ZIG–ZAG MODULES: COSHEAVES AND K-THEORY

RYAN GRADY AND ANNA SCHENFISCH

Abstract. Persistence modules have a natural home in the setting of stratified spaces and constructible cosheaves. In this article, we first give explicit constructible cosheaves for common data-motivated persistence modules, namely, for modules that arise from zig-zag filtrations (including monotone filtrations), and for augmented persistence modules (which encode the data of instantaneous events). We then identify an equivalence of categories between a particular notion of zig-zag modules and the combinatorial entrance path category on stratified $\mathbb{R}$. Finally, we compute the algebraic $K$-theory of generalized zig-zag modules and describe connections to both Euler curves and $K_0$ of the monoid of persistence diagrams as described by Bubenik and Elchesen.

1. INTRODUCTION

In this article we aim to demonstrate the utility of viewing persistent phenomena from the perspective of constructible (co)sheaves. In particular, we demonstrate how cosheaves provide a convenient interpretation of augmented descriptors of persistence modules and how cosheaves are a convenient setting for constructing invariants via algebraic $K$-theory. The present is in the same spirit of the program we first employed in [16], namely, applying stratified mathematics and higher algebra to topological data analysis (TDA).

The use of cosheaves in TDA goes back at least to Curry [14]. The work of Curry and collaborators (e.g., work with Patel [13]), serves as an inspiration for our own perspectives. The key idea interpolating between persistence modules and constructible cosheaves is that of a stratified space. A persistence module $\{V_i\}_{i \in I}$ is obtained by sampling (or otherwise selecting a discrete subset) of a larger parameter space. For concreteness, consider $I \subset \mathbb{R}_{\geq 0}$.

as a selection of “instances” in our one-dimensional ray of “time.” As our persistence module only changes at elements of \( I \), it is locally constant on \( \mathbb{R} \setminus I \), which is the defining property of a constructible cosheaf.

Constructible cosheaves are particularly nice mathematical objects for several reasons, chief among them is their equivalence to representations of the so called entrance path category; this is known as “the” Exodromy Theorem. Any stratified space has an associated entrance path category and in good cases (e.g., when the space is a combinatorial manifold), the entrance path category is a straightforward combinatorial object – in many cases it’s simply a poset. The idea of exodromy goes back to MacPherson and proofs in different settings appear in work of Curry and Patel [13], Treumann [25], Lurie [20], and Barwick with Glasman and Haine [3].

Given a parameter space (and a choice of sampling instances), exodromy allows us to consider all persistence modules/constructible sheaves on that space as a category of functors. Such categories of functors then inherit desirable properties from the target category. For instance, if we consider modules valued in vector spaces, the category of persistence modules is naturally an Abelian category. Abelian categories are the home of homological and homotopical algebra, so we are free to apply the tools of algebraic topology/homotopy theory, e.g., algebraic K-theory. The combinatorial nature of the entrance path category makes K-theory computations tractable and allows us to consider connections with other persistent invariants such as Euler curves and persistence diagrams.

In the present article, we are mainly concerned with one-dimensional parameter spaces. The resulting persistence modules are the zig-zag persistence modules of Carlsson and de Silva [11], which includes the more typically seen monotone (standard) modules.

Readers familiar with the persistent homology transform (PHT) may be interested to note that the PHT is a special type of persistence module itself. Our computation of K-theory for zig-zag persistence modules has an interpretation in the setting of the PHT where the sphere of directions is \( S^1 \). Thus, the results of this paper may be useful for future work in the computation of other invariants of the PHT. See [26] for further background on the PHT.

1.1. Why K-theory? In the later part of this article, we compute the K-theory of the category of zig-zag modules. Here, we briefly overview why K-theory is a useful invariant.

K-theory began as simply as group completion of a monoid. Indeed, let \((M, \oplus)\) be a commutative monoid and define \(K_0(M, \oplus)\) to be the unique (up to isomorphism) Abelian group, equipped with a monoid homomorphism from \( M \), satisfying the universal property: for any Abelian group \( A \) and homomorphism (of monoids) \( \varphi : M \to A \), there exists a unique group homomorphism factorization through \( K_0(M, \oplus) \). This universal property is described as the universal Euler characteristic and conveyed diagrammatically is as follows:

\[
\begin{array}{ccc}
(M, \oplus) & \xrightarrow{\forall} & A \\
\downarrow & & \downarrow \\
K_0(M, \oplus) & \cong & A
\end{array}
\]

For instance, let \( \mathcal{V} \) be the isomorphism classes of finite dimensional vector spaces over the field \( \mathbb{R} \) (with direct sum) and \( \varphi : \mathcal{V} \to \mathbb{Z} \) the rank function, then we have an induced
map $K_0(\mathcal{V}) \to \mathbb{Z}$, which happens to be an isomorphism. Expanding this example to complexes, let $\mathcal{C}$ denote isomorphism classes of bounded complexes of $\mathbb{R}$-vector spaces. The natural extension of the rank function is the Euler characteristic, which again factors uniquely through $K_0(\mathcal{C})$. (In the topological setting, the Chern character of a vector bundle is an example of such an additive map.) The universal property of $K_0$ extends to categories equipped with a symmetric monoidal structure, as isomorphism classes of objects in such a category form a commutative monoid.

K-theory is more than just a single Abelian group, but rather a spectrum, $\mathbb{K}(\mathcal{C})$, associated to a category (equipped with additional structure). Recall that spectra are the central objects of homotopy theory. The homotopy groups of $\mathbb{K}(\mathcal{C})$ define the $K$-groups of $\mathcal{C}$, i.e., $K_n(\mathcal{C}) := \pi_n(\mathbb{K}(\mathcal{C}))$. To first approximation, spectra can be thought of as the objects that parametrize cohomology theories. As such, they, so K-theory in particular, admit a wealth of computational tools, refined structures, and interpretations from algebraic topology. Cohomology theories are also the natural home for obstruction/anomaly theory and in this way, K-theory has become a central tool in topology (index theory, finiteness obstructions) and algebraic number theory (class field theory).

When refined to the level of spectra, K-theory has a remarkable additive structure with respect to split short exact sequences of categories. (We discuss this in Appendix A, see also [7].) Combined with its property as the universal Euler characteristic, K-theory is the universal additive invariant of (Waldhausen) categories.

### 1.1.1. Flavors and History of K-theory

There are several flavors and constructions of K-theory, we trace here the history to the two we use in the present article: Waldhausen’s construction and Zakharevich’s theory of assemblers. See the canonical texts of Rosenberg [22] and Weibel [28] for historical references and more details on the development of K-theory.

The genesis of K-theory came in the late 1950’s and early 1960’s through the work of Grothendieck in complex (algebraic) geometry and Atiyah and Hirzebruch in topology. Algebraic K-theory—the kind relevant to the present work—is an extension of Grothendieck’s ideas to build a family of functors from rings to Abelian groups $K_i: \text{Ring} \to \text{Ab}$. While Grothendieck only defined $K_0$, suitable definitions for $K_1$ and $K_2$ where found by the mid 1960’s; the contributions of Bass, Schanuel, and Milnor are most notable. (Bass and Karoubi also gave definitions of negative K-theory, $K_{-n}(R)$.) Definitions of higher K-groups was a major open problem in the early 1970’s, which was first solved by Dan Quillen: the $+$-construction. (Milnor had given a definition of higher K-groups as well, though this Milnor K-theory is only a summand of the now accepted definition of higher K-theory.)

Given a ring, $R$, Quillen produced a space, $BGL(R)^+$, whose homotopy groups recovered/defined the K-theory of $R$.

Quillen quickly followed his $+$-construction with the $Q$-construction. The $Q$-construction takes as input an exact category, $\mathcal{C}$, e.g., the category of finitely generated projective modules for a ring, and outputs a space, $\Omega BQC$, whose homotopy groups define K-theory. Quillen used the $Q$-construction to prove many fundamental results in algebraic K-theory that restricted to those for rings, as he also proved that $+ = Q$, that is, the $Q$-construction is a strict generalization of $+$-construction for rings.

The next revolution in algebraic K-theory came through Waldhausen’s work in manifold topology [27]. Published in 1985, Waldhausen gave a construction that takes as input categories with structure that generalizes that of exact categories—nowadays called Waldhausen
categories—and outputs a spectrum (the basic building block of homotopy theory) whose homotopy groups define the corresponding K-groups. (Segal some 15 years earlier used his \( \Gamma \)-objects to produce a K-theory spectrum in certain cases.) Waldhausen’s construction is often referred to as the \( S_\bullet \)-construction and we give a brief overview in Appendix A. The \( S_\bullet \)-construction is a strict extension of the \( Q \)-construction. Perhaps most significantly, the \( S_\bullet \)-construction satisfies an additivity result for split short exact sequences; this result has become a central tool in algebraic K-theory.

Motivated by so called *scissor congruences* and algebraic varieties, Zakharevich [29] found a simple construction of K-theory using her theory of *assemblers*. Zakharevich’s construction works well even in the absence of linear structure (Abelian and exact categories are in some way categorified linear algebra), e.g., the category of finite sets. One interpretation of this construction is that it builds a Waldhausen category from the elementary structure of the assembler and then applies the \( S_\bullet \)-construction and hence satisfies analogues of the foundational structural results: localization, additivity, etc.

Finally, we note that there has been an extension of K-theory to the higher categorical/homotopical algebraic setting as well. The work of Blumberg, Gepner, and Tabuada [7] proves that K-theory satisfies certain universal properties, such as additivity, (and hence is essentially uniquely defined by such properties) in this setting.

1.1.2. **K-theory and persistence.** Through the work of Patel, Bubenik and collaborators, K-theoretic considerations have started to appear in the TDA literature. Patel considered the Grothendick, i.e., \( K_0 \), of one-dimensional persistence modules valued in symmetric monoidal categories [21].

Subsequently, in [10], Bubenick and Milićević show that the category of persistence modules over any preorder is Abelian. The key idea—which we use below as well—is that functor categories inherit many of the properties of the target category, so if the target is Abelian or Grothendieck, i.e., AB5 with a generator, then the functor category with domain a preorder (or any small category) is Abelian or Grothendieck. It would be interesting to apply Quillen’s \( Q \)-construction to these categories of persistence modules and compare the resulting K-theories to our computations below. (We note that [10] contains much more than we just outlined, e.g., the authors prove an embedding theorem in the vain of the Gabriel–Popescu Theorem.)

More relevant for us is the recent article [9] by Bubenik and Elchesen. In this work, the group completion of the monoid of persistence diagrams is described, i.e., \( K_0(\text{Diag}) \) is defined (semi-)explicitly. Points in diagrams are counted with multiplicity, so the binary operation is simply induced by \(+: \mathbb{N}_0 \times \mathbb{N}_0 \to \mathbb{N}_0\). The input data for the construction of Bubenik and Elchesen is pretty flexible, so one can talk about diagrams (and their group completions) indexed by the entire first quadrant, the integers, etc. We make contact with this work in Section 5.2 below.

1.2. **What we do.** We have aimed to illustrate the connection between persistence modules and cosheaves and the utility of this interplay. To this end, we accomplish the following.

1.2.1. **Cosheaves from filtrations.** The relevance of cosheaves in TDA has been advocated by Curry and others for a number of years. In Section 3 we give explicit constructions of constructible cosheaves associated to persistence modules. We are particularly interested in persistence modules arising from index filtrations of spaces. In Section 3.2.3, we describe
the augmented filtration cosheaf, which records both non-instantaneous and instantaneous events. (We flag the recent work of Berkouk, Ginot, and Oudot [5] where level-set persistence is recast in terms of sheaves over $\mathbb{R}$.)

1.2.2. Equivalence Theorem. We prove an equivalence of categories between a localization of the category of zig-zag modules a la Carlsson and de Silva and constructible cosheaves on $\mathbb{R}$. The explicit statement of the result is Theorem [3.3.5]. This result is stated in passing (Example 6.3) in the recent work of Curry and Patel [13], and we make it explicit with proof. We hope the proof is as interesting to the reader as the result, though it uses techniques that are different from the rest of the paper so we relegate it to Appendix B.

1.2.3. K-theory of Zig-Zag Modules. In Section 4 we define and compute K-theory of persistence modules. To describe the K-theory of persistence modules valued in the category of sets, we use the theory of Zakharevich’s assemblers. For modules valued in $\mathcal{V}ect$, we use Waldhausen’s $S_\bullet$ construction of K-theory. A key input is additivity, in this case with respect to strata. For instance, in the case that our parameter space is one-dimensional, e.g., monotone or zig-zag persistence, the group $K_0$ is the free abelian group on the strata of parameter space (Theorems [4.1.8 and 4.2.6]).

The higher K-groups do not vanish but rather are given by the algebraic K-theory of fields and/or the sphere spectrum. In forthcoming work, we aim to interpret these higher K-groups as arising from data.

The constructions and techniques we present apply to parameter spaces of arbitrary dimension.

1.2.4. Euler Curves and Virtual Diagrams. We conclude the body of the paper by connecting our K-theoretic work back to some recent work in TDA. First, we show how the Euler curve of a persistence module has a natural interpretation as a class in K-theory. (This is as expected, e.g., Kashiwara and Schapira [19] prove that $K_0$ is isomorphic to constructible functions via a local Euler index.) With this observation, we define an Euler class for arbitrary persistence modules irregardless of dimension; this is Definition [5.1.3]. Lastly, Section 5.2 builds a group homomorphism from $K_0$ of persistence modules to Bubenik and Elchesen’s Abelian group of virtual persistence diagrams.

Conventions. We assume the reader has some familiarity with algebraic topology, and freely use concepts from Hatcher’s standard text [17].

Throughout, we will let $\mathcal{V}ect_F$ be the category of finite dimensional vector spaces over the field $F$ and linear maps. Much of our work doesn’t depend on making a choice of field and we simply use the notation $\mathcal{V}ect$.

Unless otherwise noted, we will assume all stratified spaces are combinatorial manifolds equipped with their native stratification, notions we define in the next section.

Acknowledgements. We thank David Ayala for many discussions related to the content of this and other articles. We also thank Peter Bubenik for several discussions related to zig-zag persistence and other mathematical topics in TDA.

2. Constructible coSheaves

This section is a terse introduction to terminology and notation we will use throughout the sequel. Examples and further details are abundantly available, e.g., [13] or [16].

2.1. Stratified/Constructible Basics.

Definition 2.1.1. A stratified topological space is a triple \((X, \phi, P)\) consisting of

- a paracompact, Hausdorff topological space, \(X\),
- a poset \(P\), equipped with the upward closed topology, and
- a continuous map \(\phi: X \to P\).

Note that any topological space is stratified by the terminal poset consisting of a singleton set. Moreover, the simplices of a simplicial complex, \(K\), come equipped with the structure of a poset, and we call the resulting stratification of \(K\) the native stratification.

Definition 2.1.2. A map of stratified topological spaces \((\phi: X \to P)\) to \((\psi: Y \to Q)\) is a pair of continuous maps \((f_1, f_2)\) making the following diagram commute:

\[
\begin{array}{ccc}
X & \xrightarrow{f_1} & Y \\
\downarrow{\phi} & & \downarrow{\psi} \\
P & \xrightarrow{f_2} & Q
\end{array}
\]

Definition 2.1.3. Let \(X \to P\) be a stratified space and \(x \in X\) a point. The space \(X\) is conically stratified at \(x\) if there exists an open neighborhood, \(U_x\), of \(x\) and a stratified homeomorphism \(U_x \cong Z \times CY\) where \(Z\) is a topological space and \(CY\) is the cone on a space \(Y\) stratified by \(P_{>p}\). A space is conically stratified if it is conically stratified at all of its points.

Definition 2.1.4. A piecewise linear (PL) manifold is a topological manifold along with an equivalence class of triangulations. A combinatorial manifold \(X\) is a triangulated PL manifold. That is, a combinatorial manifold is a PL manifold \(X\) along with a simplicial complex \(K\) and PL homeomorphism \(K \to X\). The manifold \(X\) inherits a native stratification from the simplicial complex \(K\).

For further details on PL and combinatorial manifolds, see [23] or Section 3.9 of [24].

Definition 2.1.5 ([16]). Let \((S, \phi, \Omega)\) be a stratified space, \(S \hookrightarrow X\) a topological embedding, and \(\pi_0(X \setminus S) = A\). Define the poset, \(\Omega^a\), as the set \(\Omega \amalg A\), subject to the following generating relations:

1. The relations of \(\Omega\);
2. For \(\ell \in \Omega\) and \(\alpha \in A\), \(\ell \leq \alpha\) if and only if \(\varphi_S^{-1}(\ell) \subseteq \alpha\), i.e., the \(\ell\)-stratum is in the closure of the connected component indexed by \(\alpha\).

There is an obvious extension of the map \(\varphi_S, \psi_S: X \to \Omega^a\) and we call this stratification the connected ambient stratification.

A typical (easy) example of the preceding is considering a discrete subset \(I \subset \mathbb{R}\). The resulting stratified space, \((\mathbb{R}, I)^a\), is a combinatorial manifold.

Definition 2.1.6. Let \(X\) be a topological space, \(\text{Op}(X)\) the poset of open sets in \(X\), and \(V\) a category. A precosheaf on \(X\) valued in \(V\) is a functor \(F: \text{Op}(X) \to V\). A precosheaf is a cosheaf if for each open \(U \subseteq X\) and any open cover of \(U\), \(\{U_i \to U\}\), there is an equivalence
For what remains, we will assume $V$ is a nice category, so that cosheafification exists. (Cosheafification is quite subtle, even compared to its dual notion of sheafification.) In particular, we will later focus on the case that $V = \textbf{Set}$ or $V = \textbf{Vect}$.

**Lemma 2.1.7.** Let $\mathcal{B}$ be a basis for the topology of the space $X$ and let $\mathcal{F}$ be a cosheaf on the poset determined by $\mathcal{B}$. There is a unique (up to isomorphism) extension of $\mathcal{F}$ to a cosheaf on $X$.

The idea of the lemma can be thought of in terms of a Kan extension picture:

$$
\begin{array}{ccc}
\mathcal{B} & \xrightarrow{\mathcal{F}} & V \\
\downarrow & \searrow & \downarrow \\
\text{Op}(X) & \exists! & \\
\end{array}
$$

**Definition 2.1.8.** Let $M \to \mathcal{P}$ be a stratified space (not nec. conical or simplicial) and $\mathcal{F}$ a cosheaf on $M$. The cosheaf, $\mathcal{F}$, is constructible if it is locally constant when restricted to any stratum of $M \to \mathcal{P}$.

**Definition 2.1.9.** Let $\mathcal{F}$ be a (pre)cosheaf on $X$ and $p \in X$. The costalk of $\mathcal{F}$ at $p$ is defined by

$$
\mathcal{F}_p := \lim_{U \ni p} \mathcal{F}(U).
$$

### 2.2. Operations on cosheaves.

Given a continuous map $\xi: X \to Y$, there is in an induced functor on the posets of opens $\hat{\xi}: \text{Op}(Y) \to \text{Op}(X)$ given by preimages with respect to $\xi$.

**Definition 2.2.1.** Let $\xi: X \to Y$ be a continuous map and $\mathcal{F}$ a (pre)cosheaf on $X$. The pushforward of $\mathcal{F}$, $\xi_* \mathcal{F}$, is the (pre)cosheaf on $Y$ given by $\xi_* \mathcal{F} := \mathcal{F} \circ \hat{\xi}$.

There is a contravariant functor as well associated to a map $\xi: X \to Y$: the pullback $\xi^*: \text{coShv}(Y) \to \text{coShv}(X)$. As a continuous map is not necessarily an open map, $\xi^*$ is (slightly) more involved to define: it is the limit over opens containing $\xi(U)$ for $U \subseteq X$ an open. Only pushforwards appear below.

**Example 2.2.2.** Let $p \in X$ be a point in the topological space $X$ and $i: p \hookrightarrow X$ the inclusion map. Let $\mathcal{F}$ be a cosheaf on $X$, then $i^* \mathcal{F}$ is the costalk at $p$ of $\mathcal{F}$, $\mathcal{F}_p$. Let $W$ be a cosheaf on $p$, then $i_* W$ is a skyscraper cosheaf on $X$.

**Example 2.2.3.** Let $\xi: (\phi: X \to \mathcal{P}) \to (\psi: Y \to \mathcal{Q})$ be a stratified map and $\mathcal{F}$ a constructible cosheaf on $X$. Although the pullback of a constructible cosheaf is always constructible, it is not necessarily the case that $\xi_* \mathcal{F}$ is constructible on $Y$.

- Consider the inclusion $\iota: [0, 1/2) \hookrightarrow [0, 1)$ and $\mathcal{V}$ be a nonzero constant cosheaf on $[0, 1/2)$. Further stratify $[0, 1/2)$ and $[0, 1)$ with zero-stratum $\{0\}$ and one-stratum $(0, 1/2)$ (resp. $(0, 1)$). The cosheaf $\iota_* \mathcal{V}$ is not constant on $(0, 1)$ as $\iota_* \mathcal{V}(0, 1/4) = \mathcal{V}$, while $\iota_* \mathcal{V}(3/4, 1) = 0$. 

Constructibility is preserved by pushforwards in certain cases. Let \( C : [0, 4] \to [0, 3] \) be the “elementary collapse” of the interval \([2, 3]\), i.e.,
\[
C(t) = \begin{cases} 
  t, & \text{if } 0 \leq t < 2 \\
  2, & \text{if } 2 \leq t \leq 3 \\
  t - 1, & \text{if } 3 < t \leq 4
\end{cases}
\]
The map \( C \) is constructible with respect to the (connected) ambient stratifications induced by \( \{0, 1, 2, 3, 4\} \subset [0, 4] \) and \( \{0, 1, 2, 3\} \subset [0, 3] \). Let \( \mathcal{F} \) be any constructible cosheaf on \([0, 4]\) it is straightforward to verify that \( C_*\mathcal{F} \) is constructible on \([0, 3]\).

2.3. Entrance Paths and Their Representations. Given a stratified space, \( M \to \mathcal{P} \), an entrance path is a continuous path in \( M \) such that it for all time it stays in a stratum or enters into a deeper (with respect to \( \mathcal{P} \)) stratum.

**Definition 2.3.1.** Let \( M \to \mathcal{P} \) be a stratified space. The entrance path category of \( M \to \mathcal{P} \), \( \text{Ent}(M, \mathcal{P}) \) has objects the points of \( M \) and morphisms (elementary) homotopy classes of entrance paths.

**Exodromy Theorem** (Theorem 6.1 of [13]). Let \( M \to \mathcal{P} \) be a conically stratified space and \( V \) a category. There is an equivalence of categories
\[
\text{cShv}_{cbl}(M, \mathcal{P}) \xrightarrow{\sim} \text{Fun}(\text{Ent}(M, \mathcal{P}), V)
\]
between constructible cosheaves on \( M \) and representations of its entrance path category.

**Definition 2.3.2.** Let \( M \to \mathcal{P} \) be a combinatorial manifold. The combinatorial entrance path category, \( \text{Ent}_\Delta(M, \mathcal{P}) \) has as objects the strata of \( M \) and a morphism \( \sigma \to \tau \) whenever \( \tau \) is a face of \( \sigma \).

**Proposition 2.3.3.** Let \( M \to \mathcal{P} \) be a combinatorial manifold. There is an equivalence of categories \( \text{Ent}(M, \mathcal{P}) \xrightarrow{\sim} \text{Ent}_\Delta(M, \mathcal{P}) \).

**Proof.** Define a functor \( F : \text{Ent}(M, \mathcal{P}) \to \text{Ent}_\Delta(M, \mathcal{P}) \), where the image of a point \( x \in \text{Ob}(\text{Ent}(M, \mathcal{P})) \) is unique simplex \( \sigma \) containing \( x \), and the image a morphism \( x \to y \) is the combinatorial entrance path from \( F(x) \to F(y) \) (well-defined since the simplex containing \( y \) must be a face of the simplex containing \( x \) in order to be an entrance path). We claim that \( F \) is fully faithful and essentially surjective. Again, let \( x \in \sigma, y \in \tau \), so that \( \tau \) is a face of \( \sigma \). Since \( \tau \) and \( \sigma \) are face-coface pairs of a non-degenerate triangulation, the subspace \( \sigma \cup \tau \) deformation retracts onto \( \tau \), meaning there is a unique homotopy class of entrance paths \( x \to y \). Furthermore, there is a unique morphism \( \sigma \to \tau \) in \( \text{Ent}_\Delta(M, \mathcal{P}) \), i.e., \( F \) is fully faithful. Next, we observe that, for any simplex \( \sigma \in \text{Ob}(\text{Ent}_\Delta(M, \mathcal{P})) \), we can always find a point \( x \) so that \( F(x) = \sigma \) (for example, let \( x \) be the barycenter of \( \sigma \)). That means we have shown \( F \) is also essentially surjective, and thus gives an equivalence of categories. \( \square \)

**Remark 2.3.4.** One might hope that there is an equivalence of entrance and combinatorial entrance path categories for a larger class of stratifications. However, even when a space is stratified by a “degenerate” triangulation, this equivalence does not generally hold. For instance, consider \( S^1 \to [1] \), stratified by \( v \), a single vertex, and \( X_1 \), a single edge. Let \( x \in X_1 \). Then there are two distinct homotopy classes of entrance paths from \( x \to v \) in \( \text{Ent}(M, \mathcal{P}) \), but only one combinatorial entrance path given by the face relation in \( \text{Ent}_\Delta(M, \mathcal{P}) \).
One useful interpretation of the preceding proposition is that the data of a constructible cosheaf on a combinatorial manifold is just a specification of costalks on the stratifying poset and linear maps between them.

3. Persistence Modules, Persistence Cosheaves, and Filtrations

We now introduce our main actors: persistence modules and persistent cosheaves. To start, we consider constructible cosheaves that arise from common types of persistence modules and/or filtrations. We construct these cosheaves in a way that is compatible with traditional models of the specific filtration or module in question. We finish the section with an equivalence result relating zig-zag modules to one-dimensional constructible cosheaves.

3.1. Persistent Definitions.

**Definition 3.1.1.** A persistence module is a functor $P : \mathbb{P} \to \Omega$, where $\mathbb{P}$ is some poset category. Specifically, we may refer to these as $\mathbb{P}$-indexed persistence modules. $\mathbb{P}$-indexed persistence modules define a category: the functor category, whose morphisms are natural transformations between the functors.

Hereafter, we take $\Omega$ to be $\mathcal{V}ect_{\mathbb{F}}$, the category of vector spaces over a field $\mathbb{F}$, and by $V^i$, we mean a vector space of dimension $i$ in $\mathcal{V}ect_{\mathbb{F}}$.

The previous definition is general – in what follows, we will mostly restrict our attention to single-parameter persistence modules. There are two flavors of such modules common in the literature: zig-zag [11] and monotone (standard) persistence modules [31]. We note that monotone persistence modules are most commonly called simply ‘persistence modules;’ we have added the word ‘monotone’ to emphasize their distinction from more general modules.

To any poset there is an associated undirected graph: its Hasse diagram. Properties of the Hasse diagram, e.g., planarity, are used in order theory as they are often more accessible than the abstract poset. We will find it useful to consider the Hasse diagram of a poset as a one-dimensional simplicial complex.

**Definition 3.1.2.** Let $\mathbb{P}$ be a poset.

- The poset $\mathbb{P}$ is zig-zag if its Hasse diagram is homeomorphic to the closed interval, half-closed interval, or $\mathbb{R}$.
- A representation of a zig-zag poset $P : \mathbb{P} \to \mathcal{V}ect$ is a zig-zag persistence module.
- If $\mathbb{P}$ is a linear order, then a representation $P : \mathbb{P} \to \mathcal{V}ect$ is a monotone persistence module.

Consider a zig-zag persistence module $P : I \to \mathcal{V}ect$, where the objects of $I$ are a discrete subset of real numbers (with potentially not-standard ordering). This, in turn, defines a stratification of $\mathbb{R}$, the connected ambient stratification $\text{Nat}(\mathbb{R}, I)^\wedge$ (where we have a zero-stratum for every object of $I$ and a one-stratum for every connected component of $\mathbb{R} \setminus I$, as in [10]). To define a cosheaf on $\mathbb{R}$, it suffices to define its values on a basis of the topology on $\mathbb{R}$.

First, we give a cosheaf theoretic interpretation of the notion of zig-zag modules found in [11]. We call this cosheaf propagated because the functor is entirely determined by the ordering of and assignments to zero strata; the value over a one-stratum is propagated from either endpoint depending on the ordering of the relevant poset.
Construction 3.1.3 (The Propagated Persistence Cosheaf on $\mathbb{R}$). Given $P : I \to \text{Vect}$ with $I \subset \mathbb{R}$ discrete, we define the \textit{propagated persistence cosheaf} $F_P : \text{Opens}(\mathbb{R}) \to \text{Vect}$ as follows. Let $B_{\epsilon} \subset \mathbb{R}$ be a metric $\epsilon$-ball so that $2\epsilon > 0$ is less than the distance between any pair of zero-strata. Then $B_{\epsilon}$ either contains a single zero-stratum or no zero-stratum, and we assign values for $F_P$ as follows:

$$F_P(B_{\epsilon}) = \begin{cases} P(i), & \text{if } i \in B_{\epsilon} \text{ with } i \in I \text{ or if } B_{\epsilon} \subset (-\infty, i) \text{ for } i \in I \\ P(k), & \text{if } B_{\epsilon} \subset (i, j) \text{ for } i \neq j \in I \cup \{\infty\} \text{ and } k = \min_I \{i, j\} \end{cases}.$$  

Next, we describe the assignment of morphisms. If $B_{\epsilon}$ contains a zero-strata, $i$, or if $B'_{\epsilon}$ is entirely contained in some one-strata $(i, j)$, then $F_P(B_{\epsilon} \hookrightarrow B'_{\epsilon}) = Id_{F_P(B_{\epsilon})}$ . Suppose instead that $B'_{\epsilon}$ contains the vertex $i$ but $B_{\epsilon} \subset (i, j)$. Then $F_P(B_{\epsilon} \hookrightarrow B'_{\epsilon}) = (P(i) \to P(j))$ if $i < j$ (or $(P(j) \to P(i))$ if $j < i$). See Figure 3.1.4.

The cosheaf $F_P$ is locally constant on strata, so it defines a constructible cosheaf on the stratified space $\text{Nat}(\mathbb{R}, I)^m$.

**Example 3.1.4.** Suppose that $I$ is the poset $k > i > j < l$, where $k, i, j, l$ are ordered with the standard ordering on $\mathbb{R}$ as in the figure above. Then $F_P(B_2 \hookrightarrow B_1) = Id_{F_P(B_2)} = Id_{P(k)}$, $F_P(B_4 \hookrightarrow B_3) = (P(j) \to P(i))$, and $F_P(B_6 \hookrightarrow B_5) = Id_{P(l)}$.

3.2. Filtered Spaces and Cosheaves. Next, we discuss how persistence-modules and persistence module cosheaves relate to filtrations of spaces.

Definition 3.2.1 (Filtration). Let $K$ be a simplicial complex. A filtration of $K$ is a sequence of subcomplexes $\{K_i\}_{i \in I}$ such that, for every $i$, there is an inclusion of spaces $K_i \hookrightarrow K_{i+1}$ and so that $K_0 = \emptyset$ and $K_{\max\{i \in I\}} = K$.

**Example 3.2.2.** If we take $I \subset \mathbb{R}$ to be the indexing set of a filtration, then there is a natural way to view $I$ as a poset with the standard ordering of $\mathbb{R}$. Passing to homology in degree $n$ defines an associated monotone persistence module via the assignment $i \mapsto H_n(K_i)$. The propagated persistence cosheaf on $\mathbb{R}$ (see Definition 3.1.3) is easy to describe. Indeed, for a single one-stratum, we have $F(i, j) = H_n(K_i)$ and that the costalk of $F$ at a zero-stratum $i$ is $H_n(K_i)$.

3.2.1. Monotone and Index Filtrations. Let $f : K \to \mathbb{R}$ be a monotone function on simplices. That is, whenever $\tau$ is a face of $\sigma$, we have $f(\tau) \leq f(\sigma)$. Let $m_1 < m_2 < \ldots < m_p$ be the ordered set of minimum values in $\mathbb{R}$ for which $f^{-1}(\infty, m_i]$ is a distinct non-empty simplicial complex. Setting $K_{m_0} = \emptyset$ and $K_{m_i} = f^{-1}(\infty, m_i]$, we define the (monotone) filtration of $K$ by $f$ as

$$\emptyset = K_{m_0} \subset K_{m_1} \subset \ldots \subset K_{m_p} = K.$$
Notice that, by construction, all inclusion maps are in the direction of increasing index. Furthermore, if \( K \) has \( n \) non-empty simplices, \( p \leq n + 1 \).

Next, suppose that \( \emptyset = \sigma_0 \prec \sigma_1 \prec \sigma_2 \prec \ldots \prec \sigma_n \) is a total order of the simplices of \( K \) so that if either \( f(\sigma_i) < f(\sigma_j) \), or if \( \sigma_i \) is a face of \( \sigma_j \), then \( i < j \). Letting \( K'_j = \{ \sigma_i \mid i \leq j \} \), the increasing sequence of \( n + 1 \) subcomplexes \( \{ K'_i \} \) is an index filtration compatible with the monotone filtration.

In what follows, we will use \( n \) to denote the number of non-empty simplices in a simplicial complex \( K \) and \( p \) to denote the number of steps in a monotone filtration.

**Remark 3.2.3.** Index filtrations are themselves monotone. Index filtrations are compatible with themselves, but to no other index filtrations.

**3.2.2. From Index to Monotone.** Suppose that \( \{ K_{m_j} \}_{m_j \in M} \) is a monotone filtration with filter function \( f \) and \( \{ K'_i \}_{i \in \{-\infty, \ldots, n\}} \) is a compatible index filtration. Then for every \( m_j \in M \setminus \{ m_0 \} \), there is some maximum interval \([\ell, r)\) for \( \ell, r \in \{1, \ldots, n\} \cup \{\pm \infty\} \) such that \( f(\sigma_i) = f(\sigma_r) = m_j \) (where, whenever \( r = \infty \) or \( r = -\infty \), we define \( \sigma_{\infty} := \sigma_n \) and \( \sigma_{-\infty} = \sigma_0 \), respectively). These intervals cover \( \mathbb{R} \), and every interval corresponds to a unique \( m_j \in M \). Then we define a map of stratified spaces, \( C : (\mathbb{R}, \text{Nat}([1, n]))^n \rightarrow (\mathbb{R}, \text{Nat}(M \setminus \{ m_0 \}^n)) \) that maps intervals with a particular value under the filter function \( f \) to intervals with that same value under \( f \) as follows.

**Definition 3.2.4.** Suppose that \( a \in [\ell, r) \), where \([\ell, r)\) is the associated interval for some \( m_j \in M \). Three cases arise: if \( -\infty < \ell, r < \infty \), we assign

\[
C(a) = \begin{cases} 
m_j, & \text{if } a < r - 1 \\
m_j(a - r) + m_{j+1}(a - (r - 1)), & \text{if } a \geq r - 1
\end{cases}
\]  

(1)

if \([\ell, r) = [-\infty, 1)\), we assign

\[
C(a) = am_1
\]  

(2)

and if \([\ell, r) = [n, \infty)\), we assign

\[
C(a) = \frac{am_p}{n}
\]  

(3)

**Lemma 3.2.5.** \( C \) is a stratified map.

![Figure 3.2](image.png)

**Figure 3.2.** An example of the map \( C \). The relevant interval for the point, e.g., \( m_2 \) is \([2, 7)\), since the image of each simplex added in that interval under the filter function \( f \) is \( m_2 \). Then \([2, 6)\) is mapped to \( m_2 \) and \([6, 7)\) is mapped to \([m_2, m_3]\).
3.2.3. Augmented Descriptors via Index Filtrations. Let \( \{K_{m_j}\}_{m_j \in M}, f \), and \( \{K'_i\}_{i \in [0, n]} \) be a monotone filtration and compatible index filtration, respectively (as in the previous section).

Given a monotone filtration, we are perhaps interested in the so-called instantaneous events that are captured in augmented topological descriptors, a remnant of the fact that many standard algorithms to produce descriptors for monotone filtrations are often actually employing compatible index filtrations. For example, an instantaneous \( n \)-dimensional homology event at time \( m_j \) records the presence of an \( n \)-boundary in the (closed) space \( K_{m_j} - K_{m_{j-1}} \).

Note that many applications of TDA, such as the classic application of manifold learning through a Vietoris-Rips filtration, discard events with a short lifespan because they may be attributed to noise, so non-augmented persistence diagrams are the traditional tool of choice (see [12]). However, recent developments in areas such as shape comparison and inverse attributed to noise, so non-augmented persistence diagrams are the traditional tool of choice (see [12]). However, recent developments in areas such as shape comparison and inverse

We aim to track both instantaneous and non-instantaneous events at every step of a monotone filtration. We introduce \( A_n \) to account for instantaneous events (the extra data of an augmented module). Let \( \beta_{m_j} \) denote the \( n \)-dimensional boundaries of \( K_{m_j} \) and let \( \kappa_{m_j} \) denote the kernel of the map on \( n \)-dimensional homology induced by the inclusion \( K_{m_{j-1}} \hookrightarrow K_{m_j} \). Although we may think of \( \beta_{m_{j-1}} \) as generated by simplices in \( K_{m_{j-1}} \), the fact that \( K_{m_{j-1}} \) includes into \( K_{m_j} \) means that \( \beta_{m_{j-1}} \) is also naturally viewed as a subgroup of \( \beta_{m_j} \). Then, we define:

\[
A_n(K_{m_j}) = \beta_{m_j} / (\beta_{m_{j-1}} \kappa_{m_{j-1}})
\]

(4)

Note that the rank of \( A_n(K_{m_j}) \) is the number of \( n \)-boundaries that appear in \( K_{m_{j-1}} \hookrightarrow K_{m_j} \), the \( j \)th step of the filtration, but that were not previously boundaries or did not kill a cycle in the inclusion. Equivalently, the rank of \( A_n(K_{m_j}) \) is the number of points (counting multiplicity) on the diagonal \((m_j, m_j)\) in the standard \( n \)-dimensional augmented persistence diagram corresponding to a monotone filtration. Thus, we can view \( A_n \) as a repackaging of the ‘entire’ information in index filtrations, independent of the choice of compatible index filtration. The connection to compatible index filtrations is made explicit in the following lemma.

Lemma 3.2.6. Suppose that \( \{K_{m_j}\}_{m_j \in M} \) is a monotone filtration corresponding to a filter function \( f \) and \( \{K'_i\}_{i \in [0, n]} \) is any compatible index filtration. Let \( \kappa_i \) denote the kernel of the map induced on homology in degree \( n \) by the inclusion \( K'_i \hookrightarrow K'_{i+1} \). Furthermore, let \( \kappa_{\Rightarrow} \) denote the kernel of the map induced on homology in degree \( n \) by the composition of inclusions \( K_{\max C^{-1}(m_j)} \hookrightarrow \ldots \hookrightarrow K_{\min C^{-1}(m_j)-1} \), where \( C \) is as in Definition 3.2.4. Then:

\[
A_n(K_{m_j}) \cong \left( \bigoplus_{i=(\min C^{-1}(m_j))-1}^{\max C^{-1}(m_j)} \kappa_i \right) / \kappa_{\Rightarrow}.
\]

(5)

Proof. Since each step in an index filtration adds a single simplex, either \( \kappa_i \cong V^0 \) (if the simplex added does not fill in any \( n \)-cycle) or \( \kappa_i \cong V^1 \) (if the simplex added in \( K_i \hookrightarrow K_{i+1} \) fills in an \( n \)-cycle). Thus, the direct sum in the equation above has nontrivial terms only for values of \( i \) such that \( K'_i \hookrightarrow K'_{i+1} \) witnesses the death of \( n \)-cycles in the index filtration. Recall that \([\min C^{-1}(m_j), \max(C^{-1}(m_j)) + 1]\) is the maximum interval whose image under the filter \( f \) is \( m_j \). This means that \( K'_{(\min C^{-1}(m_j))-1} = K_{m_{j-1}} \) and \( K'_{\max C^{-1}(m_j)} = K_{m_j} \). Thus, every
boundary of \(K_{m_j}\) that was not present as a boundary in \(K_{m_{j-1}}\) is introduced or becomes a boundary in some step of the index filtration between the values \((\min C^{-1}(m_j)) - 1\) and \((\max C^{-1}(m_j))\). That is, terms of the direct sum above are nontrivial when boundaries are created (and \(V^0\) otherwise). This is exactly the count of boundaries added in the inclusion \(K_{m_{j-1}} \hookrightarrow K_{m_j}\), i.e., it is \(\beta_{m_j}/\beta_{m_{j-1}}\), using the previously introduced in the paragraph above. However, recall that \(A_n(K_{m_j})\) should not account for boundaries that fill in a cycle from a previous step in the filtration. Thus, we quotient out by the kernel of the composition of maps between \(\min C^{-1}(m_j)\) and \(\max(C^{-1}(m_j)) + 1\). This kernel is generated by boundaries that include into themselves and by cycles in the initial filtration step that are eventually filled, i.e., cycles of \(K_{m_{j-1}}\) that are filled in \(K_{m_j}\). Since \(K'_{\min C^{-1}(m_j)} = K_{m_{j-1}}\) and \(K'_{\max C^{-1}(m_j)} = K_{m_j}\), and since the index filtration is compatible with the monotone filtration, we see that \(\kappa_{m_{j-1}} \cong \kappa_{m_{j-1}}\). Thus, the value in Equation 5 is exactly the value in Equation 4, \(A_n(K_{m_j}) = \beta_{m_j}/(\beta_{m_{j-1}}\kappa_{m_{j-1}})\), as desired. □

Example 3.2.7. Suppose that \(\{K_m\}\) and \(\{K'_m\}\) are monotone and index filtrations as in the bottom and top of Figure 3.2.2. Then \(A_n(K_m) \cong \beta_m/\beta_{m_1}\kappa_m \cong V^2/V^0 \cong V^2\). Computed using the identification of Lemma 3.2.6, we see that this is the same as \(\bigoplus_{i=1}^6 \kappa_i/\kappa_{m_{j-1}} \cong V^0 \oplus V^1 \oplus V^1/V_0 \cong V^2\).

The following cosheaf organizes the information of both instantaneous and non-instantaneous events.

Definition 3.2.8 (Augmented Filtration Cosheaf on \(\mathbb{R}\)). Let \(\{K_m\}_{m \in M}\) be a monotone filtration of a simplicial complex \(K\), and suppose \(\mathbb{R}\) is stratified by \(\text{Nat}(\mathcal{M} \setminus \{m_0\})^\wedge\). We define the augmented filtration cosheaf on \(\mathbb{R}\), \(F_A : \text{Opens}(\mathbb{R}) \to \text{Vect}\), on metric \(\epsilon\)-balls as follows.

\[
F_A(U) = \begin{cases} 
H_n(K_{m_j}) \oplus A_n(K_{m_j}), & \text{if } m_{j-1} \in U \\
H_n(K_{m_j}) & \text{if } U \subset (m_j, m_{j+1}) \text{ or } U \subset (m_j = m_0, \infty) \\
H_n(K_{m_j}) & \text{if } U \subset (-\infty, m_1) 
\end{cases}
\]

Observe that the above definition implies that the costalk at a zero-stratum \(m_{j-1}\) of \((\mathbb{R}, \text{Nat}(\mathcal{M} \setminus \{m_0\})^\wedge)\) is \(H_n(K_{m_{j-1}}) \oplus A_n(K_{m_j})\).

Remark 3.2.9. For an index filtration \(\{K'_i\}_{i \in I}\), any new \(n\)-cycles introduced through the map \(K'_{i-1} \hookrightarrow K'_i\) are not \(n\)-boundaries, since the boundaries and interiors of simplices are added at distinct filtration events. Thus, \(A_n(K'_i)\) is trivial, i.e., the augmented filtration cosheaf that arises from an index filtration is equivalent to its (non-augmented) filtration cosheaf.

An instance of the previous remark is illustrated by following example.

Example 3.2.10. Let \(\{K'_i\}\) be the index filtration in the top of Figure 3.2.2. Notice that the one-dimensional costalk of the non-augmented filtration cosheaf at \(i\) is \(H_1(K'_i) \cong V^0\), which is isomorphic to \(H_1(K'_i) \oplus A_1(K'_i) \cong V^0 \oplus V^1/V^1 \cong V^0\).

The stratified map \(C\) define above provides a clean interpolation between the augmented, non-augmented, and index cosheaves associated to a filtration.

Proposition 3.2.11. Let \(\mathcal{F}_M\) and \(\mathcal{F}_A\) be the non-augmented and augmented filtration cosheaves for some monotone filtration \(\{K_m\}_{m \in M}\) and let \(\mathcal{F}_I\) be the filtration cosheaf for a compatible index filtration \(\{K'_i\}_{i \in [0,n]}\). Let \(C : (\mathbb{R}, \text{Nat}([1,n]))^\wedge \to (\mathbb{R}, \text{Nat}(\mathcal{M} \setminus \{m_0\})^\wedge)\) be the map of stratified spaces as above. Then,
(i) We have an isomorphism of cosheaves $C_*F_I \cong F_M$;
(ii) Let $U \subset \mathbb{R}$ be open such that $U \cap M = \emptyset$, then $F_M(U) \cong F_A(U)$.

Proof. That $F_M$ and $F_A$ agree on one-strata follows directly from their definitions (they can differ at zero-strata). In claim (i), there are two parts: that $C_*F_I$ is constructible and that $C_*F_I$ is isomorphic to $F_M$. To prove the first, note that $C$ is a composition of “elementary collapses” as described in Example 2.2.3 so by functoriality $C_*F_I$ is constructible. The second part of (i) is an explicit unwinding of the definition of the pushforward. □

3.3. An Equivalence Result. Let $\text{Poset}_I$ be the category of posets with Hasse diagrams homeomorphic to the interval, half-closed interval or $\mathbb{R}$ and whose underlying set is at most countable. Morphisms in $\text{Poset}_I$ are surjective maps of posets. So from above, the category of zig-zag modules is the category of pairs $(P, \rho)$ with $P \in \text{Poset}_I$ and $\rho: P \to \text{Ve}c$ a representation of $P$.

Definition 3.3.1. Define the poset $\mathbb{Z}Z_N$ to have objects $\frac{1}{2}N$ with non-identity morphisms

\[
\frac{a}{2} \leq \frac{a+1}{2} \quad \text{and} \quad \frac{a}{2} \leq \frac{a-1}{2}
\]

for all $a \in \mathbb{N}$, with $a$ odd.

The poset $\mathbb{Z}Z_N$ arises naturally when considering $\mathbb{R}$ stratified (ambiently) by the natural numbers.

Lemma 3.3.2. There is a canonical isomorphism of categories $\mathbb{Z}Z_N \cong \text{Ent}_\Delta((\mathbb{R}, N)^\wedge)$.

We wish to “mark” our posets by passing to the under category of $\mathbb{Z}Z_N$.

Definition 3.3.3. Define the category of marked zig-zag modules, $\mathbb{Z}Z\text{mod}$, to be the category of pairs $(\mathbb{Z}Z_N \to P, \rho)$ with $\mathbb{Z}Z_N \to P \in \text{Poset}_I^{\mathbb{Z}Z_N/}$ and $\rho: P \to \text{Ve}c$ a representation. A morphism is a pair $(f, \varphi): (\mathbb{Z}Z_N \to P, \rho) \to (\mathbb{Z}Z_N \to Q, \eta)$ with $f: P \to Q$ defining a morphism in the under category and $\varphi: \rho \Rightarrow f^*\eta$ a natural transformation.

It turns out that isomorphism in $\mathbb{Z}Z\text{mod}$ is too strong to capture our preferred notion of “sameness,” so we introduce a notion of weak equivalence. An example of an operation that creates a weakly equivalent module is “subdividing” a vertex in a poset into several vertices provided that all of the new maps in the corresponding representation are isomorphisms.

Definition 3.3.4. A morphism $(f, \varphi): (\mathbb{Z}Z_N \to P, \rho) \to (\mathbb{Z}Z_N \to Q, \eta)$ in $\mathbb{Z}Z\text{mod}$ is a weak equivalence if $\varphi: \rho \Rightarrow f^*\eta$ is a natural isomorphism. Let $W$ denote the collection of weak equivalences.

We caution the data-analytically oriented reader here; notice that weakly equivalent objects of $\mathbb{Z}Z\text{mod}$ do not generally have the same indices of “events,” i.e., vertices at which the corresponding image of the representation changes. That is, the standard map from $\mathbb{Z}Z\text{mod}$ to persistence diagrams (as described in [11]) does not factor through $\mathbb{Z}Z\text{mod}[W^{-1}]$. However, the order and number of events is preserved.

Theorem 3.3.5. The category of (marked) zig-zag modules localized at weak equivalences is equivalent to the category of constructible cosheaves on $\mathbb{R}$ stratified by the natural numbers. That is, we have an equivalence of categories

$$\mathbb{Z}Z\text{mod}[W^{-1}] \cong \text{Fun}(\text{Ent}_\Delta((\mathbb{R}, N)^\wedge), \text{Ve}c) \simeq c\text{Shv}_{cbl}^{\text{Ve}c}((\mathbb{R}, N)^\wedge).$$
The second equivalence is just an example of the exodromy equivalence. The first equivalence, which is actually an isomorphism of categories, is proved in Appendix B. There are some technicalities in proving the previous theorem, but the main idea of the equivalence is as follows. Let \( \varphi : \mathcal{P} \to \mathbf{Vect} \) be a representation of \( \mathcal{P} \). Pullback \( \varphi \) along the map \( \mathbb{Z}\mathbb{Z}_{n!} \to \mathcal{P} \) to obtain a representation of \( \mathbb{Z}\mathbb{Z}_{n!} \) so that, via Lemma 3.3.2, we have a representation of the corresponding entrance path category, i.e., a constructible cosheaf.

### 4. K-theory of Zig-Zag Modules

We now shift gears and compute the K-theory of the category of zig-zag modules. The category in which our modules take values plays a central role and we consider two different constructions: one for set-valued modules and one for modules valued in vector spaces.

Let \((X \phi \to \mathcal{P})\) be a stratified space, \(\operatorname{Ent}_\Delta(X, \mathcal{P})\) its combinatorial entrance path category, and \(V\) any category. By way of the Exodromy Theorem, we will study persistence modules through the functor category \(\operatorname{Fun}(\operatorname{Ent}_\Delta(X, \mathcal{P}), V)\). Therefore, we define the K-theory of zig-zag modules as follows.

**Definition 4.0.1.** Let \((X \phi \to \mathcal{P})\) be a combinatorial manifold, \(\operatorname{Ent}_\Delta(X, \mathcal{P})\) its combinatorial entrance path category, and \(V\) any category. The K-theory of \(V\) valued zig-zag modules (parametrized by \(X\)) is given by

\[
K(\mathsf{pMod}^V(X)) := K(\operatorname{Fun}(\operatorname{Ent}_\Delta(X, \mathcal{P}), V)).
\]

One issue with the preceding definition is that for different \(V\), we may need to use different constructions of K-theory. For instance, when \(V\) is a category of vector spaces we use Waldhausen’s \(S^*\) construction. As noted previously, when multiple constructions of K-theory exist for the same category the resulting K-groups are all isomorphic.

#### 4.1. Assemblers: \(\mathbf{Set}_i\) Modules.

Let \(\mathfrak{C}\) be a category with pullbacks (the existence of pullbacks is not universally assumed in the literature, so condition (FP) below is not automatic).

**Definition 4.1.1.** A Grothendieck pretopology on \(\mathfrak{C}\) is a collection of covering families \(\{X_\alpha \to X\}\) in \(\mathfrak{C}\) such that

- **(FP)** For all \(X \in \mathfrak{C}\), any morphism \(X_0 \to X\) contained in a covering family of \(X\), and all morphisms \(Y \to X\), the pullback \(X_0 \times_X Y\) exists;
- **(BC)** For all \(X \in \mathfrak{C}\), any covering family \(\{X_\alpha \to X\}\), and all morphisms \(Y \to X\), the family \(\{X_\alpha \times_X Y \to Y\}\) is covering;
- **(L)** If \(\{X_\alpha \to X\}\) is a covering family and for each \(\alpha\), \(\{X_{\beta\alpha} \to X_\alpha\}\) is a covering family, then the composite family \(\{X_{\beta\alpha} \to X_\alpha \to X\}\) is covering;
- **(Iso)** If \(f : Y \to X\) is an isomorphism in \(\mathfrak{C}\), then \(\{Y \xrightarrow{f^{-1}} X\}\) is a covering family.

A category (with pullbacks) \(\mathfrak{C}\) equipped with a pretopology is called a Grothendieck site.

**Definition 4.1.2.** A closed assembler is a Grothendieck site \(\mathcal{A}\) such that

- **(I)** \(\mathcal{A}\) has an initial object \(\emptyset \in \mathcal{A}\) and the empty family is a covering of \(\emptyset\);
- **(M)** All morphisms in \(\mathcal{A}\) are monomorphisms.

We will let \(\mathbf{Set}_i\) be the category of finite sets and injective functions. Given a (finite) set \(S \in \mathbf{Set}_i\) declare a family \(\{T_\alpha \to S\}\) to be covering if the images of the \(T_\alpha\) is the entirety...
of $S$; we call such families \textit{jointly surjective}. We verify that, so equipped, $\text{Set}_i$ is indeed a closed assembler.

**Proposition 4.1.3.** The category $\text{Set}_i$ equipped with the jointly surjective topology is a closed assembler.

**Proof.** That pullbacks exist and that conditions (I) and (M) are satisfied is immediate. It only remains to show that collection of jointly surjective families satisfy the axioms of a pretopology. Similarly, since all pullbacks exist, condition (FP) is clear. In the category $\text{Set}_i$, an isomorphism is a bijection, so condition (Iso) is satisfied. The locality of covering families—condition (L)—follows (essentially) from the fact that the composition of surjective functions is itself surjective.

We now consider (BC). Let $i : Y \hookrightarrow S$ be a morphism, $\{T_\alpha \to S\}$ a covering family, and $y \in Y$. By definition, there is a set $T_\alpha$ and a morphism $j_\alpha : T_\alpha \to S$ such that $y$ is in the image of $j_\alpha$. Explicitly, let $t \in T_\alpha$ be an element such that $j_\alpha(t) = y$. Then $(t, y) \in T_\alpha \times Y$ maps to $y$, i.e., $\{T_\alpha \times_Y Y\}$ is indeed a jointly surjective family. □

**Lemma 4.1.4.** Let $\mathcal{D}$ be a small category and $\mathcal{A}$ a closed assembler. The category of functors $\text{Fun}(\mathcal{D}, \mathcal{A})$ is a Grothendieck site where a family $\{F_\alpha \to F\}$ is a covering family if and only if for all $d \in \mathcal{D}$ $\{F_\alpha(d) \to F(d)\}$ is a covering family in $\mathcal{A}$. So equipped, $\text{Fun}(\mathcal{D}, \mathcal{A})$ is a closed assembler.

The preceding Lemma can easily be verified directly. In our case, it specializes to the following result.

**Proposition 4.1.5.** Let $(X \xrightarrow{\phi} \mathcal{P})$ be a stratified space and $\text{Ent}_\Delta(X, \mathcal{P})$ its combinatorial entrance path category. The category of $\text{Set}_i$ representations of $\text{Ent}_\Delta(X, \mathcal{P})$, $\text{Fun}(\text{Ent}_\Delta(X, \mathcal{P}), \text{Set}_i)$, is a closed assembler.

The following is the central construction of [29] (and the content of Theorem B contained therein).

**Proposition 4.1.6.** Let $\mathcal{A}$ be a closed assembler. There exists a spectrum $\mathbb{K}(\mathcal{A})$ such that $K_0 := \pi_0 \mathbb{K}(\mathcal{A})$ is the free abelian group on the isomorphism classes of indecomposables of $\mathcal{A}$.

One way to construct the spectrum $\mathbb{K}(\mathcal{A})$ is to associate a Waldhausen category to the closed assembler $\mathcal{A}$ and apply Waldhausen’s $S_*$ construction.

To compute $K_0$ we can apply to a standard result about one-dimensional persistence modules [8, 11].

**Proposition 4.1.7.** A zig-zag module is indecomposable if and only if it is an interval module.

**Theorem 4.1.8.** Let $X$ be a combinatorial one-manifold and $\text{pMod}^{\text{Set}_i}X$ the category of injective set valued zig–zag modules parametrized by $X$. Then we have an isomorphism of abelian groups

$$K_0(\text{pMod}^{\text{Set}_i}(X)) \cong \mathbb{Z}^\oplus\{X_0\} \oplus \mathbb{Z}^\oplus\{X_1\},$$

where $\{X_i\}$ is the set of $i$-dimensional strata of $X$.

In fact, this decomposition lifts to the level of spectra as an application of Theorem D of [29]. We do not give a proof as the ideas are completely analogous to the proof of Theorem 16.
4.2.6 below. In loc. cit., that the K-theory of finite sets recovers the sphere spectrum via the Barratt–Priddy–Quillen–Segal Theorem is explained.

Theorem 4.1.9. Let $X$ be a combinatorial one-manifold, we have an equivalence of spectra

$$\mathbb{K}(\text{pMod}^\text{Set}(X)) \cong \bigvee_{X_0} \mathbb{S} \vee \bigvee_{X_1} \mathbb{S},$$

where $X_i$ is the set of $i$-strata of $X$ and $\mathbb{S}$ denotes the sphere spectrum.

Remark 4.1.10. For a general assembler, it can be difficult to identify the spectrum $\mathbb{K}(\mathcal{A})$ and its homotopy groups. In [30], Zakharevich gives an explicit description of $K_1$ arising from a closed assembler.

4.2. Abelian Categories: Vect coSheaves. Linear categories don’t have great gluing constructions, e.g., a vector space is not the union of proper subspaces! So we wouldn’t expect $\text{Vect}$ (even after restricting to injective linear maps) to be an assembler. Fortunately, the category of finitely generated modules for a commutative ring is an Abelian category, so we can define/compute K-theory using the work of Quillen and Waldhausen. (If our ring is a field, we recover our old friend $\text{Vect}$). In this section we will freely use the material of Appendix A.

Lemma 4.2.1. Let $R$ be a commutative ring, $\mathcal{M}$ the associated Waldhausen category of finitely generated modules, $X$ a (finitely, simplicially) stratified space, and $x_0 \in X$ a connected zero-dimensional stratum, i.e., a point that is a stratum. The following sequence is split short exact sequence of Waldhausen categories

$$\begin{array}{ccc}
\text{Fun}(\text{Ent}_\Delta(X \setminus x_0), \mathcal{M}) & \overset{j^*}{\longrightarrow} & \text{Fun}(\text{Ent}_\Delta(X), \mathcal{M}) \\
\overset{j_*}{\longleftarrow} & & \overset{i_*}{\longrightarrow} \\
\text{Fun}(\text{Ent}_\Delta(x_0), \mathcal{M}) & \overset{i^*}{\longrightarrow} & \text{Fun}(\text{Ent}_\Delta(x_0), \mathcal{M}),
\end{array}$$

where $i: x_0 \hookrightarrow X$ and $j: X \setminus x_0 \hookrightarrow X$ are the inclusion maps.

Proof. The content of Lemma A.0.2 is precisely that the three categories appearing are Waldhausen. We next observe that the inverse and direct image functors (in this setting) are compatible with the equivalences and cofibrations, so indeed we have a sequence of exact functors.

It is standard that $i_*$ is right adjoint to $i^*$ and in this case that counit of the adjunction is a natural isomorphism. Because our domain categories are discrete (finite even), $j_*$ is indeed left adjoint to $j^*$ and the unit is a natural isomorphism; $j_*$ is the extension by zero map. The composition $i^* \circ j_*$ is manifestly the zero functor and $i^*$ presents $\text{Fun}(\text{Ent}_\Delta(x_0), \mathcal{V})$ as the cokernel of $j_*$. In summary, the sequence is short exact and the adjointness properties we observed further show it is split.

\[ \square \]

Remark 4.2.2. The preceding lemma is straightforward as we are considering constructible cosheaves on the complement of a point (which is open). One could try to prove a version of the lemma above where $x_0$ is replaced by an arbitrary stratum and at the level of non-combinatorial entrance path categories, but—in general—this fails as $j^*$ will not have the appropriate adjointness properties. There is, however, a corresponding lemma for an arbitrary closed/open complement decomposition that is compatible with the stratification.
Lemma 4.2.3. The split short exact sequence of Lemma 4.2.1 is standard.

Proof. Condition (3) of Definition A.0.4 holds for categories of modules (see Remark 2.18 of [15]) and by the same reasoning, our category of functors valued in $\mathcal{M}$.

Let $\mathcal{F} \in \text{Fun}(\text{Ent}_\Delta(X), \mathcal{M})$. Each component of the natural transformation $j_* \circ j^*(\mathcal{F}) \to \mathcal{F}$ is an isomorphism, except for the component corresponding to $x_0$. The component corresponding to $x_0$ is the inclusion of zero, which is a cofibration. Therefore, $j_* \circ j^*(\mathcal{F}) \to \mathcal{F}$ is a cofibration in the functor category.

Finally, let $\varphi : \mathcal{F} \to \mathcal{F}'$ be a cofibration in $\text{Fun}(\text{Ent}_\Delta(X), \mathcal{M})$. We need to check that unique map $\psi : \mathcal{F} \bigoplus_{j_*j^*\mathcal{F}} \mathcal{F}' \to \mathcal{F}'$ is a cofibration. By definition, we must check this condition componentwise. For a component corresponding to $x_0 \neq S \subset X$, the kernel of $\psi$ is exactly the submodule of $\mathcal{F}(S) \oplus \mathcal{F}'(S)$ by which we quotient when constructing pushouts in categories of modules; that is, the $S$ component of $\psi$ is a monomorphism. For the $x_0$ component, the pushout is identified with $\mathcal{F}(x_0)$ and $\psi_{x_0} = \varphi_{x_0}$, so by hypothesis it is a monomorphism. □

We require one final observation/Lemma before assembling the proof of Theorem 4.2.6.

From the definition of entrance paths and the fact that K-theory preserves colimits, it immediately follows that K-theory is additive with respect to connected components of our parameter space. That is:

Lemma 4.2.4. Let $X = X_a \amalg X_b$ be a stratified space, then there is an equivalence of spectra

$$K(\text{pMod}^{\text{Vect}}(X)) \cong K(\text{pMod}^{\text{Vect}}(X_a)) \vee K(\text{pMod}^{\text{Vect}}(X_b)).$$

Although the strata of a one-dimensional stratified space are not generally disjoint, we still have an additivity result similar to the previous lemma, as we will now show.

Lemma 4.2.5. Let $X$ be a one-dimensional combinatorial manifold. There is an equivalence of spectra

$$K(\text{pMod}^{\text{Vect}}(X)) \cong \bigvee_{x_0 \in X_0} K(\text{pMod}^{\text{Vect}}(x_0)) \vee \bigvee_{x_1 \in X_1} K(\text{pMod}^{\text{Vect}}(x_1)).$$

where $X_i$ is the set of $i$-strata of $X$.

Proof. We proceed by induction over the number of zero-strata. As our base case, note that when there are no zero-strata, we have $X_0 = \emptyset$ and $x_1 = X_1 = X$, so the claim holds. Now suppose that the claim holds whenever $X$ contains $n - 1$ zero-strata, for all $n - 1 \geq 0$. Then consider the case that $X$ contains $n$ zero-strata. For an arbitrary zero-stratum $x_0^* \in X_0$, we know by Lemma 4.2.1 that

$$\text{Fun}(\text{Ent}_\Delta(X \setminus x_0^*), \text{Vect}) \to \text{Fun}(\text{Ent}_\Delta(X), \text{Vect}) \to \text{Fun}(\text{Ent}_\Delta(x_0^*), \text{Vect})$$

is a split short exact sequence of Waldhausen categories. Then by Theorem A.0.5, we see that there is an equivalence of spectra

$$K(\text{pMod}^{\text{Vect}}(X)) \cong K(\text{pMod}^{\text{Vect}}(X \setminus x_0^*)) \vee K(\text{pMod}^{\text{Vect}}(x_0^*))$$
Since $X \setminus x_0^*$ is itself a one-dimensional combinatorial manifold with $n - 1$ zero-strata, our inductive hypothesis allows us to write

$$K(pMod^{Vect}(X)) \cong \bigvee_{x_0 \neq x_0^* \in X_0} K(pMod^{Vect}(x_0^*)) \vee K(pMod^{Vect}(X_1)) \vee K(pMod^{Vect}(x_0^*)).$$

Since the zero-strata are disjoint, by Lemma 4.2.4, we may reindex by absorbing the last term into the first and we have the desired result. □

Utilizing the preceding lemma, we now prove the following theorem.

**Theorem 4.2.6.** Let $X$ be a one-dimensional combinatorial manifold. There is an equivalence of spectra

$$K(pMod^{Vect}(X)) \cong \bigvee_{X_0} K(F) \vee \bigvee_{X_1} K(F),$$

where $X_i$ is the set of $i$-strata of $X$ and where $K(F)$ denotes the K-theory spectrum of the field $F$.

**Proof.** First, we identify the $K$-theory of components of the stratification, i.e., we identify $K(pMod^{Vect}(x_0))$ and $K(pMod^{Vect}(x_1))$ for $x_0 \in X_0$ and $x_1 \in X_1$, respectively. We begin with the former.

By Definition 4.0.1, we have $K(pMod^{Vect}(x_0)) = K(Funct(Ent_\Delta(x_0), Vect_F))$. Since $Ent_\Delta(x_0)$ is the terminal category (a single object and an identity morphism), $Funct(Ent_\Delta(x_0), Vect_F)$ is isomorphic to the ucategory of $Vect_F$ itself. Thus, $K(pMod^{Vect}(x_0)) = K(Vect)$. Now, the category of finite dimensional vector spaces over $F$ is exactly the category of finitely generated projective modules over $F$ (considered as a ring). Hence, $K(Vect)$ is just the algebraic $K$-theory of $F$.

We observe that $Ent_\Delta(x_1)$ is also a single object category, so the proof that $K(pMod^{Vect}(x_1)) \cong K(F)$ is identical. Thus, we have shown the $K$-theory of each strata is a copy of $K(F)$. We know by Lemma 4.2.5 that $K(pMod^{Vect}(X))$ is additive over strata, so the result follows. □

**Remark 4.2.7.** An alternative approach to proving the preceding theorem could be to use Serre subcategories and Abelian Localization. This approach has a number of its own subtleties so we have presented the proof above.

**Corollary 4.2.8.** For $X$ a one-dimensional combinatorial manifold, we have

$$K_0(pMod^{Vect}(X)) \cong \bigoplus_{X_0} \mathbb{Z} \oplus \bigoplus_{X_1} \mathbb{Z},$$

and

$$K_1(pMod^{Vect}(X)) \cong \bigoplus_{X_0} F^\times \oplus \bigoplus_{X_1} F^\times,$$

where $X_i$ is the set of $i$-strata of $X$ and $F^\times$ is the group of units of $F$.

The higher $K$-theory of fields contains interesting torsion and other phenomena. We refer the reader to Chapter IV of [28] for an in-depth description.
In this section, we give two applications of our K-theoretic work.

5.1. Euler Curves and $K_0$. Let $\{V_i\}$ be a monotone persistence module of vector spaces, with indexing set $I$. We choose an embedding $I \hookrightarrow \mathbb{N}$ and—in what follows—identify $I$ with its image in the natural numbers. The propagated persistence cosheaf, $F_{V}$, is constructible on $\mathbb{R}$ stratified by $\mathbb{N}$.

Definition 5.1.1. The (scaled) Euler curve of $\{V_i\}$ is the constructible function $\chi_V: \mathbb{R} \to \mathbb{Z}$ given by $\chi(x) = \text{rank}(F_{V})(x)$, the rank of the costalk at $x \in \mathbb{R}$. If $\{V_i\}$ is a module of graded vector spaces, then $\chi_V$ is the alternating sum of the ranks of the graded vector space that is the costalk.

Note that any constructible $\mathbb{Z}$-valued function on $\mathbb{R}$ natural defines a class in $K_0$. As noted in the proof of Theorem 4.2.6, the class in $K_0$ of a cosheaf only depends on its dimension, so we have the following.

Proposition 5.1.2. Let $V_*$ be a standard, finite persistence module of vector spaces. Then,

$$[F_V] = [\chi_V] \in K_0(pMod^{Vect}((\mathbb{R}, \mathbb{N})^\wedge)).$$

While the statement of the proposition feels obvious, it does contain content. Indeed, one of the classical motivations for simplicial homology is fixing the functoriality of the Euler characteristic. In general, a map of complexes $f: X_* \to Y_*$ does not induce a map between $\chi(X_*)$ and $\chi(Y_*)$; only if $f$ is covering map is there a multiplicative relationship between Euler characteristics. The categorification of the Euler characteristic to homology fixes this functoriality issue. Given any (co)homological setting there is an analogue of Euler class (in topology, this can be achieved by considering orientations for cohomology theories). The preceding proposition witnesses a K-theoretic Euler class.

One consequence of realizing Euler curves/classes K-theoretically is that there is an obvious extension to arbitrary (finite) persistence modules: zig-zag, higher dimensional, etc. (As before, we only see the scaled/standardized curve/class.) This construction is an explicit realization of the yoga that K-theory is the universal Euler characteristic.

Definition 5.1.3. Let $\mathcal{F} \in pMod^V(X, \mathcal{F})$ be a persistence module. The Euler class, $\chi(\mathcal{F})$, of $\mathcal{F}$ is the $K$–class

$$\chi(\mathcal{F}) := [\mathcal{F}] \in K_0(pMod^V(X, \mathcal{F})).$$

5.2. Virtual Diagrams. In [9], Bubenik and Elchesen describe the group completion of a monoid of persistence diagrams. The resulting equivalence classes are called virtual persistence diagrams and can be realized by extending the diagrams to include arbitrary points in the (extended) first quadrant, i.e., not just points above the diagonal. We will denote Bubenik and Elchesen’s Abelian group of virtual persistence diagrams by $K_0(\text{Diag})$. We now describe a homomorphism (and its image)

$$\delta: K_0(pMod^V_{fin}((\mathbb{R}, \mathbb{N})^\wedge)) \to K_0(\text{Diag}).$$

To begin, let $pMod^V_{fin}((\mathbb{R}, \mathbb{N})^\wedge)$ denote the category of $\mathcal{V}ect$-valued constructible cosheaves on $\mathbb{R}$ (stratified by the discrete subset consisting of the natural numbers) that are eventually constant, i.e., there exists $N \in \mathbb{N}$ such that beyond $N$ the cosheaf is constant. This category
has a monoidal structure induced by $\oplus$ in $\text{Vect}$, so the objects in the category form a (commutative, unital) monoid.

We require a small tweak to the category $\text{Diag}$ from [9]. As we allow features to persist for all future time, our persistence diagrams are built from the extended real line $\mathbb{R} \cup \{\infty\}$; this is a minor point and we suppress it from notation.

Now, as noted above, we have an identification of $\text{Ent}_\Delta(\mathbb{R}, \text{Nat}(\mathbb{N})^\wedge)$ with the poset $\mathbb{Z} \mathbb{Z}_\mathbb{N}$. Hence, an object $\mathcal{F} \in \text{pMod}_{\text{fin}}^{\text{Vect}}((\mathbb{R}, \mathbb{N})^\wedge)$ is simply a representation of $\mathbb{Z} \mathbb{Z}_\mathbb{N}$ (which is eventually finite). Following [11], we use indecomposables of the associated representation of $\mathbb{Z} \mathbb{Z}_\mathbb{N}$ to associate a diagram to $\mathcal{F}$. More explicitly, we have the following assignment of a multi-set of points to a cosheaf

$$\tilde{\delta} : \text{pMod}_{\text{fin}}^{\text{Vect}}((\mathbb{R}, \mathbb{N})^\wedge) \rightarrow \text{Diag} \subset K_0(\text{Diag}), \quad \mathcal{F} \mapsto \{(b_i, d_i)\},$$

where each $b_i$ and $d_i$ correspond to the left and right indices (respectively) of an indecomposable element of the associated representation of $\mathbb{Z} \mathbb{Z}_\mathbb{N}$.

Figure 5.1. The result of applying $\delta$ to the cosheaf shown on the top of the figure is the persistence diagram shown on the bottom. In the middle, we have drawn the associated barcode. In the spirit of [11], we have shown all bars as closed intervals to emphasize that they do not necessarily arise from a monotone filtration. Note the presence of length-zero barcodes and on-diagonal points, corresponding to indecomposable elements with a single vector space.

Note that $\tilde{\delta}$ can easily be adapted to be a map into barcodes, where, instead of a point $(b, d)$, we draw a bar between $b$ and $d$. This map $\tilde{\delta}$ (and the adaptation to signed barcodes) is nearly identical to the one described in Definition 2.6 of [11] with two notable differences. Firstly, the diagrams of ibid have points only on the integer lattice, whereas our diagrams have points on the 1/2-integer lattice. This is a consequence of us additionally considering edges of the stratification rather than only vertices, and of our convention to then index vertices by non-integers. Furthermore, the diagrams of ibid contain on-diagonal points only
when the maps to a particular vertex both have a nontrivial kernel. Our diagrams allow for these type of on-diagonal points, but additionally allow for on-diagonal points when the maps from an edge to its endpoints both have a nontrivial kernel.

In general, these differences may be attributed to beginning with persistence modules (the starting place for the map in \[11\]) or beginning with persistence module cosheaves (the starting place for our map \(\delta\)). When one begins with persistence modules, the resulting cosheaf is a specific type – importantly, each edge has an identity morphism to at least one of its endpoints (see Definition [3.1.3]). This allows ibid to only consider a poset on vertices, which may be obtained from our poset of vertices and edges by collapsing these identity morphisms. The language of ibid is therefore more compatible with an explicit connection to filtrations, whereas our setting is generalized.

Returning to our primary goal, we note that our diagram map \(\delta\) takes direct sums to sums of multisets.

**Lemma 5.2.1.** The map 
\[
\tilde{\delta}: pMod^\text{Vect}_{\text{fin}}((\mathbb{R}, \mathbb{N})^n) \to K_0(\text{Diag})
\]
is a monoid homomorphism.

By the universal property of \(K_0\) we obtain our desired homomorphism.

**Corollary 5.2.2.** There is a homomorphism of Abelian groups 
\[
\delta: K_0(pMod^\text{Vect}_{\text{fin}}((\mathbb{R}, \mathbb{N})^n)) \to K_0(\text{Diag})
\]
such that the following diagram commutes
\[
\begin{array}{ccc}
pMod^\text{Vect}_{\text{fin}}((\mathbb{R}, \mathbb{N})^n) & \xrightarrow{\tilde{\delta}} & K_0(\text{Diag}) \\
& \searrow \downarrow \delta & \\
& K_0(pMod^\text{Vect}_{\text{fin}}((\mathbb{R}, \mathbb{N})^n)) &
\end{array}
\]

Because we have scaled/standardized our modules—as reflected by the parameter space \((\mathbb{R}, \mathbb{N})\)—the map \(\delta\) has zero chance of being surjective (let alone an isomorphism). Following [9], let \(\text{Diag}(\{1/2\mathbb{Z}\}^2, \{1/2\mathbb{Z}_{\geq 0}\}^2)\) be monoid of (classical) persistence diagrams with half-integer (or infinite) coefficients. This monoid is a submonoid of the monoid of all (classical) persistence diagrams, \(\text{Diag}\), and we let \(G < K_0(\text{Diag})\) denote the subgroup it generates. The following is clear from construction.

**Proposition 5.2.3.** The subgroup \(G < K_0(\text{Diag})\) is isomorphic to the image of the homomorphism
\[
\delta: K_0(pMod^\text{Vect}_{\text{fin}}((\mathbb{R}, \mathbb{N})^n)) \to K_0(\text{Diag}).
\]

**Appendix A. Waldhausen’s K-theory**

In this appendix we outline Waldhausen’s construction of algebraic K-theory. In particular, we build to a fundamental additivity result: Waldhausen Additivity. The work of Waldhausen was first published in 1985 [27]. Our notation follows the much more recent article of Fiore and Pieper [15].
**Definition A.0.1.** A Waldhausen category, $C$, is a category equipped with a subcategory of weak equivalences, $w(C)$, and a subcategory of cofibrations, $co(C)$, and a distinguished zero object. Further, the triple $(C, co(C), w(C))$ must satisfy

1. Every isomorphism in $C$ is a cofibration;
2. Each object $c \in C$ is cofibrant, i.e., the unique map $0 \to c$ is a cofibration;
3. Cokernels exist and define cofibration sequences; and
4. Weak equivalences glue along cofibrations.

Waldhausen categories are a more general setting for algebraic K-theory than Abelian and exact categories. In particular, if $R$ is a commutative ring and $M$ is the category of finitely generated modules, then declaring weak equivalences to be isomorphisms and cofibrations to be monomorphisms makes $M$ into a Waldhausen category. The following is straightforward verification.

**Lemma A.0.2.** Let $R$ be a commutative ring, $M$ the associated Waldhausen category of finitely generated modules, and $D$ a small category. The category of functors $\text{Fun}(D, M)$ is a Waldhausen category where

1. The zero object $Z \in \text{Fun}(D, M)$ is the constant functor to the distinguished zero object in $M$;
2. A natural transformation $\eta : F \Rightarrow G$ is a weak equivalence if and only if for each $d \in D$, $\eta_d : F(d) \to G(d)$ is an isomorphism; and
3. A natural transformation $\alpha : F \Rightarrow G$ is a cofibration if and only if for each $d \in D$, $\alpha_d : F(d) \to G(d)$ is a monomorphism.

Given a Waldhausen category $C$, there is an associated simplicial Waldhausen category denoted $S\cdot C$ and the subcategory, $wS\cdot C$, of weak equivalences. The $K$-theory spectrum of $C$ is defined to be the $\Omega$-spectrum whose $n$th space is given by

$$K(C)_n := |wS\cdot S\cdot \cdots S\cdot C|,$$

i.e., the realization of the subcategory of weak equivalences of the $n$-fold (degreewise) application of the $S\cdot$ construction.

**Definition A.0.3.** Let $A, E$ and $B$ be Waldhausen categories. A sequence of exact functors

$$A \xrightarrow{i} E \xrightarrow{f} B$$

is **exact** if

1. The composition $f \circ i$ is the zero map to $B$;
2. The functor $i$ is fully faithful; and

A sequence, as above, is **split** if there exist exact functors

$$A \leftarrow E \leftrightarrow B,$$

which are adjoint to $i$ and $f$ and such that the unit of the adjunction, $\text{Id}_A \to j \circ i$, and the counit of the adjunction, $f \circ g \to \text{Id}_B$, are natural isomorphisms.

\[1\text{Here, } E/A \text{ is the full subcategory of } E \text{ on objects } e \text{ such that for all } a \in A \text{ the hom set } E(i(a), e) \text{ is a point.}\]
Definition A.0.4. A split short exact sequence of Waldhausen categories

\[ A \xrightarrow{i} E \xrightarrow{f} B, \]

is standard if

1. For each \( e \in E \), the component of the counit, \((i \circ j)(e) \rightarrow e\), is a cofibration;
2. For each cofibration \( e \hookrightarrow e' \) in \( E \), the induced map

\[ e \oplus (i \circ j)(e) \rightarrow e' \]

is a cofibration; and
3. If \( a \rightarrow a' \rightarrow 0 \) is a cofibration in \( A \), then the first map is an isomorphism.

The following is one of the fundamental theorems of algebraic K-theory. It is known as Waldhausen Additivity.

Theorem A.0.5. Let

\[ A \xrightarrow{i} E \xrightarrow{f} B, \]

be a standard split SES of Waldhausen categories. Then the functors \( i \) and \( g \) induce an equivalence of spectra

\[ K(i) \vee K(g) : K(A) \vee K(B) \xrightarrow{\sim} K(E). \]

Appendix B. Proof of Theorem 3.3.5

The key ideas we use in the proof of the theorem go back to Grothendieck (and Verdier), specifically SGA4 Exposé VI. The key observation—which we make precise—is that the category of zig–zag persistence modules is a localization of the Grothendieck construction on the (psuedo)functor that sends a poset to its category of representations: \( R : \text{Poset}^{op} \rightarrow \text{Cat} \). As we will explain, the Grothendieck construction is the lax colimit of \( R \). Our domain category has an initial object, \( \mathbb{Z}\mathbb{N} \), hence, the colimit of \( \Phi \) is isomorphic to the evaluation \( \Phi(\mathbb{Z}\mathbb{N}) \). Finally, in Lemma 3.3.2 we recognized \( \mathbb{Z}\mathbb{N} \) as the poset underlying the (combinatorial) entrance path category of \( \mathbb{R} \) stratified with respect to the subset of natural numbers.

Throughout this appendix we will work with bicategories. Recall that any category can be considered as a bicategory with the only 2-morphisms being identities. The bicategory of categories, \( \text{Cat} \), consists of (small) categories, functors, and natural transformations. A reader who finds this appendix terse may find the recent book of Johnson and Yau of great use.

B.1. Psuedo and lax (co)limits. When going from 1-categories to 2-categories there is more flexibility in definitions. This is already apparent when considering the notion of 2-functor and extends to limits and colimits as well. Many details of (co)limits in 2-categories were explicated in the 1980’s by Ross Street and collaborators, for instance. As an orienting exercise, let us recall the definition of lax and pseudo functors.

Definition B.1.1. Let \( \mathcal{A} \) and \( \mathcal{B} \) be bicategories. A lax functor \( P : \mathcal{A} \rightarrow \mathcal{B} \) consists of

- A function \( P : \text{Obj}(\mathcal{A}) \rightarrow \text{Obj}(\mathcal{B}) \);
• For each hom-category \( \mathcal{A}(X,Y) \) in \( \mathcal{A} \), a functor 
\[ P_{X,Y} : \mathcal{A}(X,Y) \to \mathcal{B}(P_X, P_Y); \]

• For each object \( X \in \mathcal{A} \) a 2-cell \( P_{\text{id}_X} : \text{id}_{P_X} \Rightarrow P_{X,X}(1_X); \)

• For each triple of objects and morphisms \( f : X \to Y \) and \( g : Y \to Z \), a natural (in \( f \) and \( g \)) transformation 
\[ P_{f,g} : P_{Y,Z}(g) \circ P_{X,Y}(f) \Rightarrow P_{X,Z}(g \circ f). \]

This data satisfies a sequence of coherence diagrams specifying unity and associativity.

A lax functor is a pseudofunctor if the 2-cells/natural transformations in the definition above are invertible. So a pseudofunctor is more strict than a lax functor, but not yet a strict 2-functor, which would require all higher morphisms to be identities. Correspondingly we have variable notions of colimit. For details see Chapter 5 of [18] and/or [6].

**Definition B.1.2.** Let \( \Phi : \mathcal{A} \to \mathcal{B} \) be a lax functor.

- A **lax colimit** of \( \Phi \) is an initial object in the category of lax cocones under \( \Phi \);
- A **psuedocolimit** of \( \Phi \) is an initial object in the category of psuedococones under \( \Phi \).

The lax colimit of \( \Phi \) is unique up to equivalence, while the psuedocolimit is unique up to isomorphism. We will use the notation \( \text{colim} \Phi \) for “the” psuedocolimit of \( \Phi \).

**Lemma B.1.3.** Let \( \Phi : \mathcal{A} \to \mathcal{B} \) be a lax functor, \( \mathcal{A} \) an honest 1-category and \( \mathcal{T} \in \mathcal{A} \) a terminal object. Then, we have an isomorphism
\[ \text{colim} \Phi \cong \Phi(\mathcal{T}). \]

Correspondingly, if \( \Psi : \mathcal{A}^{\text{op}} \to \mathcal{B} \) is a lax functor, \( \mathcal{A} \) an honest 1-category and \( \mathcal{I} \in \mathcal{A} \) is initial, then
\[ \text{colim} \Psi \cong \Psi(\mathcal{I}). \]

**B.2. The Grothendieck Construction.**

**Definition B.2.1.** Let \( \mathcal{C} \) a category and \( \Phi : \mathcal{C}^{\text{op}} \to \text{Cat} \) be a lax functor. The **Grothendieck construction**, \( \int \Phi \), is the following category:

- An object of \( \int \Phi \) is a pair, \( (A, X) \), with \( A \in \mathcal{C} \) and \( X \in \Phi(A) \);
- A morphism \( (f, p) : (A, X) \to (B, Y) \) consists of
  - A morphism \( f : A \to B \) in the category \( \mathcal{C} \); and
  - A morphism \( p : X \to \Phi(f)(Y) \) in \( \Phi(A) \).

There are (reasonably) clear composition and identities in \( \int \Phi \) and it is standard to verify that \( \int \Phi \) actually defines a category. The symbol “\( \int \)” is meant to convey that the Grothendieck construction is amalgamating the data of \( \Phi \) “over” the domain category \( \mathcal{C} \). Indeed, projection defines a functor \( \int \Phi \to \mathcal{C} \) that is a fibration.

**Proposition B.2.2** (Theorem 10.2.3 of [18]). Let \( \mathcal{C} \) a category and \( \Phi : \mathcal{C}^{\text{op}} \to \text{Cat} \) be a lax functor. The Grothendieck construction, \( \int \Phi \), is a lax colimit of \( \Phi \).

Let \( U : \mathcal{E} \to \mathcal{C} \) be a functor and \( \varphi : e \to e' \) a morphism in \( \mathcal{E} \). Recall that \( \varphi \) is cartesian if every commutative triangle in \( \mathcal{C} \) involving \( U(\varphi) \) with a chosen lift of a 2-horn has a unique filler. (This definition is a bit colloquial, see Section 9.1 of [18].)
Corollary B.2.3. After localizing $\int \Phi$ at the collection of cartesian morphisms (with respect to projection $\int \Phi \rightarrow C$) we obtain a pseudocolimit of $\Phi$, i.e., if Cart denotes the class of cartesian morphisms in $\int \Phi$, then $\int \Phi[\text{Cart}^{-1}] \cong \text{colim} \Phi$.

B.3. Proving the Theorem. Let $\mathcal{R}: \text{Poset}_{I}^{\mathbb{Z}\mathbb{N}} \rightarrow \text{Cat}$ be the psuedofunctor of linear representations, i.e., $\mathcal{R}(\mathbb{Z}\mathbb{N} \rightarrow \mathcal{P}) := \text{Fun}(\mathcal{P}, \text{Vect})$.

By design, the Grothendieck construction of $\mathcal{R}$ recovers the category of marked zig-zag modules.

Lemma B.3.1. For $\mathcal{R}$ defined above, $\int \mathcal{R} \cong \mathbb{Z}\text{mod}$.

Lemma B.3.2. A morphism $(f, \varphi): (\mathbb{Z}\mathbb{N} \rightarrow \mathcal{P}, \rho) \rightarrow (\mathbb{Z}\mathbb{N} \rightarrow \mathcal{Q}, \eta)$ in $\mathbb{Z}\text{mod}$ is cartesian if and only if $\varphi$ is a natural isomorphism.

Proof. Let $(f, \varphi): (\mathbb{Z}\mathbb{N} \rightarrow \mathcal{P}, \rho) \rightarrow (\mathbb{Z}\mathbb{N} \rightarrow \mathcal{Q}, \eta)$ be a morphism and $(g, \psi): (\mathbb{Z}\mathbb{N} \rightarrow \mathcal{R}, \alpha) \rightarrow (\mathbb{Z}\mathbb{N} \rightarrow \mathcal{Q}, \eta)$ a morphism such that $h: (\mathbb{Z}\mathbb{N} \rightarrow \mathcal{R}) \rightarrow (\mathbb{Z}\mathbb{N} \rightarrow \mathcal{P})$ defines a commutative triangle in $\text{Poset}_{I}^{\mathbb{Z}\mathbb{N}}$. We need to find a (unique) natural transformation $\chi: \alpha \Rightarrow h^* \rho$ such that $(h, \chi)$ fills the 2-horn upstairs in $\mathbb{Z}\text{mod}$. This is possible precisely when $\varphi: \rho \Rightarrow \eta$ is an isomorphism. Indeed, $g^* = h^* \circ f^*$, and $\psi: \alpha \Rightarrow g^* \eta$, so if $\varphi$ is an isomorphism we define $\chi := \psi: \alpha \Rightarrow g^* \eta \cong h^*(\phi^* \eta) \cong h^* \rho$.

Lemma B.3.3. The object $(\mathbb{Z}\mathbb{N} \rightarrow \mathbb{Z}\mathbb{N})$ is initial in $\text{Poset}_{I}^{\mathbb{Z}\mathbb{N}}$.

Proof. Let $(\varphi: \mathbb{Z}\mathbb{N} \rightarrow \mathcal{P}) \in \text{Poset}_{I}^{\mathbb{Z}\mathbb{N}}$. A map in the under category from $(\mathbb{Z}\mathbb{N} \rightarrow \mathbb{Z}\mathbb{N})$ is a commutative diagram in $\text{Poset}_{I}$

$$
\begin{array}{ccc}
\mathbb{Z}\mathbb{N} & \rightarrow & \mathbb{Z}\mathbb{N} \\
\downarrow \text{Id} & & \downarrow \psi \\
\mathbb{Z}\mathbb{N} & \rightarrow & \mathcal{P}.
\end{array}
$$

By commutativity of the square, the map $\psi = \varphi$, so there is indeed a unique map in the under category.

The precedings lemmas assemble to a proof of Theorem 3.3.5. More precisely, we have shown that $\mathbb{Z}\text{mod}[\mathcal{W}^{-1}] \cong \int \mathcal{R}[\text{Cart}^{-1}] \cong \text{colim} \mathcal{R} \cong \mathcal{R}(\mathbb{Z}\mathbb{N} \rightarrow \mathbb{Z}\mathbb{N}) \cong \text{Fun}(\mathbb{Z}\mathbb{N}, \text{Vect})$.
