtain open balls $W(v_i, f) \subseteq W(v_i v_{i+1}, f) \subseteq W(f)$ satisfying (i)–(iv) of Lemma 6.2. As $W(f)$ is an open ball, we can embed a closed disk D_f in $W(f)$ in the following way: its boundary is the union of three curves $C_{f,1}, C_{f,2}, C_{f,3}$ where $C_{f,i}$ lies in $W(v_i v_{i+1}, f) = W(v_i v_{i+1}, g_i)$ for each $i \in [3]$, and the point $C_{f,i} \cap C_{f,i+1}$ lies in $W(v_{i+1}, f)$. We can further ensure that all those disks D_f are disjoint from each other for different f .

Consider two directed faces $f, g \in S$ locally related via an edge uv , and consider the S -local-disk D at u containing f, g , and the S -local-disk D' at v containing f, g . Then we can continuously deform the disks to merge the corresponding boundaries $C_{f,i}$ and $C_{g,j}$ (where i, j are indices such that both $C_{f,i}$ and $C_{g,j}$ lie in $W(v_i v_{i+1}, f)$) except the parts where they intersect $W(v_i, f) \cup W(v_{i+1}, f)$. For two faces f, f' , the sets $W(f)$ and $W(f')$ are disjoint if $f \cap f' = \emptyset$ by (ii), and $W(f) \cap W(f') = W(h, f)$ if h is the cell consisting of the vertices in $f \cap f'$. Hence we can perform this deformation without two disks intersecting except at the merged boundaries.

Now for each vertex v , and each S -local-disk D at v , let $D = \{f_1, \dots, f_s\}$ with f_i locally related to f_{i+1} via an edge vu_i . Assume that a part of $C_{f_i,j}$ and a part of $C_{f_{i+1},j'}$ are merged. Then the not-yet-merged parts of $C_{f_i,j}$ and $C_{f_{i+1},j'}$ lie in $W(v, f_i) = W(v, f_{i+1})$ and $W(u, f_i)$. The parts in $W(v, f_i)$ all together form a topological circle in $W(v, f_i)$. Hence, we can continuously deform this circle into s curves sharing one endpoint by merging the remaining part of $C_{f_i,j}$ and the remaining part of $C_{f_{i+1},j'}$. Furthermore, this will ensure that the point on the boundaries of D_{f_1}, \dots, D_{f_s} corresponding to v are all identified.

By mapping each face h_f as in the definition of $\text{fat}(X)$ into D_f in such a way that each boundary edge of h_f maps to $C_{f,1}, C_{f,2}, C_{f,3}$, we obtain an embedding of all cells h_f for each $f \in X$. Let ϕ'' be the resulting embedding of all such disks D_f . Then $\phi \cup \phi''$ extends ϕ by embedding all the faces of the form h_f , that mirror the original faces f of X . It remains to embed the ‘rectangular’ faces of the form $R_{f,h}$ that we used to connect the h_f back to X . This can be done similarly to the definition of ϕ'' by introducing discs inside balls of the form $W(uv, f)$, using again appropriate deformations to stitch them together where needed. We omit the rather tedious, though straightforward, details.

We thus obtain an embedding ϕ' of $\text{fat}(X)$ which coincides with ϕ when restricted on X . This embedding is locally flat by construction.

We now prove the second part of our statement. In order to check that a local surface S' of $\text{fat}(X)$ is a surface, it is sufficient to prove that there exists at most one S' -local-disk at v for each vertex v . Indeed, Lemma 5.2 implies that if there exists at most one S' -local-disk at v for each vertex v , then S' is locally a topological disk around each of its vertices, and so it is a 2-manifold.

We consider two types of local surfaces of $\text{fat}(X)$, and show that each local surface belongs to one of these two types. The first type will be denoted by S_{fat} . For each local surface S of X with respect to σ , consider $S_{\text{fat}} := \{h_f : f \in S\}$ with h_f directed in the same way as $f \in S$ is directed. If f, g are locally related, h_f and h_g are locally related too by the construction of ϕ' . Hence, S_{fat} is indeed a local surface of $\text{fat}(X)$ with respect to σ' .

The other type will be denoted by T_f . For each directed face $f = \langle v_1, v_2, v_3 \rangle \in S$, let D_i be the S -local-disk at v_i containing f . There is exactly one directed face g_i such that $\{f, g_i\} \subseteq D_i \cap D_{i+1}$ and f, g_i are locally related via the edge $v_i v_{i+1}$. Let $T_f := \{f, h_f^{-1}, R_{f,g_i} : i \in [3]\}$ where the rectangular faces R_{f,g_i} are directed so that they are locally related, and each of them is locally related to f and h_f^{-1} . Then T_f is a local surface of $\text{fat}(X)$ with respect to σ' .

Each directed face of $\text{fat}(X)$ belongs either to a local surface of type S_{fat} or a local surface of type T_f . Thus each local surface of $\text{fat}(X)$ belongs to one of those types.

We first verify our statement for a local surface of type S_{fat} . First, note

that each vertex in S_{fat} is of type v_D for some S -local disk D . Moreover, as the local-relatedness of f and g implies the local-relatedness of h_f and h_g , the S_{fat} -local disks are exactly $\{h_f : f \in D\}$ for some S -local disk D . Conversely, for each S -local disk D , the set $\{h_f : f \in D\}$ is an S_{fat} -local disk. As we have constructed $\text{fat}(X)$ so that v_D and $v_{D'}$ are (even if D and D' are S -local disk at the same vertex) different vertices for two distinct S -local disks $D \neq D'$, we conclude that $\{h_f : f \in D\}$ is the unique S_{fat} -local disk at v_D . This shows that for every vertex v_D of S_{fat} , there exists exactly one S_{fat} -local disk $\{h_f : f \in D\}$ at v_D as desired.

We now consider a local surface of the second type T_f . From the construction of T_f , it is easy to see that any two of its directed faces sharing an edge are locally related. Thus for each vertex v in T_f , there exists a unique T_f -local disk at v , which is exactly the collection of directed faces in T_f containing v .

We have checked that in all cases, there is exactly one S' -local disk at v for any vertex v of S' as claimed. \square

6.3 $\text{fat}(X)$ preserves the Whitney property

We conclude this section by proving that any fattening of a Whitney complex is itself Whitney.

Lemma 6.3. *Suppose that X is a simply connected, Whitney, simplicial, 2-complex, $\phi : X \rightarrow \mathbb{S}^3$ is a locally flat embedding, and σ is the planar rotation system induced by ϕ . Then every link graph of $\text{fat}(X, \sigma)$ is a subdivision of a 3-connected planar graph or a theta graph and every edge of $\text{fat}(X, \sigma)$ belongs to at least three cells of $\text{fat}(X, \sigma)$. In particular, $\text{fat}(X, \sigma)$ is Whitney.*

Proof. Since ϕ is locally flat, for each $v \in X^0$ there exists an open neighbourhood U_v of $\phi(v)$ such that $(U_v, U_v \cap \phi(X))$ is homeomorphic to $(B_1, U_{L_X(v)})$, where B_1 and $U_{L_X(v)}$ are as defined in Section 2.4. This yields an embedding of the link graph $L_X(v)$ on the boundary of B_1 , which is \mathbb{S}^2 . Note that each S -local-disk D at v corresponds to a face C_D in this planar embedding. Thus $L_{\text{fat}(X)}(v)$ is obtained from $L_X(v)$ by adding a vertex v_D for each S -local-disk D , and making v_D adjacent to all vertices in C_D . Note that $L_X(v)$ contains no parallel edges, hence no 2-cycle, because X is assumed to be a simplicial complex. It follows that if $L_X(v)$ is a subdivision of a 3-connected planar graph, then so is $L_{\text{fat}(X)}(v)$. Similarly, if $L_X(v)$ is a cycle or theta graph, then $L_{\text{fat}(X)}(v)$ is a 3-connected planar graph.

For a newly added vertex v_D , the link graph $L_{\text{fat}(X)}(v_D)$ is a wheel, so it is also a 3-connected planar graph. Thus every link graph of $\text{fat}(X)$ is a subdivision of a 3-connected planar graph as claimed.

Moreover, as X is locally 2-connected, every edge $uv \in X^1$ belongs to at least two faces and there are two local disks D and D' containing a face f . Thus uv belongs to at least one more face in $\text{fat}(X)$. Moreover, it is straightforward to check that every newly added edge in $\text{fat}(X)^1 \setminus X^1$ also belongs to at least three cells. \square

Remark: In the last two sections we never assumed X to be finite. Thus all the results we obtained can be applied to embeddings in \mathbb{R}^3 instead of \mathbb{S}^3 , because \mathbb{S}^3 is the 1-point compactification of \mathbb{R}^3 and so any (locally flat) embedding in \mathbb{R}^3 gives rise to a (locally flat) embedding in \mathbb{S}^3 .

7 Putting the pieces together to prove Theorems 3.3 and 3.4

We are ready to prove our main theorems. The following lemma states that we can establish a homeomorphism between ϕ and ψ as in Theorem 3.3 if all local surfaces are surfaces. Since $\text{fat}(X)$ satisfies this condition by Lemma 6.1, Theorem 3.3 will follow easily.

Lemma 7.1. *Suppose that X is a finite, simply connected, Whitney, simplicial 2-complex and $\phi, \psi : X \rightarrow \mathbb{S}^3$ are two locally flat embeddings. If the ϕ -image and ψ -image of every local surface S of X with respect to σ is a surface, then there exists a homeomorphism $\alpha : \mathbb{S}^3 \rightarrow \mathbb{S}^3$ such that $\phi = \alpha \circ \psi$.*

We stated Lemma 7.1 for finite complexes embedded in \mathbb{S}^3 , but the analogous statement for infinite, locally finite, complexes with accumulation-free embeddings in \mathbb{R}^3 with bounded chambers can be proved along the same lines using the remark at the end of the previous section, and it will be used in the proof of Theorem 3.4.

Proof. Let σ and ρ be the planar rotation systems induced by ϕ and ψ , respectively. By Lemma 4.2, σ and ρ coincide up to reversion. Hence, by taking a composition of an orientation-reversing automorphism with ψ , we may assume that ϕ and ψ both induce the rotation system σ .

Claim 1. *For each $\xi \in \{\phi, \psi\}$, there exists a bijection i_ξ mapping ξ -chambers to local surfaces of X with respect to σ in such a way that $\partial C = \xi(i_\xi(C))$ for every ξ -chamber C .*

By Proposition 2.1, ∂C is a union of ξ -images of faces. Let A be the set of those directed faces f such that $\xi(f) \subseteq \partial C$ and f touches C in ξ . As σ is a rotation system induced by ξ , the definition of local-relatedness implies that if a directed face f touches C in ξ , then any directed face f' locally related to f also touches C in ξ . Hence, A is a disjoint union of local surfaces.

As we are assuming each local surface to be a surface, A is a surface, so Lemma 5.1 together with the simple connectedness of X implies that $\xi(A)$ is homeomorphic to \mathbb{S}^2 . As \mathbb{S}^2 is not a disjoint union of two nonempty surfaces, A is a local surface. Hence we have $\partial C = \xi(S)$ for a local surface S , and we let $i_\xi(C) := S$. As every directed face touches a chamber, every local surface is an image of i_ξ . Thus i_ξ is the desired bijection, and Claim 1 is proved.

By Claim 1, the map $i_\psi^{-1} \circ i_\phi$ is a bijection from the ϕ -chambers to the ψ -chambers. Moreover, for a ϕ -chamber C_ϕ , let $C_\psi = (i_\psi^{-1} \circ i_\phi)(C_\phi)$. We deduce that for some local surface S of X , $\partial C_\phi = \phi(S)$ and $\partial C_\psi = \psi(S)$ are both surfaces. By Lemma 5.1, both ∂C_ϕ and ∂C_ψ are homeomorphic to \mathbb{S}^2 . Applying the generalized Schoenflies Theorem 1.2 to each of ∂C_ϕ and ∂C_ψ we obtain automorphisms α_ϕ, α_ψ of \mathbb{S}^3 that map the equator to ∂C_ϕ and ∂C_ψ , respectively. Note that α_ϕ, α_ψ must map one of the two 3-dimensional balls into which the equator separates \mathbb{S}^3 onto C_ϕ, C_ψ , respectively, and we may assume without loss of generality that it is the same ball in both cases. Therefore, $\alpha_\psi \circ \alpha_\phi^{-1}$ restricts to a homeomorphism $\alpha_{C_\phi} : C_\phi \cup \partial C_\phi \rightarrow C_\psi \cup \partial C_\psi$ extending the canonical homeomorphism $\psi \circ \phi^{-1}$ from ∂C_ϕ to ∂C_ψ .

Finally, we define α to be the map obtained by taking the union of all α_{C_ϕ} for all ϕ -chambers C_ϕ . For two different ϕ -chambers C and C' , the domains of α_C and $\alpha_{C'}$ are $C \cup \partial C$ and $C' \cup \partial C'$, respectively. As C and C' are disjoint, the intersection of these domains lies in $\partial C \cap \partial C' \subseteq \phi(X)$. Since both α_C and $\alpha_{C'}$ extend $\psi \circ \phi^{-1}$, these two maps coincide on $\partial C \cap \partial C' \subseteq \phi(X)$. As this holds for any two distinct ϕ -chambers C and C' , this union α defines a homeomorphism from \mathbb{S}^3 to \mathbb{S}^3 with $\phi = \alpha \circ \psi$ as desired. \square

We can now put the ingredients together to prove our main results:

Proof of Theorem 3.3. By considering the barycentric subdivision of X (defined in Section 2.2), we may assume that X is a simplicial complex, because barycentric subdivisions do not affect local flatness.

Let σ be the rotation system of X induced by the embedding ϕ and let ρ be the rotation system induced by the embedding ψ . By Lemma 4.2, σ and ρ coincide up to reversion. By composing an orientation-reversing automorphism with ψ if necessary, we may assume that σ and ρ coincide (without a reversion), and so from now on we will let σ denote the common planar rotation system of ϕ and ψ .

This rotation system allows us to define local surfaces. Consider a fattening $\text{fat}(X)$ of X with respect to σ . By Lemma 6.1 there are embeddings $\phi', \psi' : \text{fat}(X) \rightarrow \mathbb{S}^3$ such that each of them coincides with ϕ, ψ respectively when restricted to X . By Lemma 6.1 and Lemma 6.3, $\text{fat}(X)$ satisfies the assumptions of Lemma 7.1. Hence, there exists a homeomorphism $\alpha : \mathbb{S}^3 \rightarrow \mathbb{S}^3$ such that $\phi' = \alpha \circ \psi'$. As each of ϕ' and ψ' coincide, when restricted to X , with ϕ and ψ , respectively, this implies that $\phi = \alpha \circ \psi$ as desired. \square

Proof of Theorem 3.4. We follow the lines of the above proof. Lemmas 4.2, 6.1 and 6.3 used above can be applied to embeddings in \mathbb{R}^3 instead of \mathbb{S}^3 by using the remark at the end of the previous section. As mentioned above, Lemma 7.1 also readily adapts to accumulation-free embeddings in \mathbb{R}^3 . \square
