Abstract. We discuss the power of third-generation gravitational wave detectors to constrain cosmographic parameters in the case of electromagnetically bright standard sirens focusing on the specific case of the Einstein Telescope. We analyze the impact that the redshift source distribution, the number of detections and the observational error in the luminosity distance have on the inference of the first cosmographic parameters, and show that with a few hundreds detections the Hubble constant can be recovered at sub-percent level whereas the deceleration parameter at a few percent level, both with negligible bias.

1 Introduction

The rising of Gravitational Wave (GW) Astronomy has opened new ways to investigate phenomena not only in astronomy, but also in fundamental physics and cosmology. The large interferometric *second generation* detectors LIGO [1] and Virgo [2] are presently in their *advanced* phase, and they will be joined in the next observation run by KAGRA [3], having already confirmed over 50 detections [4–6]. In the next decade *third-generation* GW detectors, like Einstein Telescope [7] and Cosmic Explorer [8], will join the scientific quest for GWs and detections of coalescing binaries will become a routine in astronomy, being already at the level of $\sim O(1)$ per week with second-generation detectors.

For cosmological applications, GWs from coalescing binaries are an invaluable tool as they are *standard sirens* [9] (see also [10–12]): the intrinsic property of a binary system, like masses and spins, can be inferred from a detailed analysis of the characteristic *chirp* shape of the signal, leading to an unbiased estimation of the luminosity distance, modulo a degeneracy with some geometric orientation angles, which can in principle be disentangled by observation via multiple detectors, see e.g. [13] for explicit simulations. It follows that an outstanding cosmological application of GW detections from coalescing binaries is to measure the distance versus redshift relation, if the redshift of the source is available. On general grounds GW detections cannot measure the redshift of the source, but redshift can be estimated by adding extra information, like host galaxy identification via electromagnetic counterpart, as it happened for the GW170817 detected jointly with the short GRB 170817A and the optical transient AT 2017gfo [14], or cross-correlating galaxy catalogs with GW sky localization [9, 15, 16]. Other possibilities to fold in redshift information have been investigated using e.g. tidal effects which can break the gravitational mass-redshift degeneracy [17], the astrophysical mass-gap [18] in solar mass black holes, as done in [19–22], or the prior knowledge of source redshift distributions [23, 24].

In this work we focus on the case in which the host galaxy is identified via an electromagnetic counterpart, so that redshift can be measured with negligible error, while the luminosity distance is measured gravitationally, aiming at determining the luminosity distance versus redshift relation in a model-independent way, i.e. without relying in a specific background cosmological model, adopting the *cosmography* approach [25]. We thus investigate how well

the time derivatives of the cosmological scale factor can be determined using the information that electromagnetically bright GW standard sirens will reveal with third-generation detectors, expected to be operating in the next decade.

The paper is organized as follows: in Sec. 2 we briefly review the cosmographic expansion whereas the simulated data used in the statistical analysis are detailed in Sec. 3. The main results of the paper are presented and discussed in Sec. 4. Sec. 5 presents the main conclusions that can be drawn from our analysis.

2 The cosmographic expansion

Let us consider the flat Friedmann-Lemaître-Robertson-Walker metric ($c = 1$)

$$ds^2 = -dt^2 + a^2(t) [dr^2 + r^2(d\theta^2 + \sin^2\theta d\phi^2)] , \quad (2.1)$$

where $a(t)$ is the scale factor. One can Taylor-expand its time dependence

$$a(t) = a_0 \left\{ 1 + H_0(t - t_0) - \frac{1}{2}q_0[H_0(t - t_0)]^2 + \frac{1}{6}j_0[H_0(t - t_0)]^3 + \frac{1}{24}s_0[H_0(t - t_0)]^4 + \frac{1}{120}l_0[H_0(t - t_0)]^5 + O(6) \right\} , \quad (2.2)$$

where H_0 is the Hubble constant, $a_0 \equiv a(t_0)$ being t_0 the present time, and the remaining constants appearing in the expansion have been conveniently expressed as

$$\begin{aligned} q_0 &= -\frac{1}{H_0^2} \left(\frac{1}{a} \frac{d^2 a}{dt^2} \right) \Big|_{t=t_0} , & j_0 &= \frac{1}{H_0^3} \left(\frac{1}{a} \frac{d^3 a}{dt^3} \right) \Big|_{t=t_0} , \\ s_0 &= \frac{1}{H_0^4} \left(\frac{1}{a} \frac{d^4 a}{dt^4} \right) \Big|_{t=t_0} , & l_0 &= \frac{1}{H_0^5} \left(\frac{1}{a} \frac{d^5 a}{dt^5} \right) \Big|_{t=t_0} , \end{aligned} \quad (2.3)$$

where $H \equiv a^{-1} da/dt$. The parameters q_0, j_0, s_0, l_0 are called respectively *deceleration*, *jerk*, *snip* and *lerk* parameters [26–29]. From these equations we can also obtain [30]

$$\begin{aligned} H(z) &= H_0 \left\{ 1 + (1 + q_0)z + \frac{1}{2}(j_0 - q_0^2)z^2 + \frac{1}{6}[3q_0^2 + 3q_0^3 - 4q_0j_0 - 3j_0 - s_0]z^3 + \right. \\ &+ \left. \frac{1}{24}(-12q_0^2 - 24q_0^3 - 15q_0^4 + 32q_0j_0 + 25q_0^2j_0 + 7q_0s_0 + 12j_0 - 4j_0^2 + 8s_0 + l_0)z^4 + O(z^5) \right\} \end{aligned} \quad (2.4)$$

where $1 + z \equiv 1/a(t)$. To make contact with observations it is useful to define the luminosity distance expression

$$d_L(z) = (1 + z) \int_0^z \frac{dz'}{H(z')} , \quad (2.5)$$

which, in terms of the cosmographic parameters Eq. (2.4), can be expressed as

$$\begin{aligned}
d_L(z) = & \frac{1}{H_0} \left[z + z^2 \left(\frac{1}{2} - \frac{q_0}{2} \right) + z^3 \left(-\frac{1}{6} - \frac{j_0}{6} + \frac{q_0}{6} + \frac{q_0^2}{2} \right) \right. \\
& + z^4 \left(\frac{1}{12} + \frac{5j_0}{24} - \frac{q_0}{12} + \frac{5j_0q_0}{12} - \frac{5q_0^2}{8} - \frac{5q_0^3}{8} + \frac{s_0}{24} \right) + \\
& + z^5 \left(-\frac{1}{20} - \frac{9j_0}{40} + \frac{j_0^2}{12} - \frac{l_0}{120} + \frac{q_0}{20} - \frac{11j_0q_0}{12} + \frac{27q_0^2}{40} - \frac{7j_0q_0^2}{8} + \frac{11q_0^3}{8} + \frac{7q_0^4}{8} - \frac{11s_0}{120} - \frac{q_0s_0}{8} \right) \\
& + z^6 \left(\frac{1}{30} + \frac{7j_0}{30} - \frac{19j_0^2}{72} + \frac{19l_0}{720} + \frac{m_0}{720} - \frac{q_0}{30} + \frac{13j_0q_0}{9} - \frac{7j_0^2q_0}{18} + \frac{7l_0q_0}{240} - \frac{7q_0^2}{10} + \frac{133j_0q_0^2}{48} \right. \\
& \left. - \frac{13q_0^3}{6} + \frac{7j_0q_0^3}{4} - \frac{133q_0^4}{48} - \frac{21q_0^5}{16} + \frac{13s_0}{90} - \frac{7j_0s_0}{144} + \frac{19q_0s_0}{48} + \frac{7q_0^2s_0}{24} \right) + O(z^7) \Big]. \quad (2.6)
\end{aligned}$$

Observation of a set of $\{d_{Li}\}$ and corresponding $\{z_i\}$ data points will enable the determination of the cosmographic parameters, whose accuracy will depend on the quality and range of available data, as we will discuss in the next Section. Note that any finite order truncation of the series (2.6) is badly behaved for $z > 1$. However, as it will be shown, for the range of redshift of interest for the present work, we can safely work with Eq. (2.6).

3 Simulated data

To test the accuracy of the cosmographic expansion applied to GW standard sirens, we set the fiducial model to be the flat Λ CDM cosmology, with the matter density parameter $\Omega_M = 0.311$ and $H_0 = 67.66$ km/sec/Mpc, in agreement with the current Cosmic Microwave Background analysis of [31]. Note that the present controversy on the value of H_0 – with low-redshift determinations in contrast with early-Universe ones by more than 4σ level [32–35] – does not affect our analysis, which aims at quantifying the uncertainties on the cosmographic parameters expected from upcoming joint GW and electromagnetic data.

The cosmographic parameters (up to sixth order) for the Λ CDM model are written as:

$$\begin{aligned}
q_0 &= \frac{3}{2}\Omega_M - 1, \\
j_0 &= 1, \\
s_0 &= 1 - \frac{9}{2}\Omega_M, \\
l_0 &= 1 + 3\Omega_M - \frac{27}{2}\Omega_M^2, \\
m_0 &= 1 - \frac{27}{2}\Omega_M^2 - 81\Omega_M^3 - \frac{81}{2}\Omega_M^4,
\end{aligned} \quad (3.1)$$

whose numerical values for our fiducial model are summarized in Tab. 1.

q_0	j_0	s_0	l_0	m_0
-0.533	1	-0.4	0.627	-9.365

Table 1. Cosmographic parameters in a flat Λ CDM cosmology with $\Omega_M = 0.311$.

As mentioned earlier, the d_L expansion in z converges for $z < 1$ [27]. However, to have a faithful reconstruction of the underlying model with only a handful of terms one needs to restrict the redshift to lower values. In Fig. 1 (left panel) we show the behavior of d_L as

Figure 1. *Left)* The luminosity distance d_L for different orders of the cosmographic series – Eq. (2.6). The black curve represents the fiducial Λ CDM model adopted in the analysis. *Right)* Relative difference between the cosmographic series and the fiducial cosmology. The shadowed horizontal region stands for a difference of 1%, which is reached at $z_{cut} = 0.72$ (vertical dotted line) by the third order series.

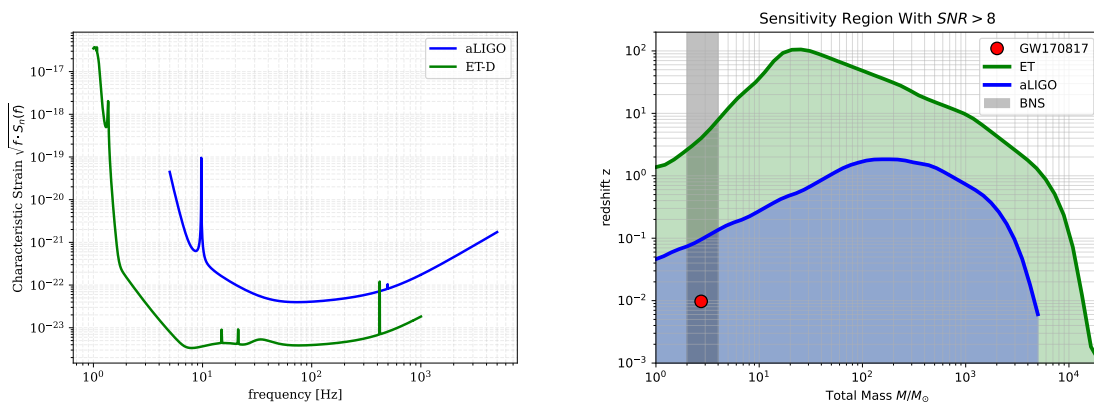

Figure 2. *Left)* Dimensionless strain sensitivity for Advanced LIGO, from “Zero Detuning High Power” spectral noise density implemented in LALSuite [36], and Einstein Telescope, adopting the noise spectral density “D” from [37]. *Right)* Sensitivity region, defined as the distance at which the SNR of Eq. (3.2) is larger than the conventional threshold value 8, for spin-less equal mass systems with optimal orientation with respect to the detector (only the GW dominant mode has been used).

a function of the redshift for different orders of the cosmographic series given in Eq.(2.6). For comparison, our fiducial model is also shown (black curve). The right panel shows the relative difference between the cosmographic series and the fiducial cosmology. As it can be seen, the series truncated at third order deviates less than 1% from the fiducial model in the redshift interval $0 < z < 0.72$, which in turn defines the redshift interval adopted in this work to assess the precision with which one can recover the first three cosmographic parameters.

Figure 3. *Left)* Expected distributions of EM bright GW events detected in coincidence by the Einstein Telescope and future EM observatory Theseus Eq. (3.7) [38] or dictated by (delayed) star formation rate (Eq. 3.6). For comparison, the distribution of presently confirmed events by the LIGO/Virgo/KAGRA collaboration and of the SuperNovae catalog events [39–41] are also reported. *Right)* Error budget of luminosity distance gravitational measure – see Eqs. (3.8) and (3.9).

3.1 Source Distributions

For the simulation of third generation detector observation we focus on the Einstein Telescope [7], whose noise spectral density is report in Fig. (2) together with the advanced LIGO one.

The signal-to-noise ratio SNR of a real-time GW signal $h(t)$ is defined in terms of its Fourier-transform $\tilde{h}(f)$ via¹

$$SNR^2 \equiv 4 \int_0^\infty \frac{|\tilde{h}(f)|^2}{S_n(f)} df, \quad (3.2)$$

where the noise spectral density $S_n(f)$ is defined in terms of the detector noise $\tilde{n}(f)$ averaged over many realizations

$$\langle \tilde{n}(f) \tilde{n}^*(f') \rangle = S_n(f) \delta(f - f'). \quad (3.3)$$

The redshift distribution of coalescing events is largely unknown, hence to make an analysis as comprehensive as possible we follow [42] and produce and analyse mock data corresponding to three astrophysical source distributions to check how they affect the parameter estimation. We thus consider:

1. Detected merger distribution per comoving volume following the star formation rate given in [43]:

$$\psi(z) \propto \frac{(1+z)^{2.7}}{1 + \left(\frac{1+z}{2.9}\right)^{5.6}}, \quad (3.4)$$

2. Merger distribution obtained with a stochastic delay with respect to the star formation rate, the delay being Poisson-distributed with average $\tau = 10$ Gyr, as shown in [44], with a merger rate per unit comoving volume \mathcal{R}_m given by (modulo normalization)

$$\mathcal{R}_m(z_m, \tau) \propto \int_{z_m}^\infty dz_f \frac{dt}{dz_f} \psi(z_f) \exp \left[-\frac{t(z_f) - t(z_m)}{\tau} \right]. \quad (3.5)$$

¹Here, $h(t)$ is the scalar time series representing the projection onto the detector of the two GW polarizations.

Note that in both this and the previous case, the detected merger rate R_m is related to the density merger rate of (3.5) via

$$\begin{aligned} R_m(z, \tau) &\equiv \frac{d^2 N_m}{dt_o dz} = \frac{1}{1+z} \frac{dV_c}{dz} \mathcal{R}_m(z, \tau) \\ &= \frac{4\pi d_L^2(z)}{(1+z)^3 H(z)} \mathcal{R}_m(z, \tau). \end{aligned} \quad (3.6)$$

3. A distribution considering that only close enough events will have a detectable EM counterpart. With a dedicated EM detector like THESEUS [45, 46] it can be represented as shown in Fig. (3) (“EMobs” line) [42]

$$R_{EMobs} \propto \frac{z^3}{1 + \exp(10.6 z^{0.6})}. \quad (3.7)$$

3.2 Luminosity distance uncertainty

Having fixed the source redshift distribution, we now discuss the uncertainties in the luminosity distance measurements by the third generation gravitational wave detector *Einstein Telescope*. The main contributions are given by [47, 48]

$$\frac{\Delta d_L(z)}{d_L(z)} = \left[\left(\frac{\Delta d_L(z)}{d_L(z)} \right)_{ET}^2 + \left(\frac{\Delta d_L(z)}{d_L(z)} \right)_{Lensing}^2 + \left(\frac{\Delta d_L(z)}{d_L(z)} \right)_{v_{pec}}^2 \right]^{1/2}, \quad (3.8)$$

with

$$\begin{aligned} \left(\frac{\Delta d_L(z)}{d_L(z)} \right)_{ET} &\approx 0.1449z - 0.0118z^2 + 0.0012z^3, \\ \left(\frac{\Delta d_L(z)}{d_L(z)} \right)_{Lensing} &\approx 0.066 \left[4 \left(1 - (1+z)^{-1/4} \right) \right]^{1.8}, \\ \left(\frac{\Delta d_L(z)}{d_L(z)} \right)_{v_{pec}} &\approx \left| 1 - \frac{(1+z)^2}{H(z)d_L(z)} \right| \frac{\sigma_v}{c}, \quad \sigma_v = 331 \text{ km/s}, \end{aligned} \quad (3.9)$$

where the error budget has been divided respectively into instrumental, lensing and peculiar velocity contributions. As the systematic errors due peculiar velocities of galaxies are important only for $z \lesssim 0.1$, they do not play an important role in this work. In Fig. (4), we show the simulated data of $d_L(z)$ using the EMobs distribution given by Eq. (3.7). The red curve represents the fiducial model used in the simulation whereas the light blue and dark blue regions stand respectively for 1- and 2- σ error band, being σ the quantity Δd_L , given the error budget (Eq. 3.8).

3.3 Parameter Estimation

We adopt a Bayesian framework to estimate the parameters $\{\theta_i\} = \{H_0, q_0, j_0\}$ given the model \mathcal{M} represented by the cosmographic expansion (2.6) truncated at third order. In this context the combined probability distribution functions of parameters θ_i are given by

$$P(\{\theta_i\}|d, \mathcal{M}) = \frac{P(d|\{\theta_i\}, \mathcal{M})P(\{\theta_i\}, \mathcal{M})}{P(d)}, \quad (3.10)$$

where the likelihood $P(d|\{\theta_i\}, \mathcal{M})$ is given by:

$$P(d|\{\theta_i\}, \mathcal{M}) = \exp \left[-\frac{1}{2} \sum_{i=1}^N \frac{|d_i - f_i(\{\theta_i\}, z_i)|^2}{\sigma_i^2} \right], \quad (3.11)$$

Figure 4. Mock data using the EMobs distribution Eq. (3.7). The fiducial Λ CDM model is denoted by the red line, blue bands denote $1\text{-}\sigma$ confidence regions.

being N the number of detections, d_i the data with error σ_i and $f_i(\{\theta_i\}, z_i)$ is the parameter-dependent model function (third order truncation of Eq. 2.6) and the priors on H_0 , q_0 , and j_0 are taken to be flat. Note that we have neglected the error on the redshift, consistently with the assumption of an EM counterpart for the GW signal, that allows determination of the host galaxy determination. To perform our analysis we use the `Bilby` software [49] with the `Nestle` sampler, [50] which implements the nested sampling algorithm [51], with 500 live points.

In the next section we estimate the errors and the biases in the cosmographic parameters H_0 , q_0 and j_0 for the three source distributions introduced in Subsec. 3.1, and discuss how such estimates change as data at different redshift ranges are considered.

4 Results

As mentioned earlier, we restrict the redshift range to $0 < z < 0.72$, which corresponds to the region where the third order cosmographic expansion can faithfully reproduce the underlying cosmological model up to one percent level. Incidentally, this is the redshift range for which the large majority of detection will be made if sources follow the realistic distribution (3.7). Besides the parameter uncertainty σ_{θ_i} , defined by the 68% confidence interval of its probability distribution function, we also report the relative bias, defined as the absolute value of the difference between the average value recovered and injected one normalized by σ_{θ_i} .

In Fig. (5) we report the measurement of the uncertainty for the three cosmographic parameters. For each of them we show how such error varies with the redshift range of the detections, for five fixed values of total number of detections, ranging from 125 up to 2,000. The total number of detections refer to the complete redshift range up to $z = 0.72$, hence the process of accumulating detections in a realistic case will move the parameter uncertainty from lighter lines (smaller numbers of total detections) to darker lines (larger numbers). For completeness, we also consider two possible values of the luminosity distance uncertainties in the measure, the value given in Eq. (3.8) and 20% of that, which saturates the lensing contribution in (3.9). For each set of simulations, the result is obtained by averaging over 500 random realizations of injections extracted from the relevant redshift distribution. Similarly,

Figure 5. Results for parameter estimation error for (top) the source distribution following star formation rate (3.4), (middle) 10 Gyr average delay between star formation and binary merger, and (bottom) EMobs (3.7) as a function of the highest redshift detection. Lines get thicker as the number of total detections increases. Solid lines are for luminosity distance error as in Eq. (3.8), dot-dashed for 20% of such value. The right vertical scale refers to the normalized cumulative distribution of detections, displayed in light grey.

in Fig. (6) we show the bias for the three cosmographic parameters, computed as the absolute value of the difference between the mean value and the injected value, normalized by σ_{θ_i} . For each of them we report how they vary with redshift range for the same five fixed values of total number of detections. For completeness, we also show in Fig. (7) the marginalized posterior distribution of the mean values of the cosmographic parameters H_0 , q_0 , and j_0 for the different source distributions discussed in Subsec. 3.1.

Finally, we also find useful to compare the results obtained from GW detections with the current estimates of the first three cosmographic parameters from type Ia supernovae (SNe) data [41]. We adopt the same cutoff in redshift, $z_{cut} = 0.72$, which results in a SNe subsample with 972 data points, and fix the absolute peak magnitude at $M_B = -19.214 \pm 0.037$ mag, as given by [52]. Our analysis gives $H_0 = 75.23_{-0.38}^{+0.40}$ km/sec/Mpc, $q_0 = -0.70 \pm 0.10$, $j_0 = 1.78_{-0.74}^{+0.78}$, with the error bars corresponding to 68% confidence limit. As shown in Fig. (8), GWs detections can reach a better precision than current SNe data in measurements of H_0 for a number of detection larger than about 1,000 considering the standard errors on d_L , and for ~ 100 detections when the errors are reduced to 20%, the value of Eq. (3.9), see also Tab. 2 and Tab. 3.

5 Conclusions

We analyzed how future detections of gravitational wave standard sirens by a third generation detector can measure the Hubble constant, the deceleration and the jerk parameters of the cosmographic expansion. As it is well known, truncated cosmographic expansions are not supposed to describe correctly the cosmological expansions beyond redshift of order unity, and we showed that our choice for $z_{cut} = 0.72$ leads to a faithful cosmographic model with

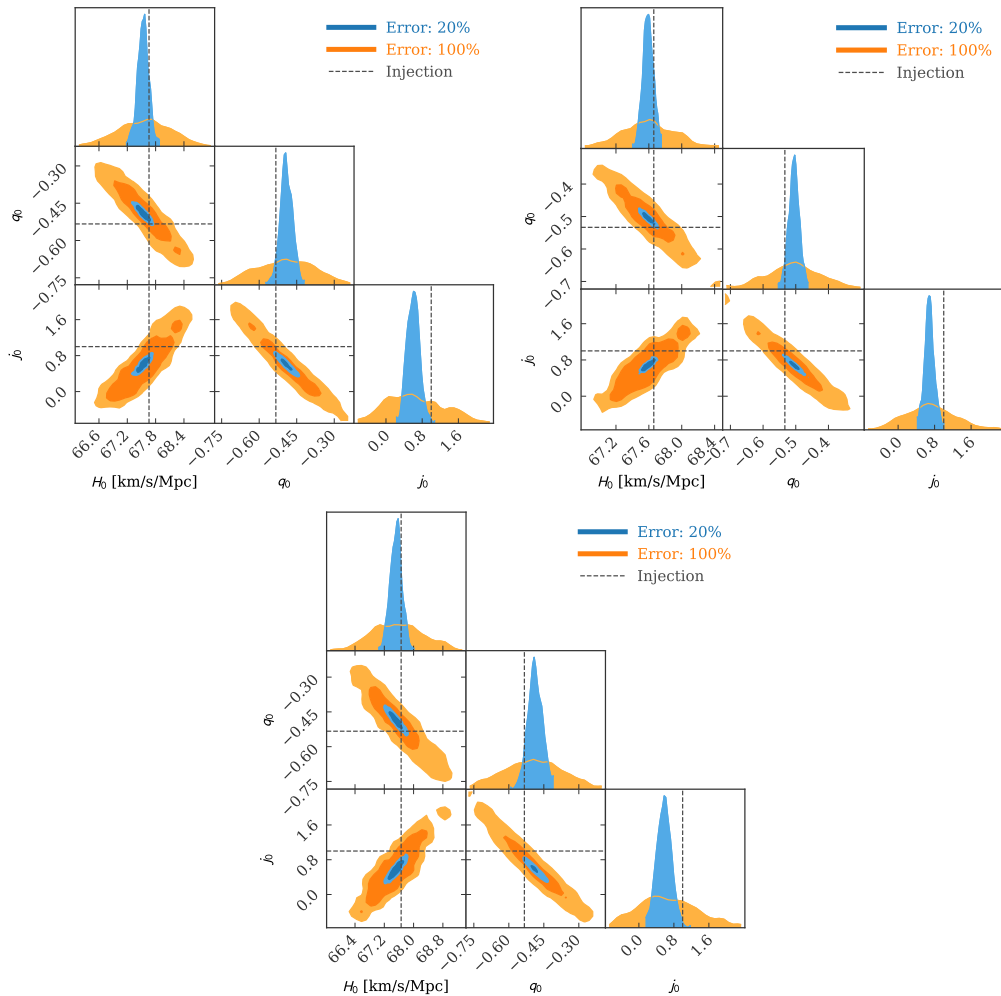

Figure 7. Marginalized posterior distributions of the cosmographic parameter mean values for 500 realizations of 1,000 events drawn from No-Delay distributions (top left), $\tau = 10Gyr$ delay (top right) and EMobs (bottom), see Subsec. 3.1. For each distribution the case for 100% and 20% the error given in Eq. (3.9) are reported.

Table 3. Parameter uncertainties σ_{θ_i} from 500 and 1000 standard sirens detections up to redshift $z = 0.72$ with 20% of d_L error content for sources distributed according to the *EMobs*, *10Gyr* and *NoDelay* distributions.

only the first three cosmographic parameters. The simulated data assumed the contemporary observation of electromagnetic counterparts ensuring redshift determination, and overall detections up to moderate redshift z_{cut} .

The results show that the Hubble constant can be measured with sub-percent precision

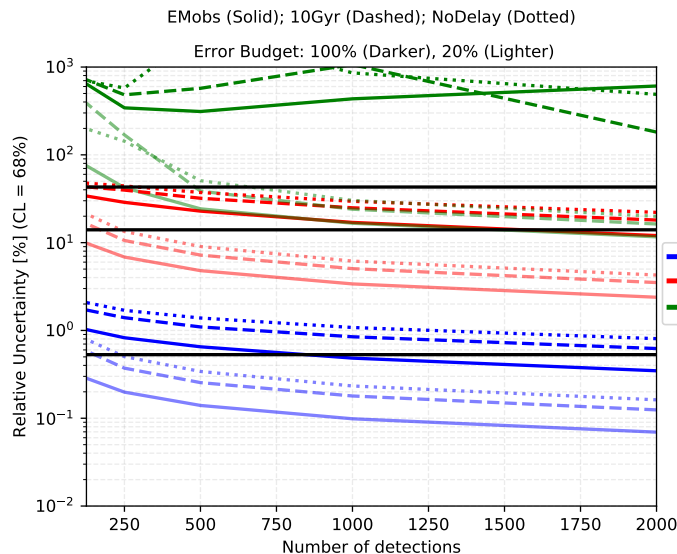

Figure 8. Comparisons between the error estimations for H_0 , q_0 , and j_0 from standard sirens (for three source distributions and different number of detections) and SNe data [40] (horizontal black lines from bottom to top). In all cases only SNe up to redshift $z_{cut} = 0.72$ have been considered, which correspond to 972 detections.

with a few hundred of detections. For higher order parameter in the cosmographic expansion precision is degraded, e.g. for q_0 one can reach 10% level with 2,000 detections, whereas for j_0 it is hard to limit precision below 100% level, with detections at high redshift tending to “overshrink” its error. We also showed that the recovered parameter has no strong bias, as their deviations from the injected values are consistently below the measurement error for the Hubble constant and the deceleration parameter, with biases being driven towards higher values by detections with the largest redshift values in our samples for the case of reduce error in luminosity distance measurements.

We also analyzed how such results vary with the distribution of events, showing that a distribution more concentrated at low redshifts allows a sharper determination of the H_0 and q_0 . Besides, the error in the parameter determination is mostly determined by the detections at low redshifts ($\lesssim 0.2$), and then levels off accumulating detections at higher redshifts unless thousands of events are accumulated. We also varied the number of expected detections, whose rate at present is wildly unknown, between realistic values of $O(10^2)$ and $O(10^3)$, showing an expected monotonic, sharpening of precision with increasing number of detection. Our projection for the H_0 measure precision with $\sim 1,000$ sources is of the same order the one that can be obtained analyzing the presently available SNe data up to z_{cut} , as shown in Fig. 8, its exact value varying non-negligibly with the number of detections, their redshift distributions and luminosity distance measurement uncertainty.

Finally, we showed that a crucial ingredient to reduce the measurement error in the cosmographic parameters is represented by the observational error in d_L , which can in principle be reduced by correlating observations from separately located detectors, to reach the “lensing wall”, which at moderate redshifts amount to about 20% of the error budget for a single interferometer.
