Abstract

Topological materials are often characterized by unique edge states which are in turn used to discern different topological phases in experiments. Recently, with the discovery of various higher-order topological insulators, such spectral topological characteristics are extended from edge states to corner states. However, the chiral symmetry protecting the corner states is often broken in most materials, leading to vulnerable corner states even when the higher-order topological numbers (such as fractional corner charges) remain quantized and invariant. Here, we propose a single-plaquette artificial gauge flux insertion as a robust spectral probe of the Wannier type higher-order topological insulators which is effective even when the chiral symmetry is broken. Remarkably, the single-plaquette artificial gauge flux leads to the topological Wannier cycles that emerge essentially due to the cyclic transformation of the Wannier orbitals composing the energy bands. Topological Wannier cycles are cyclic spectral flows that may appear in single or multiple band gaps when the single-plaquette gauge flux is acting on the Wannier orbitals. Therefore, in real space topological Wannier cycles probe the location of the Wannier orbitals and distinguish various higher-order topological phases. In finite systems, topological Wannier cycles probe the filling anomaly and fractional corner charges which are the two key features of higher-order topological insulators. Finally, we illustrate how such scenario can be implemented in phononic systems in sonic crystals via step screw dislocations.

Introduction

The discovery of higher-order topological insulators (HOTIs) generalizes the celebrated bulk-edge correspondence [1, 2] to various multidimensional bulk-boundary correspondences
such as the bulk-edge-corner correspondence. For instance, in two-dimensional (2D) HOTIs, the emergence of zero-dimensional (0D) corner states in the bulk band gap is often used as a spectral signature of the multidimensional topological physics and the higher-order topology. Such a phenomenon, though convenient for experimental measurements [12-33], however, has deficiencies. Due to chiral symmetry breaking in most materials, the frequencies of the corner states are not pinned to the middle of the bulk band gap. Under certain situations, these corner states can even be tuned out of the bulk band gap and merge into the bulk bands [34]. In these situations, the spectral probe of the higher-order topology becomes impossible, making the detection of the higher-order topology relying on the detection of the fractional corner charges [11, 35] which are much more difficult to measure in experiments.

Here, we propose a way to create a highly localized, single-plaquette artificial gauge flux $\Phi$ that embraces the full gauge phase range of $0$ to $2\pi$ and argue that such an artificial gauge flux can be a powerful tool to probe the higher-order band topology. Most importantly, the local gauge flux induces topological Wannier cycles in HOTIs that are Wannier representable [10, 11, 36, 37] (i.e., having well-defined Wannier centers). This emergent effect, which is the center of this paper, is due to the cyclic evolution of the Wannier orbitals at the same Wyckoff position but of different symmetries. These Wannier orbitals compose the energy bands above and below the band gaps. Topological Wannier cycles are manifested as the cyclic spectral flows that traverse one or multiple band gaps when the single-plaquette gauge flux encloses the Wannier centers and acts on the Wannier orbitals. These spectral flows evolve from bulk states at $\Phi = 0$ and $\Phi = 2\pi$, and gradually become localized states bound to the local gauge flux in the bulk band gaps. Topological Wannier cycles are protected by the crystalline and time-reversal symmetries and are dictated by the real-space topological invariants (RSTIs) [10, 38]. The RSTIs connect the filling anomaly of the bulk bands with the topological Wannier cycles. Since the filling anomaly dictates the fractional corner charges [11], our study thus establishes topological Wannier cycles as a topologically protected, gapless spectral signature of 2D HOTIs. Finally, we demonstrate the above principles using designed sonic crystals with step screw dislocations where topological Wannier cycles are confirmed by numerical simulations.

**HOTIs with various symmetry**

Let us revisit two prototype models of HOTIs that are defined for spinless particles on lattices with four-fold ($C_4$) and three-fold ($C_3$) rotation symmetry. These tight-binding models are
introduced in Fig. 1. Specifically, a 2D Su-Schrieffer-Heeger (SSH) model realizes the HOTI with $C_4$ rotation symmetry [Fig. 1(a)], while a breathing kagome model realizes the HOTI with $C_3$ rotation symmetry [Fig. 1(b)].

![Fig. 1](image)

Fig. 1 | (Color online) (a) and (b) Schematic illustrations of the 2D SSH model with $C_4$ symmetry and the 2D breathing kagome lattice with $C_3$ symmetry. (c) and (d) Band structures and symmetry properties of the bands for the models in (a) and (b), separately. For each panel, the left figure indicates the trivial phase while the right figure indicates the topological phase. Insets illustrate the location of the Wannier centers in a unit-cell. Symbols represent the little group representations at the high-symmetry points of the Brillouin zone. Symbols in colored circles are used to highlight the different symmetry properties between the trivial and topological phases. The tight-binding parameters are listed on top of each figure.

We first give the energy bands and their properties for these tight-binding models in both the topological and the trivial phases. The Wannier orbitals of these energy bands are illustrated in Fig. 2. As shown in Fig. 1(c), the 2D SSH model has four bands separated by two energy gaps. These energy bands are composed of Wannier orbitals with different $C_4$-rotation eigenvalues, $g_n^{(4)} = e^{\frac{in2\pi}{4}}$ ($n = 0, 1, 2, 3$) [see Fig. 2(a)]. These Wannier orbitals are the $s, p_x + ip_y, d_{xy},$ and $p_x - ip_y$ like orbitals. In the trivial phase, all the Wannier centers (i.e., the center of the Wannier orbitals) locate at the unit-cell center. In contrast, in the topological phase, all the Wannier centers locate at the corners of the unit-cell. The trivial phase is realized when the intra-unit-cell coupling $t_1$ is stronger than the inter-unit-cell coupling $t_2$, while the topological phase is realized when the inter-unit-cell coupling $t_2$ is stronger than the intra-unit-cell coupling $t_1$. 
Similarly, for the breathing kagome model, if the inter-unit-cell coupling \( t_2 \) is stronger than the intra-unit-cell coupling \( t_1 \), the system is in the topological phase and the Wannier centers are at the corners of the unit-cell. Reversing the inter-unit-cell and the intra-unit-cell couplings leads to the trivial phase where the Wannier centers are at the unit-cell center. There are three bands in the model with one band below the energy gap and two bands above it. These bands originate from three Wannier orbitals with different \( C_3 \)-eigenvalues, \( \varrho_n^{(3)} = e^{in2\pi/3} (n = 0, 1, 2) \) [see Fig. 2(b)].

![Fig. 2](Color online) Wannier orbitals in the 2D SSH model (a) and the breathing kagome lattice model (b). The phase differences between adjacent petals indicate the rotation symmetries.

**Single-plaquette artificial gauge flux**

We now create the single-plaquette artificial gauge flux from three consecutive procedures. These procedures are illustrated in Fig. 3(a). The first procedure is dimension extension. For instance, the 2D SSH model is stacked along the \( z \)-direction periodically to extend the system from a 2D model to a three-dimensional (3D) model. Similarly, the breathing kagome model is extended to a 3D model. Note that here the coupling in the \( z \)-direction is not essential. We, in fact, consider the limit that the coupling along the \( z \)-direction vanishes. We then create a step screw dislocation at the center of these dimension-extended systems. We specifically consider systems that are finite in the original dimensions but periodic in the \( z \)-direction. For instance, we create a step screw dislocation at the center of the dimension-extended 2D SSH model that is finite in the \( x \)- and \( y \)-directions but periodic in the \( z \)-direction. Here, the step screw dislocation consists of four flat sectors (“steps”). But the couplings between the adjacent sectors are tilted in such a way that these flat steps form a screw dislocation with a clear chirality. Specifically, in our calculations, the system has \( 4N^2 \) unit-cells (with \( N = 10 \)) in the \( x-y \) plane where the dislocation core is at the center of this plane [see Fig. 3(b)]. Therefore, each sector has \( N^2 \) unit-cells. Such a designed system has an emergent screw symmetry \( S_{1z} = C_4 \ast L_z (\frac{1}{4}) \) with
$L_z(\frac{1}{4}) = z \rightarrow z + \frac{1}{4}$ (we set the lattice constants along all directions as unit for the tight-binding models in this work) which play a pivotal role in the emergent physics.

Similarly, we can create a step screw dislocation in the dimension-extended kagome model that is finite in the $x$-$y$ plane and periodic in the $z$-direction [see Fig. 3(c)]. The system then has an emergent screw symmetry $S_{3z} = C_3 \ast L_z(\frac{1}{3})$.

After the dimension extension and the creation of the dislocations, we now employ the dimensional reduction procedure. Dimensional reduction [39] is a tool to map higher dimensional physics into lower dimensional physics which is widely used in the study of topological physics. Here, this procedure is achieved by the Fourier transformation along the $z$-direction. After the Fourier transformation, the dimension along the $z$-direction becomes a system with parameter $k_z$ and thus leads to the reduction of dimension by one.

Fig. 3 | (Color online) (a) Schematic illustration of the three consecutive procedures that are used to create the artificial gauge flux: dimension extension, creating a step screw dislocation and dimensional reduction.
(b) and (c) Realization of the single-plaquette artificial gauge flux insertion in the 2D SSH model (b) and the breathing kagome model (c) via the three consecutive procedures. The resultant effective models after these procedures are presented in (d) and (e), separately. The artificial gauge fields are reflected by the couplings with arrows: hopping along the arrow pick up a gauge phase term of $e^{i\Phi/4}$ with $\Phi = k_z$. The effective models after the three consecutive procedures are given in Figs. 3(d) and (e). Due to the step screw dislocation. Due to the Fourier transformation along the $z$-direction, each tilted coupling between the adjacent sectors will pick up a gauge phase factor $e^{i\theta}$ along the arrows indicated in Figs. Figs. 3(d) and (e). This gauge phase is $\theta = \frac{k_x}{4}$ or $\frac{k_x}{3}$, separately for the 2D SSH model and the breathing kagome model. With the gauge phase configurations illustrated in Figs. 3(d) and (e), highly localized artificial gauge flux confined in a single-plaquette, $\Phi = k_z \in [0, 2\pi]$ (note that in this work, we abbreviate the gauge flux as a phase which is adequate to capture the essential physics in the systems studied), emerge at the center of the system for the two models discussed above.

**Topological Wannier cycles induced by the local gauge flux**

We now show that the single-plaquette artificial gauge flux can lead to the topological Wannier cycles. The key here is to understand the cyclic transformation of the Wannier orbitals under the local gauge flux insertion. For instance, for the 2D SSH model, the four bands are made of four Wannier orbitals with the $C_4$-rotation eigenvalues, $g^{(4)}_n = e^{in\pi/4}$ ($n = 0, 1, 2, 3$). With a finite gauge flux, these Wannier orbitals now have the $C_4$-rotation eigenvalues, $e^{i(n(2\pi/4) + \Phi/4)}$. This change can also be understood by replace the $C_4$ rotation to the $S_{4z}$ rotation in the structure with a step screw dislocation. Since $S_{4z} = C_4 \ast L_z(\frac{1}{4})$, the $C_4$-eigenstates at $k_z$ pick up an additional phase, $e^{i\phi/4} = e^{i\Phi/4}$, due to the translation along the $z$-direction $L_z(\frac{1}{4})$. With a $\Phi = 2\pi$ gauge flux, the rotation eigenvalues transform as, $g^{(4)}_n \rightarrow g^{(4)}_{n+1}$. Because $n = 0,1,2,3$ is a modulo 4 quantity, such transformation forms a closed cycle, $g^{(4)}_0 \rightarrow g^{(4)}_1 \rightarrow g^{(4)}_2 \rightarrow g^{(4)}_3 \rightarrow g^{(4)}_0$.

The above picture is consolidated in the molecule limit of the 2D SSH model. It is known that the 2D SSH model is adiabatically equivalent to a molecule limit where the intra-unit-cell coupling is set to zero, $t_1 = 0$ [see Fig. 4(a)]. In this limit, the energy bands become flat, yet the topological properties remain the same as the topological phase shown in Fig. 1. The flat bands also imply that the Bloch states are made of isolated Wannier orbitals (molecular orbitals...
in the plaquettes comprised of the $t_2$ couplings. Imposing the artificial gauge fields induced by the procedures in Fig. 3, one obtains a simple model in Fig. 4(a). In this model, the artificial gauge flux acts only on the Wannier orbitals in the central plaquette. There are four such Wannier orbitals that transform cyclically, $g_0^{(4)} \rightarrow g_1^{(4)} \rightarrow g_2^{(4)} \rightarrow g_3^{(4)} \rightarrow g_0^{(4)}$, when a $\Phi = 2\pi$ gauge flux is inserted in the central plaquette. Since each Wannier orbital comprises and represents a bulk band, the cyclic transformation among the Wannier orbitals leads to a cyclic spectral flow among the bulk bands [see Fig. 4(c)], which is exactly the topological Wannier cycles. In contrast if the system is trivial, i.e., $t_1 = -1$ and $t_2 = 0$, then the Wannier orbitals live on the plaquettes that do not carry any gauge flux, and the inserted gauge flux thus has no effect on the spectrum [see Figs. 4(d)-(f)].

![Image](image.png)

Fig. 4 | (Color online) Emergence and disappearance of the topological Wannier cycles in the molecule limit of the 2D SSH model. (a)-(c) the topological phase. (d)-(f) the trivial phase. (a): Illustration of the tight-binding model in the molecule limit with $t_1 = -1$ and $t_2 = 0$. The artificial gauge fields are reflected by the couplings with arrows: hopping along the arrow pick up a gauge phase term of $e^{2\pi i / N}$ with $\Phi = k_x$, according to Fig. 3(d). (b): Band structure of the model in (a) without the artificial gauge fields. (c): Energy spectrum of the model in (a) with the artificial gauge fields as a function of $k_x$ for a finite system with $N = 10$. The orange curves represent the spectral flows between the bulk bands which are manifested as the localized states on the central plaquette (see inset for the wavefunction of an in-gap state where the wavefunction is fully localized on the central plaquette.). (d): Illustration of the tight-binding model in the molecule limit with $t_1 = 0$ and $t_2 = -1$. The artificial gauge fields have no effect here since they are associated with $t_2$ as illustrated in Fig. 3(e). (e): Band structure of the model in (d) without the artificial gauge fields. (f): Energy
spectrum of the model in (d) with the artificial gauge fields as a function of \( k_z \) for a finite system with \( N = 10 \).

The Aharonov-Bohm principle [40] states that essentially the gauge flux induces a change in the phase of the wavefunctions. Normally, inserting a gauge flux \( \Phi = 2\pi \) has no physical effect, since the phase \( 2\pi \) is equivalent to the phase 0. However, in topological systems, inserting a gauge flux \( \Phi = 2\pi \) can lead to nontrivial effects. The topological Wannier cycle is one of the nontrivial effects that can emerge in topological crystalline systems.

We now analyze the filling anomaly of the 2D SSH tight-binding model. Note that the former has chiral symmetry, while the latter does not. We will show that this difference has some consequences in the spectrum but does not affect the emergence or disappearance of the topological Wannier cycles. Consider a square, finite 2D system with \( 2N \times 2N \) unit-cells without the artificial gauge flux. Such a finite system has the \( C_4 \) rotation symmetry, while the lattice translation symmetry is broken. In the trivial case, because the Wannier orbitals are at the unit-cell center, there are \( 4N^2 \) bulk states in each bulk band.

In the topological case, because the Wannier orbitals are at the 1\( b \) Wyckoff position (i.e., the unit-cell corner), the situation is quite different. We find that there are \( 4(2N - 1) \) edge states in each band gap. In addition, there are four corner states pinned to zero energy due to the higher-order topology and the chiral symmetry. Most importantly, there are \( 4(N^2 - N) + 1 \) states in each bulk band. This number of bulk states is a consequence of the band topology and has several highly nontrivial features. First, it predicts a fractional corner charge. Since the finite system is \( C_4 \) symmetric, each quarter sector then has \( (N^2 - N) + 1/4 \) states. Therefore, filling the bulk bands below the first (second) gap leads to a fractional corner charge of \( e/4 \) (or \(-3e/4\), if we consider the fractional corner charge as a modulo 1 quantity), where \( e \) is the electron charge. Note that because the numbers of the edge and corner states are both integer multiples of four, filling the edge and corner states do not lead to any fractional corner charge. Second, the number of bulk states also dictates the topological Wannier cycles. Because when a \( \Phi = 2\pi \) gauge flux is inserted into the central plaquette, the eigenstates transform cyclically, \( g_0^{(4)} \rightarrow g_1^{(4)} \rightarrow g_2^{(4)} \rightarrow g_3^{(4)} \rightarrow g_0^{(4)} \), as illustrated in Fig. 5(a). This cyclic transformation must be completed within a group of four eigenstates. However, the number of bulk states in each bulk band, \( 4(N^2 - N) + 1 \), is not an integer multiple of four. Therefore, the cyclic transformation of eigenstates cannot be fulfilled within each bulk band. Consequently, there must be a cyclic transformation of eigenstates among different bulk bands across the band.
gaps, which is just the emergent topological Wannier cycles shown in Fig. 5(c) [also depicted in the right panel of Fig. 5(a)]. The energy spectrum in Fig. 5(d) is obtained from the calculation based on the tight-binding model in Fig. 3(e). It is seen that the edge states appear in both band gaps, yet they do not evolve with the inserted gauge flux and have nothing to do with the spectral flows and the topological Wannier cycles. We emphasize that since the numbers of the edge and corner states are both integer multiples of four, whether these states are filled or not does not change the above reasoning.

![Figure 5](image)

Figure 5 | (Color online) Topological Wannier cycles in the 2D SSH and breathing kagome models. (a) and (b): Schematic illustration of the transformation of the eigenstates due to the single-plaquette gauge flux insertion $\Phi = k_z$. The eigenstates are labeled by either the $C_4$ eigenvalues $g_n^{(4)} = e^{i\pi n/2}$ with $n = 0, \pm 1, 2$ for (a) the 2D SSH model, or the $C_3$ eigenvalues $g_n^{(3)} = e^{i\pi n/3}$ with $n = 0, \pm 1$ for (b) the breathing kagome model. The symmetry eigenvalues of the eigenstates evolve cyclically when $\Phi$ goes from 0 to $2\pi$. The right panels give the schematic illustrations of the emergent cyclic spectral flows across the band gaps induced by the local gauge flux insertion. (c) and (d): The energy spectra of the tight-binding models as functions of the artificial gauge flux $\Phi = k_z$ for the finite systems in Fig. 3(d) with $N = 10$ and in Fig. 3(e) with $N = 4$. The grey and green regions denote the bulk and edge states, respectively. The orange curves with red arrows represent the spectral flows between the bulk bands. The blue line in (d) denotes the corner states. Both the edge and corner states have nothing to do with the spectral flows across the band gaps, i.e., the topological Wannier cycles.

Closer examination of the spectral flows indicates that at $\Phi = 0$ the system returns to the 2D SSH model. The spectral flows start from the bulk states in the $\Phi = 0$ limit and evolve
gradually into the localized states bound to the artificial gauge flux at the central plaquette. At $\Phi = \pi$, two time-reversal symmetric topological boundary states become degenerate. This degeneracy is dictated by, $\theta_z^2 = -1$ with $\theta_z = S_{2z}^2 * T$ ($T$ is the time-reversal operator), and thus is protected by the screw rotation symmetry and the time-reversal symmetry. At $\Phi = 2\pi$, each spectral flow ends at a bulk band that is different from the original bulk band it starts from. The cyclical spectral flows perfectly satisfy the periodicity as $\Phi = k_z$ goes from $0$ to $2\pi$, yet with the connections determined by the bulk invariants (see analysis below), they manifest the nontrivial topological spectral evolutions across the band gaps.

The above analysis shows that the number of eigenstates in each bulk band is a crucial indicator of the higher-order band topology. More precisely, the number of eigenstates modulo four for all the bulk bands below the concerned band gap is the true indicator. We now connect this indicator with the bulk topological invariants which are called as the real-space topological invariants (RSTIs). The theory of RSTIs is proposed and developed in Refs. [10, 38]. The RSTIs are good quantum numbers in real space that connect to the symmetry indicators of the Bloch bands [36] and the topological invariants (such as the Chern and $Z_2$ numbers) related to the symmetry indicators [38]. For a finite $C_4$-symmetric 2D system, the eigenstates have four irreducible representations (IRs), i.e., $A, 2E, 1E$ and $B$, corresponding to the four $C_4$ rotation eigenvalues $g_n^{(4)} = e^{i\pi n^2/4}$ with $n = 0, \pm 1$ and $2$ mod $4$, separately. The RSTIs are defined as the following three integer invariants

$$\delta_1, \delta_2, \delta_3 = (m(g_{-1}) - m(g_0), m(g_2) - m(g_0), m(g_1) - m(g_0)).$$

(1)

Here, $m(g_n)$ denotes the multiplicity of the eigenstates with $C_4$ eigenvalue $g_n$ for the finite system. Note that $\delta_3$ is equal to $\delta_1$ in the presence of time-reversal symmetry. Interestingly, although the above definition is based on finite systems, the RSTIs can be deduced from the symmetry indicators of the Bloch bands below the concerned band gap at the high-symmetry points (HSPs) in the Brillouin zone [38]. In our $C_4$-symmetric system, the RSTIs are calculated as follows [38],

$$\delta_1 = -\frac{1}{4} m(A_R) + \frac{1}{4} m(2E_R) + \frac{1}{2} m(B_R) - \frac{1}{4} m(A_M) - \frac{3}{4} m(2E_M) - \frac{1}{2} m(B_M) + \frac{1}{2} m(A_X),$$

$$\delta_2 = -\frac{1}{2} m(A_R) + \frac{1}{2} m(2E_R) + \frac{1}{2} m(A_M) - \frac{1}{2} m(2E_M),$$

$$\delta_3 = -\frac{3}{4} m(A_R) - \frac{1}{4} m(2E_R) - \frac{1}{2} m(B_R) + \frac{1}{4} m(A_M) - \frac{1}{4} m(2E_M) + \frac{1}{2} m(B_M) + \frac{1}{2} m(A_X).$$

(2)

Here, the symbols in the bracket represent the IRs at the HSPs in the Brillouin zone (the HSPs are the $\Gamma$, $M$, and $X$ points which are represented by the subscripts). The $m$’s denote the
multiplicity of the IRs below the band gap. For instance, \( m(A_r) \) denotes the multiplicity of the IR \( A \) at the \( \Gamma \) point. Based on the IRs labeled at the HSPs in Fig. 1c, the RSTIs of the first and second band gaps are, separately, \((-1, -1, -1)\) and \((0, -1, 0)\) for the topological case. In contrast, for the trivial case, both the first and the second band gaps have the RSTIs \((0,0,0)\).

Using the above RSTIs, we find that, for the process with \( \Phi = k_z \) varying from 0 to \( 2\pi \), the imbalance of the bulk eigenstates is given by \( \Delta(g_0) = m(g_{-1}) - m(g_0) = \delta_1 = -1 \), \( \Delta(g_2) = m(g_1) - m(g_2) = \delta_1 - \delta_2 = 0 \), \( \Delta(g_{-1}) = m(g_2) - m(g_{-1}) = \delta_2 - \delta_1 = 0 \) and \( \Delta(g_1) = m(g_0) - m(g_1) = -\delta_1 = 1 \) for the first band gap. This implies that there is one excess bulk state with the IR \( A \) below the first band gap and one excess bulk state with the IR \( ^2E \) above the gap. Here, the signs \( \pm \) denote whether the excess bulk state is above or below the concerned band gap.

For the second band gap, we find that \( \Delta(g_0) = \delta_1 = 0 \), \( \Delta(g_2) = \delta_1 - \delta_2 = 1 \), \( \Delta(g_{-1}) = \delta_2 - \delta_1 = -1 \) and \( \Delta(g_1) = -\delta_1 = 0 \). This predicts that there is one excess bulk state with the IR \( B \) above the second band gap and one excess bulk state with the IR \( ^1E \) below the gap. The emergent topological Wannier cycles are due to the cyclic transformation of these excess bulk states that cannot find their partners within the bulk bands they belonged to. The resultant spectral flows across the first and second band gaps are presented in Fig 5(d).

We now turn to the analysis of the breathing kagome system. First, the insertion of the artificial gauge flux changes the \( C_3 \) eigenvalues of the eigenstates from \( g_n^{(3)} = e^{i[n(\frac{2\pi}{3})]} \) to \( e^{i[n(\frac{2\pi}{3})+\Phi]/3} \) with \( n = 0,1,2 \mod 3 \). This change can be understood as when the \( C_3 \) rotation is replaced by the \( S_{32} \) rotation in the structure with a step screw dislocation. The translation along the \( z \)-direction \( L_z^{(\frac{1}{3})} \) leads to the additional phase, \( e^{ikz/3} = e^{i\Phi/3} \). At \( \Phi = 2\pi \) (i.e., with the gauge flux insertion of \( 2\pi \)), the \( C_3 \) eigenvalues transform cyclically, \( g_0^{(3)} \rightarrow g_1^{(3)} \rightarrow g_2^{(3)} \rightarrow g_0^{(3)} \), which is one of the key mechanisms that drives the emergence of the topological Wannier cycles in the breathing kagome model.

In the topological case, there are \( \frac{9N(N-1)}{2} + 1 \) bulk eigenstates in the first bulk band in a finite system with \( 3N(3N-1)/2 \) unit-cells. Besides, there are \( 9(N-1) \) edge states and three corner states in the bulk band gap. If one divides the finite system into three sectors that are connected by the \( C_3 \) rotations, then a fractional corner charge of \( e/3 \) emerges at each sector because the filling of the first bulk band yields \( \frac{3N(N-1)}{2} + \frac{1}{3} \) bulk states in each sector. Because
the numbers of the edge and corner states are both integer multiples of three, these states cannot change the fractional corner charge—no matter whether they are filled or empty.

Connected with the above filling anomaly and fractional corner charge, which are two key features of the higher-order topological phase in the breathing kagome lattice, the strange number of bulk states also leads to the topological Wannier cycles, if the artificial gauge flux is inserted into the central plaquette. Due to the filling anomaly, there is one bulk state below the gap which cannot find its partner in the first bulk band to fulfill the cyclic transformation illustrated in Fig. 5(b), \( g_0^{(3)} \rightarrow g_1^{(3)} \rightarrow g_2^{(3)} \rightarrow g_0^{(3)} \). Simultaneously, there are two bulk states above the gap which cannot find their partner as well. These excess bulk states transform cyclically across the band gap, which leads to the emergence of the topological Wannier cycles as depicted in Fig. 5(b) and shown explicitly in Fig. 5(d) from the calculation based on the tight-binding model in Fig. 3(c). Again, we notice that the edge and corner states do not evolve with the inserted gauge flux and have nothing to do with the topological Wannier cycles.

The RSTIs for the breathing kagome lattice are elaborated below. The eigenstates of a finite 2D system with \( C_3 \) rotation symmetry have three IRs, \( A, 2E \) and \( 1E \), corresponding to the three \( C_3 \) rotation eigenvalues \( g_n^{(3)} = e^{in(2\pi/3)} \) with \( n = 0 \) and \( \pm 1 \) mod 3. The RSTIs are then defined as [38]

\[
(\delta_1, \delta_2) = (m(g_{-1}) - m(g_0), m(g_1) - m(g_0)).
\]

Here, \( \delta_2 \) is equal to \( \delta_1 \) in the presence of time-reversal symmetry. Analogous to the above \( C_4 \)-symmetric case, the RSTIs can be calculated from the symmetry indicators in momentum space as follows [38],

\[
\delta_1 = \frac{2}{3} m(2E_F) + \frac{1}{3} m(1E_F) - m(A_K) - m(2E_K),
\]

\[
\delta_2 = \frac{1}{3} m(2E_F) + \frac{2}{3} m(1E_F) - m(2E_K).
\]

Based on the IRs labeled at the HSPs in Fig. 1(d), the RSTIs of the band gaps are calculated as \((-1, -1) \) and \((0, 0) \) for the topological and trivial cases, respectively.

Using the above RSTIs, we find that, for the process with \( \Phi = k_z \) varying from 0 to \( 2\pi \), the imbalance of the bulk eigenstates in the topological case is given by \( \Delta(g_0) = m(g_{-1}) - m(g_0) = \delta_1 = -1 \), \( \Delta(g_1) = m(g_0) - m(g_1) = -\delta_2 = 1 \) and \( \Delta(g_{-1}) = m(g_1) - m(g_{-1}) = \delta_2 - \delta_1 = 0 \). This implies that there is one excess bulk state with the IR \( A \) below the band gap and two excess bulk states with the IRs \( 2E \) and \( 1E \) above the band gap. The nonzero \( \Delta(g_0) \) and \( \Delta(g_1) \) account for the cyclic transformation of excess bulk states across the band gap. The resultant spectral flows are presented in Fig 5(d). \( \Delta(g_{-1}) = 0 \) indicates the
transformation between the excess bulk states with IRs $^{2}E$ and $^{1}E$ is within the bulk continuum above the band gap.

**Realizations in phononic systems via sonic crystals**

We now present the phononic realization of the above studied models. The phononic models are realized by connected acoustic resonators in the 2D SSH and breathing kagome lattices. In each model, a site is realized by an acoustic resonator which is a cylindrical cavity, while the couplings between the sites are realized by the tubes connecting them. In our setup, the strength of a coupling between two resonators is controlled by the diameter of the tube connecting them. Specifically, we use tubes of the diameter $d_1 = 0.1a$ ($d_2 = 0.2a$) to realize the intra-unit-cell (inter-unit-cell) couplings where $a$ is the lattice constant.

![Figure 6](image)

Figure 6 | (Color online) Phononic realization of the artificial gauge flux insertion in a single plaquette and topological Wannier cycles. (a) and (b): The designed sonic crystal structures for (a) the 2D SSH model and (b) the breathing kagome model when the procedures in Fig. 3(a) are applied. Inset shows that a site is realized by a cylindrical acoustic resonator with the diameter $D$ and the height $h$, while the intra- and inter-unit-cell couplings are realized by the tubes of diameters $d_1$ and $d_2$, respectively. The red tubes denote the slanted couplings between the adjacent sectors. The periodicity along the $z$-direction is $H$. (c) and (d) The corresponding phononic spectra as functions of $\Phi = k_z H$ for the structures in (a) with $N = 4$ and in (b) with $N = 6$. The grey region denotes the bulk states. The orange curves represent the spectral
flows across the band gaps. Each inset shows the phononic wavefunction of an in-gap state (blue square) that are localized around the local gauge flux at the central plaquette.

We simulate the phononic system using the commercial software COMSOL Multiphysics. The calculated spectra in unit of the frequency $v/a$ ($v$ is the sound velocity in air) as functions of the inserted single-plaquette artificial gauge flux for the 2D SSH and the breathing kagome models with a step screw dislocation are presented in Fig. 6. The results confirm the emergence of the topological Wannier cycles in realistic materials which are confirmed in a recent experimental study [41]. In fact, these numerical results are even more encouraging: Due to the absence of the chiral symmetry in these phononic systems, the edge and corner states disappear in the phononic realization of the 2D SSH model. However, even in this situation, the topological Wannier cycle still emerges and can thus serve as a reliable experimental signature of higher-order band topology and the filling anomaly. In fact, the breaking of the chiral symmetry is common in higher-order topological materials. Such an effect imposes challenges for experimental detection of the higher-order band topology. The topological Wannier cycle then serves as an unprecedented way to solve such a problem.

**Conclusion and outlook**

We propose a mechanism for realizing single-plaquette artificial gauge flux via the procedures involving dimension extension, introducing a step screw dislocation and dimensional reduction. Through such highly localized artificial gauge flux, we show that a cyclic transformation of the eigenstates in finite systems can be induced. When the lattice system is in the higher-order topological phases that are Wannier representable, such artificial gauge flux insertion leads to emergent topological Wannier cycles that are manifested as cyclic spectral flows across the band gaps. These gapless spectral flows are revealed to be gapless topological boundary states propagating along the z-direction and bound to the single-plaquette gauge flux. By designing sonic crystal systems as higher-order topological insulators for phonons, we show that the topological Wannier cycles can serve as robust, gapless spectral features for the experimental identification of higher-order topological phases, even when the chiral symmetry is broken. Our work reveals an unprecedented topological phenomenon and a regime for the creation of highly localized artificial gauge flux that has not been reached before. Such single-plaquette artificial gauge flux can be valuable in the manipulation of phononic, photonic and electronic waves as well as in the realization of exotic topological phases.
