

# Funding liquidity, credit risk and unconventional monetary policy in the Euro area: a GVAR approach

Graziano Moramarco\*

*University of Bologna*

## Abstract

This paper investigates the transmission of funding liquidity shocks, credit risk shocks and unconventional monetary policy within the Euro area. To this aim, a financial GVAR model is estimated for Germany, France, Italy and Spain on monthly data over the period 2006-2017. The interactions between repo markets, sovereign bonds and banks' CDS spreads are analyzed, explicitly accounting for the country-specific effects of the ECB's asset purchase programmes. Impulse response analysis signals core-periphery heterogeneity and persistent flight to quality. A simulated reduction in any ECB programme ultimately results in rising yields and bank CDS spreads in Italy and Spain, as well as in falling repo trade volumes and rising repo rates in all four countries.

**Keywords:** GVAR, liquidity, repo market, sovereign bonds, banks, CDS

## 1 Introduction

Large increases in government bond yield spreads and banks' CDS spreads have been among the main symptoms of the Euro area debt crisis. Both heightened credit risk and liquidity concerns contributed to fuel the sovereign-banking vicious circle. In response to market distress, unprecedented policy interventions were implemented. Restoring adequate liquidity conditions was a stated goal of these interventions. For instance, the ECB launched the Securities Markets Programme (SMP) to ensure "depth and liquidity" to "dysfunctional" markets, and extended its long-term refinancing operations (LTRO) to "support bank lending and liquidity".<sup>1</sup>

In this paper we address the empirical relationships between funding liquidity, sovereign bond yields and credit risk in the banking industry within the Euro area, as well as the effects of the ECB's asset purchase programmes. To this aim, we estimate a financial global vector autoregressive (GVAR) model (Pesaran, Schuermann and Weiner 2004) for Germany, France, Italy and Spain on monthly data from 2006 to 2017. The endogenous variables of the model are interest rates and trading volumes in the repo markets, sovereign bond yields and CDS spreads for large banks. Trading volume in the repo market is taken as a proxy for funding liquidity, while CDS spreads isolate credit risk components in the banking sector, which are closely related to sovereign risk in the Euro area. Also, the presence of government yields in the model allows to characterize the empirical behavior of the market value of collateral. Collateralized borrowing, especially through the repo market, is an important source of funding for traders and is a key determinant of market liquidity.

To account for the effects of the ECB policy interventions, we include both the policy rate (i.e., the interest rate on ECB's main refinancing operations) and the amounts of assets purchased by the ECB as weakly exogenous variables in all four country-specific VARX\* models composing the GVAR. We distinctly consider the different asset purchase programmes carried out by the ECB. First, the long-term refinancing operations (LTRO), which during the global financial crisis were extended to 6-month and 12-month maturities. Second, the Securities Markets Programme (SMP), introduced in May 2010. Then, in September 2012 the ECB launched the Outright Monetary Transactions (OMT) programme, promising unlimited government bond purchases for distressed countries that complied to the rules of the European Stability Mechanism (ESM). However, no OMTs have been actually implemented, so that there are no purchased volumes associated with this programme. Nonetheless, since the mere announcement of the programme is thought to have been considerably effective in reducing yield spreads, we include a dummy variable which takes on value 1 in all periods following the announcement that the ECB would undertake outright transactions in secondary sovereign bond markets (i.e., from August 2012) and value 0 in previous periods. Finally, in late 2014 the ECB launched its asset purchase programme (APP), which was then expanded in early 2015. The APP consists of four sub-programmes: the third covered bond purchase programme (CBPP3, Oct. 2014), the asset-backed securities purchase programme (ABSPP, Nov. 2014), the public sector purchase programme (PSPP, Mar. 2015) and the corporate sector purchase programme (CSPP, Jun. 2016). We include in the GVAR model the total APP volumes, summing up the four sub-programmes.

We perform impulse response analysis to assess the dynamic cross-country effects of shocks to the repo markets, to sovereign bond yields and to CDS spreads. Moreover,

---

<sup>1</sup>See <https://www.ecb.europa.eu/press/pr/date/2010/html/pr100510.en.html>.

we simulate reductions in the ECB programmes in order to quantify the effects of policy interventions on the endogenous variables. Overall, the results point at core-periphery heterogeneity and flight-to-quality phenomena. Reductions in the ECB programmes invariably lead to increases in government yields and bank CDS spreads for Italy and Spain, to declines in funding liquidity and to increases in repo rates.

The paper relates to the literature on liquidity in times of crisis (e.g., Brunnermeier and Pedersen 2008; Adrian, Fleming, Shachar and Vogt 2016), on the effects of central banks' asset purchases on yields (Krishnamurthy, Nagel and Vissing-Jorgensen 2014; De Pooter, Martin and Pruitt 2016) and on financial GVAR models (Giese and Tuxen 2007; Chudik and Fratzscher 2012, 2012, Gross and Kok 2013; Gray, Gross, Paredes and Sydow 2013).

The remainder of the paper is organized as follows: Section 2 introduces the data, Section 3 illustrates the GVAR model, Section 4 presents the results, and Section 5 concludes.

## 2 Data

The country-specific financial variables considered in this paper are: repo interest rates, repo trading volumes, 10-year government bond yields and 1-year bank CDS indices.

Time series of repo interest rates and trading volumes have been provided by the MTS/BrokerTec RepoFunds Rate initiative, using data from repo transactions executed on either the BrokerTec or the MTS electronic platforms.<sup>2</sup> The repo rates are volume-weighted average rates and represent the effective cost of funding for the majority of repo trades in each of the relevant sovereign bond markets. Data for France, Germany and Italy start in 2006. Data for Spain are only available from 2012 onwards, so that including them would dramatically reduce the sample length. For this reason, in the sub-model for Spain we only include the 10-year government bond yield and the 1-year bank CDS index as domestic endogenous variables.

Data on 10-year sovereign bond yields are taken from the OECD.

Country-specific 1-year bank CDS indices are computed as simple averages of individual CDS spreads across domestic banks. For Germany, Deutsche Bank and Commerzbank are considered. For France: Crédit Agricole, BNP Paribas and Société Générale. For Italy: Mediobanca, Unicredit, Intesa Sanpaolo and Monte dei Paschi di Siena. For Spain: Santander, Banco Popular Español and Banco Sabadell. All data on bank-specific CDS are provided by Datastream.

In each country model, Euro-area-wide monetary policy variables are included as weakly exogenous. These reflect both conventional and unconventional monetary policy operations. First of all, the policy rate, i.e., the interest rate on the ECB's main refinancing operations, is included. Cumulative volumes of assets purchased by the ECB under its purchase programmes are also considered.

In every country-specific model (VARX\*) composing the GVAR, domestic macroeconomic variables are related to their foreign counterparts. These foreign variables are built as cross-country weighted averages. The weights are based on data on gross bilateral financial positions. In particular, we use total portfolio liability data from the IMF's Coordinated Portfolio Investment Survey (CPIS) of December 2015. As an example, when building foreign variables for Italy, the weight assigned to Germany is equal to the

---

<sup>2</sup><https://www.mtsmarkets.com/repofunds-rate>

amount of Italian liabilities towards Germany, as a share of the total liabilities of Italy towards France, Germany and Spain (hence, the weights sum to 1).

Data on repos, sovereign bonds, CDS spreads and the ECB policy rate are available with a daily frequency. Data on ECB programmes are available at a weekly frequency. To smooth out the high volatility exhibited by daily/weekly data, we conduct our analysis on monthly data, obtained by averaging the original higher-frequency data within the month. The estimation sample spans the period from January 2006 to March 2017. As regards variable transformations, repo trading volumes are included in logarithms, while ECB's purchased assets are transformed as follows: given the level  $x_t$ , the variable  $\ln(1 + x_t)$  is used in the model (simple log cannot be used, since the level can assume value 0). The other variables are included in levels.

### 3 The GVAR model

#### 3.1 The model

First introduced by Pesaran, Schuermann and Weiner (2004), the GVAR model results from the aggregation of country-specific VARX\* models. Consider a generic country  $i$ , with  $i = 1, \dots, N$ , where  $N$  is the total number of countries in the GVAR. Denote with  $\mathbf{x}_{it}$  the  $k_i \times 1$  vector of domestic macroeconomic variables of country  $i$  at time  $t$ , with  $\mathbf{x}_{it}^*$  the  $k_i^* \times 1$  vector of foreign variables and with  $\mathbf{d}_t$  the vector of common exogenous variables. In this paper,  $\mathbf{x}_{it}$  comprises domestic repo rates and trading volumes (except for Spain), the 10-year government bond yield and the 1-year bank CDS index, while  $\mathbf{d}_t$  comprises the ECB policy rate, the amounts of assets purchased under the LTRO, SMP and APP and a dummy variable for the OMT programme. The VARX\* model for country  $i$  can be written as:

$$\mathbf{x}_{it} = \mathbf{a}_{0i} + \mathbf{a}_{1i}t + \Phi_i \mathbf{x}_{i,t-j} + \Lambda_{0i} \mathbf{x}_{i,t}^* + \Lambda_{1i} \mathbf{x}_{i,t-1}^* + \Psi_{0i} \mathbf{d}_t + \Psi_{1i} \mathbf{d}_{t-1} + \boldsymbol{\nu}_{it} \quad (1)$$

where  $\mathbf{a}_{0i}$  and  $\mathbf{a}_{1i}$  are vectors of deterministic constants and trends respectively,  $\Phi_i$ ,  $\Lambda_{li}$  and  $\Psi_{li}$ , with  $l = 0, 1$ , are matrices of parameters and  $\boldsymbol{\nu}_{it}$  is the vector of i.i.d. errors. Let's call  $k = \sum_i^N k_i$  the total number of national variables in the global economy. Domestic and foreign variables can be expressed in terms of the  $k \times 1$  global vector of stacked endogenous variables  $\mathbf{x}_t$ :

$$\begin{pmatrix} \mathbf{x}_{it} \\ \mathbf{x}_{it}^* \end{pmatrix} = \mathbf{W}_i \begin{bmatrix} \mathbf{x}_{1t} \\ \vdots \\ \mathbf{x}_{Nt} \end{bmatrix} = \mathbf{W}_i \mathbf{x}_t \quad (2)$$

where  $\mathbf{W}_i$  is the  $(k_i + k_i^*) \times k$  matrix of weights based on bilateral financial positions.

Stacking all country-specific VARX\* models delivers a vector autoregressive representation of the global economy:

$$\mathbf{G} \mathbf{x}_t = \mathbf{a}_0 + \mathbf{a}_1 t + \mathbf{H} \mathbf{x}_{t-1} + \Psi_0 \mathbf{d}_t + \Psi_1 \mathbf{d}_{t-1} + \boldsymbol{\nu}_t \quad (3)$$

where  $\mathbf{a}_0 = (\mathbf{a}_{01}, \mathbf{a}_{02}, \dots, \mathbf{a}_{0N})'$  and  $\mathbf{a}_1 = (\mathbf{a}_{11}, \mathbf{a}_{12}, \dots, \mathbf{a}_{1N})'$  are the  $k \times 1$  stacked vectors of global constants and trends,  $\boldsymbol{\nu}_t = (\boldsymbol{\nu}_{1t}, \boldsymbol{\nu}_{2t}, \dots, \boldsymbol{\nu}_{Nt})'$  is the  $k \times 1$  stacked vector of

errors and

$$\mathbf{G} = \begin{pmatrix} (\mathbf{I}_1, -\mathbf{\Lambda}_{01}) \mathbf{W}_1 \\ (\mathbf{I}_2, -\mathbf{\Lambda}_{02}) \mathbf{W}_2 \\ \vdots \\ (\mathbf{I}_N, -\mathbf{\Lambda}_{0N}) \mathbf{W}_N \end{pmatrix}, \quad \mathbf{H} = \begin{pmatrix} (\mathbf{\Phi}_{11}, \mathbf{\Lambda}_{11}) \mathbf{W}_1 \\ (\mathbf{\Phi}_{12}, \mathbf{\Lambda}_{12}) \mathbf{W}_2 \\ \vdots \\ (\mathbf{\Phi}_{1N}, \mathbf{\Lambda}_{1N}) \mathbf{W}_N \end{pmatrix}, \quad \mathbf{\Psi}_0 = \begin{pmatrix} \Psi_{01} \\ \Psi_{02} \\ \vdots \\ \Psi_{0N} \end{pmatrix}, \quad \mathbf{\Psi}_1 = \begin{pmatrix} \Psi_{11} \\ \Psi_{12} \\ \vdots \\ \Psi_{1N} \end{pmatrix} \quad (4)$$

The reduced form of the global model is obtained by inverting the  $\mathbf{G}$  matrix:

$$\mathbf{x}_t = \mathbf{c}_0 + \mathbf{c}_1 t + \mathbf{F} \mathbf{x}_{t-1} + \mathbf{\Gamma}_0 \mathbf{d}_t + \mathbf{\Gamma}_1 \mathbf{d}_{t-1} + \boldsymbol{\epsilon}_t \quad (5)$$

where:

$$\mathbf{c}_0 = \mathbf{G}^{-1} \mathbf{a}_0, \quad \mathbf{c}_1 = \mathbf{G}^{-1} \mathbf{a}_1, \quad \mathbf{F} = \mathbf{G}^{-1} \mathbf{H}, \quad (6)$$

$$\mathbf{\Gamma}_0 = \mathbf{G}^{-1} \mathbf{\Psi}_0, \quad \mathbf{\Gamma}_1 = \mathbf{G}^{-1} \mathbf{\Psi}_1 \quad (7)$$

and  $\boldsymbol{\epsilon}_t = \mathbf{G}^{-1} \boldsymbol{\nu}_t$  are the reduced-form global shocks. Let  $\boldsymbol{\Sigma}$  denote the covariance matrix of these shocks.

### 3.2 Impulse response analysis

The tool typically used to analyze the dynamic properties of a GVAR model consists in the generalized impulse response functions (GIRF), which trace out the response of the model at different future periods to a shock in one variable in one country at time  $t$ . This shock is assumed to equal one estimated standard error of the variable. The estimated error covariance matrix is then used to assign consistent shocks to all other variables in the model at time  $t$ . Finally, the dynamic properties of the GVAR determine how the variables' responses to the initial shock evolve through time.

Formally, the  $h$ -step ahead GIRF with respect to a shock in the endogenous variable  $q$  in country  $i$  at time  $t$  is defined as:

$$\mathbf{GIRF}_{iq}(h) = E(\mathbf{x}_{t+h} | \varepsilon_{iqt} = \sigma_{ii,qq}, \mathcal{I}_{t-1}) - E(\mathbf{x}_{t+h} | \mathcal{I}_{t-1}) \quad (8)$$

where  $\sigma_{ii,qq}$  is the standard error the shocked variable and  $\mathcal{I}_{t-1} = (\mathbf{x}_{t-1}, \mathbf{x}_{t-2}, \dots)$  is the information set at time  $t-1$ . Assuming that the variable  $q$  in country  $i$  is the  $j$ -th element of the global endogenous vector  $\mathbf{x}_t$ , the GIRF vector can be expressed as:

$$\mathbf{GIRF}_j(h) = \frac{1}{\sigma_j} \mathbf{F}^h \mathbf{G}^{-1} \boldsymbol{\Sigma} \mathbf{s}_j \quad (9)$$

where  $\mathbf{s}_j$  is a  $k \times 1$  selection vector, i.e., a vector in which the  $j$ -th element is equal to 1 and all other elements are zeros.

Analogously, generalized impulse response functions can be derived with respect to shocks to the exogenous variables. However, this would require specifying a dynamic process for the exogenous variables. As will be explained in the following section, we adopt an alternative approach to assess the impact of shocks to the ECB asset purchase programmes.

## 4 Results

This section presents the results, in terms of dynamic responses to shocks in the variables of the estimated GVAR model. When interpreting the results, it is important to stress that the response functions should not be given any causal or structural interpretation. They just capture empirical dynamic correlations between the variables.

The effects of shocks to the endogenous variables are assessed by means of GIRF functions computed over a horizon of 24 months after the time of the shock, which is denoted as time 1. In order to assess the responses of the endogenous variables to shocks in the exogenous variables, we follow a different approach. More specifically, we simulate the model over the period 2015M1-2017M3 under alternative “shock scenarios” for the exogenous variables. In each such scenario, a single ECB programme is shocked. Shocking the LTRO, SMP and APP consists in assuming that the amount of assets held by the ECB under the relevant programme was 50% lower than the amount actually held. The shock scenario for the OMT programme is defined by setting the OMT dummy variable to 0 over the 2015M1-2017M3 period, thereby assuming the termination of the programme. Finally, the responses of the endogenous variables are computed as the differences between the time profiles of the variables in the shock simulation and the baseline time profiles, i.e., the dynamic forecast of the model over the 2015M1-2017M3 period obtained by considering the actual values for the ECB variables.

### 4.1 Shocks to the endogenous variables

Figures 1-4 summarize the empirical relationships between repo market conditions and government yields/bank CDS spreads. Figure 1 plots the responses of repo trading volumes to a positive shock to the yield of the European safe asset, i.e., the German Bund. The response is negative for Germany (-2% approx. after 2 years) and France (-6%), but not for Italy. Figures 2-3 show that a positive shock in domestic repo trading volume is associated with increasing government yields and banks’ CDS in Italy and decreasing yields and CDS in Germany. These results appear to capture flight-to-quality effects. Figure 4 shows the responses of CDS spreads to a shock in the Italian repo market rate. The figure highlights the distinction between Italy and Spain, on one side, and Germany and France, on the other: after 1 year, the Italian and Spanish CDS increase by 40 basis points (bps), while German and French CDS spreads by just 10 bps.

Figure 5-8 summarize the dynamic relationships between government bond yields and CDS spreads in the four countries. “Core-periphery” heterogeneity and flight to quality are particularly evident here. As shown in Figure 5, following increases in domestic government yields, CDS spreads tend to increase in Spain (reaching +80 bps) and Italy (+20 bps), while the effects are almost negligible in Germany. Increases in the German government yield have very little impact on CDS spreads, with a negative sign in the first months (Figure 6), which seems consistent with the assumption that higher Bund rates are associated with improving economic conditions. A shock to the Italian sovereign yield results in higher Italian and Spanish CDS spreads (+20 bps to +0.35 bps), while French and German CDS spreads are almost unaffected (Figure 7). Following a shock in the Italian CDS spreads, government yields decrease in Germany and France (-0.12% approx.), while they increase in Italy and Spain (+0.1% approx.), as shown in Figure 8.

## 4.2 Shocks to the exogenous ECB programmes

The effects of shocks to the exogenous variables (ECB policy) are assessed by simulating several “shock scenarios”. In each scenario, a single ECB programme is shocked. For programmes involving actual asset purchases, such as the LTRO, SMP and APP, the shock scenario consists in a 50% reduction in the asset amounts held by the ECB over the period 2015M1-2017M3, while for the OMT it is defined by setting the OMT dummy variable to zero (termination of the programme).

Figures 19-34 show the responses of the endogenous variables to these simulated shocks to ECB programmes. For each asset purchase programme, downsizing (or termination, in the case of the OMT) eventually results in higher government bond yields and bank CDS spreads for Italy and Spain, as well as in lower repo trading volumes and higher repo interest rates in all countries.

A 50% reduction in LTRO causes the Italian 10-year yield to soar by 2.5% at the end of 2015 and by almost 3% at the end of the simulation period. The Spanish yield climbs up by almost 3.5% over the two-year simulation horizon. The German and French yields also rise, but to a lesser extent: the German yield rises by 1%, the French by 1.5%. Accordingly, Italian and Spanish sovereign spreads rise. This “core-periphery” type of heterogeneity is even more striking when the effects on bank CDS are considered. The Spanish and Italian CDS indices rise by 450 basis points and 200 basis points respectively at the end of simulation period, while the German and French CDS increase by approximately 50 bps. Although positive on impact (especially for Germany), all responses of trading volumes become negative within 9 months. All volumes drop by more than 10% by March 2017. The final increases in repo rates range between 1.1% and 1.2%.

Shocking the SMP delivers results which are qualitatively similar but quantitative smaller. In response to the shock, the Italian yield rises by up to 0.65%, the Spanish yield by around 0.8%, the German yield by 0.3% and the French yield by 0.4%. The reponse of the bank CDS spreads eventually exceeds 100 bps for Spain and 40 bps for Italy, while French and German banks are almost unaffected.

The simulated termination of the OMT delivers more dramatic increases in Italian and Spanish yields and CDS. Yields increase by around 6% relative to the baseline scenario, CDS spreads shoot up by 1500 bps for Spain and by 800 bps for Italy. The German Bund is not affected, while the French yield increase by 1%. Both core countries experience 200-bps increases in CDS. Repo trading volumes plummet, while the responses of repo

rates are negative on impact and their final increases are smaller than in the LTRO shock.

Finally, the APP shock exhibits the smallest effects. After reaching 30-40 bps on impact, the responses of government yields decline to 5-20 bps. Italy and Spain still witness the highest responses. CDS responses are negative on impact but end up unaffected, except for Spain (+30 bps in 2017). All repo trading volumes rise on impact, then turn negative and eventually decline by no more than 3%. Repo rates increase by 10 bps at the end of the period.

To conclude, the OMT shock scenario is associated with the largest increases in Italian and Spanish government yields and CDS spreads and with the largest declines in repo trading volumes. It should be underlined, however, that the nature of the OMT shock is different from those of the other ECB programmes: purchased volumes are assumed to be halved, while the OMT dummy can only assume value 0 or 1, so that a complete termination of the programme is simulated.

### 4.2.1 LTRO

## 5 Conclusions

This paper has developed a financial GVAR model to study the empirical relationships between repo funding conditions, sovereign bond markets and banks' credit risk in major Euro area economies, as well as the effects of the ECB's asset purchase programmes. Impulse response analysis suggests that the ECB's unconventional monetary policy prevented large drops in repo funding liquidity in all countries, as well as sizeable increases in Italian and Spanish government spreads and bank CDS. The estimates show important differences in the dynamics of liquidity and credit risk between Germany and France, on one side, and Italy and Spain, on the other.
