Augmented RBMLE-UCB Approach for Adaptive Control of Linear Quadratic Systems

Akshay Mete 1 Rahul Singh 2 P. R. Kumar 1

Abstract

We consider the problem of controlling a stochastic linear system with quadratic costs, when its system parameters are not known to the agent called the adaptive LQG control problem. We re-examine an approach called "Reward-Biased Maximum Likelihood Estimate" (RBMLE) (Kumar & Becker, 1982) that was proposed more than forty years ago, and which predates the "Upper Confidence Bound" (UCB) method as well as the definition of "regret" (Lai & Robbins, 1985b). It simply added a term favoring parameters with larger rewards to the estimation criterion. We propose an augmented approach that combines the penalty of the RBMLE method with the constraint of the UCB method (Abbasi-Yadkori & Szepesvári, 2011), uniting the two approaches to optimization in the face of uncertainty. We first establish that theoretically this method retains $\mathcal{O}(\sqrt{T})$ regret, the best known so far. We show through a comprehensive simulation study that this augmented RBMLE method considerably outperforms the UCB and Thompson sampling approaches, with a regret that is typically less than 50% of the better of their regrets. The simulation study includes all examples from earlier papers as well as a large collection of randomly generated systems.

1. Introduction

Consider a linear dynamical system (Åström, 2012) in which system evolution is given as $x_{t+1} = Ax_t + Bu_t + w_{t+1}$, where $x_t \in \mathbb{R}^N$ is the system state at time t, $u_t \in \mathbb{R}^N$ is the control applied at time t by an "agent" (Sutton & Barto, 2018), and w_t is i.i.d. Gaussian noise at time t. (A, B) are

system matrices that describe the system dynamics. The instantaneous cost incurred at time t is a quadratic function $\left(x_t^TQx_t+u_t^TRu_t\right)$ of the current state and control. The goal of the agent is to minimize the expected value of the cumulative costs $\sum_{t=1}^T \left(x_t^TQx_t+u_t^TRu_t\right)$ incurred during T steps. This objective serves the purpose of keeping the system state close to the origin by using minimal control energy. The controller/agent has to attain this goal without knowing the parameter $\theta:=(A,B)$. Let $J^*(\theta)$ denote the optimal average LQG cost when the true parameter is equal to θ , and is known to the agent. The goal is to choose u_t adaptively on the basis of the information collected during system operation, so as to minimize the expected "regret" (Lattimore & Szepesvári, 2020)

$$\sum_{t=1}^{T} \left(x_t^T Q x_t + u_t^T R u_t \right) - T J^*(\theta)$$

This is called the adaptive LQG control problem.

In this work we use an approach called "Reward-Biased" Maximum Likelihood Estimate" (RBMLE) that was first proposed more than four decades ago for the problem of online learning (Kumar & Becker, 1982; Kumar, 1983a; Mete et al., 2021). We begin by giving a brief description of RBMLE. Consider a system with state space X, an action set U, and with controlled transition probabilities $p_{\theta^*}(i,j;u)$ for $i, j \in X$ and $u \in U$ dependent on an unknown parameter θ^* . The goal is to maximize a long-term average reward $\liminf_{T\to\infty} \frac{1}{T} \sum_{t=0}^{T-1} r(x(t), u(t))$, where x(t) and u(t) are the state and action at time t. The parameter θ^* is not known; all that is known is that it belongs to a known set Θ . If one knew θ^* , one could take action $u(t) = \pi^{\theta^*}(x(t))$ at time t, where for each $\theta \in \Theta$, π^{θ} denotes a stationary policy that is optimal if the parameter is θ . In the absence of knowledge of θ^* , one could employ a "certainty equivalent" approach where one simply makes an estimate of θ^* at time t, and simply use the action in state x(t) that would be optimal if θ^{\star} were the true parameter. Specifically, let $\hat{\theta}(t) \in \operatorname{ArgMax}_{\theta \in \Theta} \Pi_{t=0}^{T-1} p_{\theta}(x(t), x(t+1); u(t))$ be the maximum likelihood estimate (MLE) of θ^{\star} at time $t, \pi^{\theta}(\cdot)$. Then, under the certainty equivalent approach, the action taken at time t is $u(t) = \pi_{\hat{\theta}(t)}(x(t))$. Mandl (Mandl, 1974) was the first to analyze this CE approach. Rec-

¹Department of Electrical and Computer Engineering, Texas A& M University, College Station, TX, USA. ²Department of Electrical and Computer Engineering, Indian Institute of Science, Bengaluru, India.. Correspondence to: Akshay Mete <akshaymete@tamu.edu>.

ognizing that CE generally suffers from being unable to converge to θ^* unless one can distinguish θ^* from other θ s irrespective of what action is taken in what state, he showed that if $p_{\theta}(i,\cdot;u) \neq p_{\theta'}(i,\cdot;u)$ for all $\theta \neq \theta'$, then $\hat{\theta}(t) \to \theta^{\star}$. Borkar and Varaiya (Borkar & Varaiya, 1979) performed a further analysis of the CE rule, and showed that one only obtains a certain "closed-loop identifiability" property, i.e., if $\hat{\theta}(t) \to \hat{\theta}(\infty)$ denotes the limiting value of the ML estimates under the CE rule, then the system dynamics associated with the parameter, controller tuple $(\hat{\theta}(\infty), \pi^{\hat{\theta}(\infty)})$ are the same as that of $(\theta, \pi^{\hat{\theta}(\infty)})$, i.e., $p_{\hat{\theta}(\infty)}(i,j,\hat{\theta}(\infty)(i)) = p_{\theta^*}(i,j,\hat{\theta}(\infty)(i))$ for all $i,j \in X$. The problem is that as the parameter estimates begin to converge, exploration ceases, and one ends up only identifying the behavior of the system under the limited actions being applied to the system. One misses out on other potentially valuable policies. Since the limiting policy $\pi^{\hat{\theta}(\infty)}$ need not be an optimal long-term average policy for the true system θ , the CE rule leads to a sub-optimal performance. Indeed this problem goes by various names in different fields, the dual control problem (Feldbaum, 1960; Wittenmark, 1995), the closed-identifiability problem (Borkar & Varaiya, 1979; Berry & Fristedt, 1985; Gittins et al., 2011), or the problem of exploration vs. exploitation (Lattimore & Szepesvári, 2020).

This problem was resolved without resort to forced exploration in (Kumar & Becker, 1982).

the following indistinguishability condition holds the problem of "insufficient exploration," i.e. there is a positive probability with which the MLE $\hat{\theta}_t$ does not converge to θ , and hence asymptotically it applies sub-optimal controls.

how it was discovered in (Kumar & Becker, 1982) that when maximum likelihood estimator (MLE) is inherently biased towards parameters for which the optimal rewards is less than the true optimal rewards, and how it proposed RBMLE as a natural solution to overcome this bias. Let $J(\pi,\theta)$ denote the average LQG cost when a stationary control policy π is applied to the linear system with parameter θ .

This exploration-exploitation problem (or equivalently the dual control problem) was finally resolved in the work. Their approach is summarized as follows. (Kumar & Becker, 1982) begins by observing that $J^*(\hat{\theta}(\infty) \geq J^*(\theta))$. To see why this is true, we note that since $(\hat{\theta}(\infty), \pi^{\hat{\theta}(\infty)})$ and $(\theta, \pi^{\hat{\theta}(\infty)})$ induce the same stationary probability distribution on the state-space, we have that $J(\pi^{\hat{\theta}(\infty)}, \theta) = J(\pi^{\hat{\theta}(\infty)}, \hat{\theta}(\infty)) = J^*(\hat{\theta}(\infty))$. However, since $\pi^{\hat{\theta}(\infty)}$ might not be optimal for θ , we have $J^*(\theta) \leq J(\pi^{\hat{\theta}(\infty)}, \theta)$. Upon combining these, we obtain $J^*(\hat{\theta}(\infty)) \geq J^*(\theta)$. This relation shows the following fundamental property of the ML estimates when they are also used for generating controls: the estimates are inherently biased towards those pa-

rameters that have a higher operating cost than the true parameter value. After making this fundamental observation, (Kumar & Becker, 1982) proposed to counteract this bias by providing a bias in the likelihood objective function in the reverse direction, i.e. by favoring those θ which yield a larger optimal reward or equivalently those θ which have a smaller value of optimal average cost $J^*(\theta)$. More specifically, the RBMLE algorithm they developed generates a reward biased MLE by solving the following problem at each time t:

$$\theta(t) \in \arg\min_{\theta \in \Theta} \alpha(t) \left[f(J^{*}(\theta)) \right]$$

$$+ \sum_{s=1}^{t-1} \mathcal{L}(x_{s}, u_{s}, x_{s+1}; \theta),$$
(1)

where $\mathcal{L}(x,u,y;\theta)$ denotes the negative log-likelihood probability associated with the system state transitioning to state y when control u is applied in state x, and the true parameter is θ . $f(\cdot)$ is any strictly increasing function, $\alpha(t)>0$ is a biasing parameter that must be chosen so as to satisfy the following two desired properties:

- (i) it should be sufficiently large enough so that asymptotically RBMLE does choose parameters $\theta(t)$ that have a larger optimal reward than under θ . If this were not the case, then the resulting learning algorithm would suffer from the same drawbacks as that of the CE rule of (Mandl, 1974).
- (ii) $\alpha(t)$ should also not be too large so that the ML estimates are asymptotically inconsistent.

They showed that in order for (i), (ii) to be satisfied, we should let $\alpha(t) = o(t)$, and $\lim_{t \to \infty} \alpha(t) = \infty$. The resulting RBMLE algorithm was shown to attain the same average cost performance as the case when θ is known, in which case the agent can compute and use the optimal stationary policy. In the parlance of machine learning community, the limiting normalized regret (Lai & Robbins, 1985b; Lattimore & Szepesvári, 2020; Auer et al., 2002) (normalized by operating time T) vanishes.

RBMLE is the first algorithm that did not resort to "forced exploration" in order to solve the adaptive control /RL problem. It attained this by introducing the idea of favoring parameters that yield better performance, which is now known as the principle of "optimism in the face of uncertainty" (Lai & Robbins, 1985b; Agrawal, 1995; Auer et al., 2002) Since its introduction in (Kumar & Becker, 1982), RBMLE has been applied to solve a variety of online learning problems. As an example, it has been used to learn optimal policies for more general MDPs (Kumar, 1982; Kumar & Lin, 1982; Borkar, 1990), LQG systems (Kumar, 1983a; Campi & Kumar, 1998a;b; Prandini & Campi, 2000), LTI systems (Bittanti et al., 2006), non-linear systems (Kumar, 1983b), ergodic problems (Stettner, 1993), control of diffusions (Borkar, 1991; Duncan et al., 1994). These works only

showed that RBMLE yields the optimal long-term average performance.

After the seminal works (Kumar & Becker, 1982; Kumar, 1982; Kumar & Lin, 1982) in the field of adaptive control, the work (Lai & Robbins, 1985a) studied in detail the multi-armed bandit (MAB) problem, and introduced the notion of "regret" in order to characterize the performance of a learning algorithm for MAB. Regret of an algorithm is the difference between the expected rewards earned by the algorithm, and the mean reward of an optimal arm times the operating time-horizon. Clearly, regret is a much finer metric to judge the performance of a learning algorithm as compared with the long-term average reward. (Lai & Robbins, 1985a) showed that asymptotically the optimal regret scales as $O(\log T)$, and also developed an "Upper Confidence Bounds" (UCB) algorithm that assigns an index to each arm, and then plays the arm with the highest value of the index. This index is an optimistic estimate, i.e. a high-probability upper-bound, of the true (but unknown) mean reward of that arm. Since the work (Lai & Robbins, 1985a), the criterion of regret has become very popular to characterize the performance of RL algorithms. For example UCRL (Auer & Ortner, 2007), UCRL2 (Jaksch et al., 2010), Thompson Sampling (Brafman & Tennenholtz, 2002; Agrawal & Goyal, 2012; Ouyang et al., 2017b).

Though the seminal works on RBMLE showed that it is optimal with respect to long-term average reward, the finite-time performance analysis for various learning tasks, or its learning regret, is an overdue topic of topical interest. Recently, several works have addressed this issue. For example, (Liu et al., 2020) analyzes RBMLE for MABP and shows that it enjoys a regret that is comparable to other state-of-the-art algorithms such as UCB and Thompson Sampling, while the empirical performance of RBMLE is much better than these. Similar results were obtained when RBMLE was used to optimize rewards in the case of linear bandits (Hung et al., 2020). The case of RL for discrete MDPs was treated in (Mete et al., 2021). In this work we analyze RBMLE algorithm in the context of RL for LQG control systems.

1.1. Previous Works

The seminal work on adaptive LQG control (Kumar, 1983a) showed that the RBMLE algorithm attains the optimal infinite horizon average cost asymptotically by utilizing reward-biased estimates of the system parameters in order to generate controls. However, it assumed that the unknown parameters can assume values from only a discrete set. This assumption was removed in (Campi & Kumar, 1998a; Prandini & Campi, 2000). Meanwhile, works such as (Lai & Wei, 1982; 1987; Chen & Guo, 1987) used forced exploration techniques in order to ensure that the algorithm does not suffer from the problem of insufficient exploration, i.e. the asymp-

totic estimates of the unknown parameters converge to their true value. These are somewhat similar in spirit to the ϵ_t greedy learning algorithm (Sutton & Barto, 2018; Auer et al., 2002). More recently, inspired by the RBMLE principle, the work (Abbasi-Yadkori & Szepesvári, 2011) uses the principle of optimism in the face of uncertainty for adaptive LOG control, and derives bounds on its learning regret by building upon the techniques introduced in (Campi & Kumar, 1998b). The algorithm proposed therein is "UCB-type," i.e. it optimizes the function $J^{\star}(\theta)$ over a high-probability confidence ball, to get an optimistic estimate of θ , and is shown to have a regret that is bounded as $\tilde{O}(\sqrt{T})$. (Ibrahimi et al., 2012) also uses the OFU principle to address the adaptive LQG control problem. More recently, (Dean et al., 2020a) studies a related "sample complexity" problem associated with LQG control, i.e. it quantifies the number of samples required in order to generate a sufficiently precise estimate of the parameters (A, B). However, it does this under the assumption that the controls are generated in an i.i.d. manner (which is somewhat equivalent to forced exploration). An alternative approach to OFU principle for designing learning algorithms is Thompson sampling (Thompson, 1933), or posterior sampling. Works (Abbasi-Yadkori & Szepesvári, 2015; Ouyang et al., 2017a) considered the adaptive LQG control problem in the Bayesian setup, and showed that the expected regret of Thompson sampling is $O(\tilde{T})$.

Key Challenges:

Several critical questions need to be answered in order to tailor the RBMLE to LQG control.

- The average reward optimality proved in prior RBMLE studies for LQG control (Kumar, 1983a; Campi & Kumar, 1998a;b; Prandini & Campi, 2000) is a gross measure which implies that only the regret (defined below) is o(T), while a much stronger finite-time orderoptimal regret such as that of OFU (Abbasi-Yadkori & Szepesvári, 2011) or Thompson Sampling (Abbasi-Yadkori & Szepesvári, 2015; Ouyang et al., 2017a) (both these regrets are $\tilde{O}(\sqrt{T})$) is desired. What is the regret bound of the RBMLE algorithms for adaptive LOG?
- The above options for $\alpha(T)$ described in (1) are very broad, and not all of them lead to order-optimality of regret. How should one choose the function $\alpha(T)$ in order to attain order-optimality?
- What are the advantages of RBMLE algorithms as compared with the existing methods?

We make several contributions.

• We perform a finite-time performance analysis of the RBMLE algorithm for the setup of adaptive LQR prob-

lem. We show that its regret is $\tilde{O}(\sqrt{T})$ and is competitive with the OFU algorithm of (Abbasi-Yadkori & Szepesvári, 2011).

- We reveal the general interplay between the choice of $\alpha(t)$ and the regret bound.
- We evaluate the empirical performance of RBMLE algorithms in extensive experiments. They demonstrate competitive performance in regret as well as scalability against the current best policies.

OFU	$\mathcal{O}(\sqrt{T})$
Thompson Sampling	$\mathcal{O}(\sqrt{T})$
RBMLE	$\mathcal{O}(\sqrt{T})$

2. Problem Formulation

Consider the following linear system (Kumar & Varaiya, 2015),

$$x_{t+1} = \bar{A}x_t + \bar{B}u_t + w_{t+1} \tag{2}$$

where $x_t \in \mathbb{R}^n$, $u_t \in \mathbb{R}^m$ are the state and the control input respectively at time t. $w_t \in \mathbb{R}^n$ represents the noise in the system at time t. The system parameters, represented by matrices $A \in \mathbb{R}^{n \times n}$, $B \in \mathbb{R}^{n \times m}$ are unknown.

The system incurs a cost c_t at time t given by,

$$c_t = x_t^T Q x_t + u_t^T R u_t, (3)$$

where $Q \in \mathbb{R}^{n \times n}$ and $R \in \mathbb{R}^{m \times m}$ are known positive semi-definite matrices, The sample-path average cost incurred by the controller that chooses u_t is:

$$\limsup_{T \to \infty} \frac{1}{T} \sum_{t=0}^{T} c_t. \tag{4}$$

Denote the history of states and inputs until time t by

$$\mathcal{F}_t = \{(x_0, u_0), (x_1, u_1), \cdots, (x_t, u_t)\}. \tag{5}$$

Define $z_t := (x_t^T, u_t^T)^T$ and let $\bar{\theta} := (\bar{A}, \bar{B})$ be the unknown system parameter. Then, the linear system (2) can equivalently be written as

$$x_{t+1} = \bar{\theta}z_t + w_{t+1}. (6)$$

2.1. Assumptions

We make the following assumptions regarding the system in (2). These have been used in earlier works on adaptive LQG control (Abbasi-Yadkori & Szepesvári, 2011; Campi & Kumar, 1998b).

Assumption 1. The system is controllable and observable (Kailath, 1980), and there exists a known constant positive c such that $\bar{\theta} \in \mathcal{S} = S_0 \cap S_1$ where,

$$S_0 = \bigg\{\theta = (A,B) \,|\, (A,B) \text{ is controllable and}$$

$$(A,M) \text{ is observable where } Q = M^TM\bigg\},$$

$$S_1 = \bigg\{\theta = (A,B) \,|\, trace(\theta^T\theta) \leq c\bigg\}.$$

Assumption 2. We assume that the system noise is elementwise sub-Gaussian. Thus.

$$\mathbb{E}\left[exp(\gamma w_{t,j})|\mathcal{F}_t\right] \le exp(\frac{\gamma^2 L^2}{2}) \ \forall \ j \ and \ \forall \ t = 1, 2, \dots$$
(7)

Moreover, $\{w_t\}$ has the following properties.

- 1. $w_t \forall t = 1, 2, ...,$ is a martingale difference sequence.
- 2. $\mathbb{E}[w_{t+1}|\mathcal{F}_t] = 0$, and $\mathbb{E}[w_{t+1}w_{t+1}^T|\mathcal{F}_t] = I_n$.

2.2. Controller Design for a Known LQG Control System

Consider the following linear system,

$$x_{t+1} = \theta z_t + w_{t+1}, \tag{8}$$

where $\theta \in S$. Then the following facts are true (Kumar & Varaiya, 2015). There is a unique positive definite matrix $P(\theta)$ that satisfies the Riccati equation

$$P = Q + A^{T}PA - A^{T}PB(B^{T}PB + R)^{-1}B^{T}PA.$$
 (9)

The optimal control law for this system which minimizes the average cost (4) is given by $u_t = K(\theta)x_t$, where the "gain matrix" $K(\theta)$ is

$$K(\theta) := -(B^T P(\theta)B + R)^{-1} B^T P(\theta)A. \tag{10}$$

The optimal average cost is

$$J^{\star}(\theta) = trace(P(\theta)). \tag{11}$$

As a consequence of Assumption 1, the parameter set S is bounded, hence one can show that $P(\theta)$ is bounded as well, let D be a constant such that

$$D = \sup_{\theta \in \mathcal{S}} ||P(\theta)||_2 < \infty.$$
 (12)

Assumption 3. *For all* $\theta \in S$ *, we have*

1. $||A + BK(\theta)||_2 < 1$, therefore there exist a positive constant ρ such that,

$$\rho := \sup_{\theta \in \mathcal{S}} ||A + BK(\theta)||_2. \tag{13}$$

2. There exists a positive constant c_0 such that,

$$c_0 = \sup_{\theta \in \mathcal{S}} ||K(\theta)||_2 < \infty.$$
 (14)

2.3. Construction of Confidence Interval

In this section, given the history \mathcal{F}_t , we construct a "high-probability confidence ball," i.e., a set of plausible system parameters that contains the true parameter $\bar{\theta}$ with a high probability.

For $\lambda > 0$, define

$$Z_t = \lambda I + \sum_{s=0}^t z_s z_s^T, \tag{15}$$

where I is the identity matrix of dimension $(n+m) \times (n+m)$. The squared error of θ is given as

$$V_t(\theta) := \sum_{s=0}^{t-1} ||(x_{s+1} - \theta z_s)||_2^2.$$
 (16)

Then the L_2 -regularized squared error with regularization parameter $\lambda > 0$ is given by:

$$E_t(\theta) = \lambda ||\theta||_2^2 + V_t(\theta). \tag{17}$$

Let $\hat{\theta}_t$ be the L_2 regularized least-squares estimate of $\bar{\theta}$, i.e.

$$\hat{\theta}_t = \arg\min_{\theta \in \mathcal{S}} E_t(\theta). \tag{18}$$

Let $C_t(\delta)$ be the following confidence ball around $\hat{\theta}$,

$$C_t(\delta) := \left\{ \theta : trace\left((\theta - \hat{\theta}_t)^T Z_t(\theta - \hat{\theta}_t) \right) \le \beta_t(\delta) \right\}$$

where,

$$\beta_t(\delta) := \left(nL \sqrt{2 \log \left(\frac{\sqrt{\det(Z_t) \det(\lambda I)}}{\delta} \right)} + \sqrt{\lambda} c \right)^2.$$
(19)

Next, we show that $\bar{\theta}$ lies within the ball $C_t(\delta)$ with high probability.

Lemma 2.1. Define

$$E_1(t) = \left\{ \bar{\theta} \in \mathcal{C}_s(\delta/4), \ \forall \ s = 1, 2, \cdots, t \right\},$$

$$E_2(t) = \left\{ ||x_s|| \le d_t, \ \forall s \le t \right\},$$

where.

$$d_t := \frac{1}{1-\rho} \left(\frac{\eta}{\rho}\right)^{n+m} \left[2L\sqrt{n\log\frac{4nt(t+1)}{\delta}} + GZ_T^{\frac{n+m}{n+m+1}} \beta_t \left(\frac{\delta}{4}\right)^{(2(n+d+1))^{-1}}\right],$$

$$\eta := \max\left\{1, \sup_{\theta \in \mathcal{S}} ||\bar{A} + \bar{B}K(\theta)||\right\},$$

$$Z_T := \max_{0 \le t \le T} ||z_t||,$$

$$G := 2\left(\frac{2c(n+d)^{n+m+0.5}}{\sqrt{U}}\right)^{(n+m+1)^{-1}},$$

$$U := \frac{U_0}{H},$$

$$U_0 := \frac{1}{16^{n+d-2} \max\{1, c^{2(n+m-2)}\}},$$

$$H \text{ is constant such that } H > \max\left\{16, \frac{4c^2M^2}{(n+m)U_0}\right\},$$

$$M := \sup_{Y \ge 0} \frac{nL\sqrt{(n+d)\log\left(\frac{1+\frac{TY}{\lambda}}{\delta}\right)} + \lambda^{1/2}c}{Y}.$$

Let
$$E_1 := E_1(T)$$
 and $E_2 := E_2(T)$. Then,

$$\mathbb{P}\left(E_1 \cap E_2\right) \ge 1 - \frac{\delta}{2}.\tag{20}$$

Proof. See Lemma 4 in (Abbasi-Yadkori & Szepesvári, 2011). □

Lemma 2.2. On the event $E_2(t)$ defined in Lemma 2.1, the following holds,

$$\max_{1 \le s \le t} ||x_s|| \le X_t = Y_t^{n+m+1} \ \forall t = 1, 2, \dots, where,$$

$$Y_t := \max\left(e, \lambda(n+d)(e-1), \\ 4\left(c_1\log\left(\frac{1}{\delta}\right) + c_2\log\left(\frac{t}{\delta}\right)\right)\right) \times \\ \left(\log^2\left(4c_1\log(\frac{1}{\delta}) + 4c_2\log(\frac{t}{\delta})\right)\right),$$

where, c_1 and c_2 are problem dependant constants.

Proof. See Lemma 5 in (Abbasi-Yadkori & Szepesvári, 2011). □

3. RBMLE for LQG Systems

We employ a version of the RBMLE algorithm that proceeds in an episodic manner. Let t_k denote the starting time of the

Algorithm 1 RBMLE

Initialize:
$$t=0$$
 for $k=0,1,\cdots$ do
$$\operatorname{Set} \tau_k=0 \text{ and}$$

$$\theta_{t_k}=\arg\min_{\theta\in\mathcal{S}\cap\mathcal{C}_{t_k}(\delta)}\left\{V_t(\theta)+\alpha(t_k)J^*(\theta)\right\},$$
 while $\tau_k<2^k$ do
$$\theta_t=\theta_{t-1}$$

$$u(t)=K(\theta_t)x(t)$$

$$\tau_k\to\tau_k+1 \text{ and } t\to t+1$$
 end while end for

k-th episode. It lasts for 2^k time steps. At time t_k , it solves the following optimization problem:

$$\theta_{t_k} = \arg\min_{\theta \in \mathcal{S} \cap \mathcal{C}_{t_k}(\delta)} \left\{ V_t(\theta) + \alpha(t_k) J^*(\theta) \right\}, \quad (21)$$

where $\alpha(t) := \alpha_0 \sqrt{t}$ is the multiplicative pre-factor associated with the cost-bias term. Thus, θ_{t_k} is the cost-biased estimate of $\bar{\theta}$ given the operational history of the system \mathcal{F}_t . It implements the following control policy during episode k:

$$u(t) = K(\theta_{t_k})x(t) \ \forall \ t \in [t_k, t_{k+1}).$$

We note the key difference between RBMLE and OFU lies in the objective function that is being optimized at the beginning of an episode. While OFU optimizes the function $J^*(\theta)$ over the confidence ball $\mathcal{C}_t(\delta)$, RBMLE on the other hand optimizes the function $\alpha(t)J^*(\theta)+V_t(\theta)$. The second term $V_t(\theta)$ in the objective function is responsible for a better empirical performance of the RBMLE algorithm, which is shown in detail in Section 5. It is an interesting question to connect this the term $V_t(\theta)$ to a better regret bound of RBMLE.

We note that this is slightly modified version of the RBMLE algorithm that was proposed in (Campi & Kumar, 1998b) for LQG systems. The algorithm of (Campi & Kumar, 1998b) does not explicitly maintain a confidence interval. Instead it chooses θ_{t_k} as the minimizer of (21) over the set $\mathcal S$ i.e.

$$\arg\min_{\theta\in\mathcal{S}}\left\{V_t(\theta) + \alpha(t_k)J^{\star}(\theta)\right\}. \tag{22}$$

In the next couple of sections, we provide guarantees on the performance of RBMLE in terms of upper-bound on its regret, and also demonstrate that its empirical performance is better than other popular algorithms.

4. Regret Analysis

In this section, we focus on the theoretical analysis of the RBMLE algorithm that was discussed in Section 3. More specifically, we derive an upper bound on the regret of the RBMLE algorithm. The regret of a learning algorithm for LQG systems is defined as (Abbasi-Yadkori & Szepesvári, 2011):

$$R(T) = \sum_{t=0}^{T} c_t - TJ^*(\bar{\theta}). \tag{23}$$

The notion of regret was first introduced in (Lai & Robbins, 1985b) in context of multi-armed bandit problem. It has been widely used for characterizing the finite-time performance of algorithms that make sequential decisions (Lattimore & Szepesvári, 2020; Auer et al., 2002). Note that minimizing the regret is equivalent to minimizing the performance cost.

The following result allows us to decompose the regret R(T) into easy-to-analyze terms.

Lemma 4.1. The regret of a learning algorithm which implements $u(t) = K(\theta_t)x(t)$ is upper bounded as follow:

$$R(T) = R_1 + R_2 + R_3 + R_4, (24)$$

where,

$$R_{1} = \sum_{t=0}^{T} \left\{ x_{t}^{T} P(\theta_{t}) x_{t} - \mathbb{E} \left[x_{t+1}^{T} P(\theta_{t+1}) x_{t+1} | \mathcal{F}_{t} \right] \right\},$$

$$R_{2} = \sum_{t=0}^{T} \mathbb{E} \left[x_{t}^{T} \left(P(\theta_{t+1}) - P(\theta_{t}) \right) x_{t} | \mathcal{F}_{t} \right],$$

$$R_{3} = \sum_{t=0}^{T} \left\{ \left(\bar{A} x_{t} + \bar{B} u_{t} \right)^{T} P(\theta_{t}) \left(\bar{A} x_{t} + \bar{B} u_{t} \right) - \left(A_{t} x_{t} + B_{t} u_{t} \right)^{T} P(\theta_{t}) \left(A_{t} x_{t} + B_{t} u_{t} \right) \right\},$$

$$R_{4} = \sum_{t=0}^{T} \left(J(\theta_{t}) - J(\bar{\theta}) \right).$$

Proof. See Appendix A.

Next, we provide individual bounds on each of R_1, R_2, R_3 and R_4 on the event $E_1 \cap E_2$.

4.1. Bound on R_1

Theorem 4.2. On the event $E_1 \cap E_2$,

$$R_1 \le 2DW^2 \sqrt{2T\log\frac{8}{\delta}} + n\sqrt{B_\delta}$$

where,
$$B_{\delta} := b \log \left(\frac{4n\sqrt{b}}{v\delta}\right)$$
, $b := v + T(cDX_T)^2(1+c_0^2)$ and $W = nL\sqrt{2n\log\left(\frac{8nT}{\delta}\right)}$.

Proof. The proof is the same as that of Lemma 7 in (Abbasi-Yadkori & Szepesvári, 2011). □

4.2. Bound on R_2

Theorem 4.3. On the event $E_1 \cap E_2$,

$$R_2 \le 2DX_T^2 \log_2 T$$
,

where, X_T is defined in Lemma 2.2.

Proof. As defined in Lemma 4.1,

$$R_2 = \sum_{t=0}^{T} \mathbb{E}[x_t^T \left(P(\theta_{t+1}) - P(\theta_t) \right) x_t | \mathcal{F}_t].$$

Each term in the summation is non-zero only at the end of an episode when there is a policy change. Since there are $\log_2 T$ episodes till time T, there are $\log_2 T$ non-zero terms and each of them is bounded by $2DX_T^2$.

4.3. Bound on R_3

Theorem 4.4. On the event $E_1 \cap E_2$,

$$R_3 \le \frac{8cX_T^2D(1+c_0^2)}{\sqrt{\lambda}}\sqrt{T\beta_T\left(\frac{\delta}{8}\right)\log\frac{det(Z_T)}{det(\lambda I)}}.$$

where, $Z_T := \max_{0 \le t \le T} \|z_t\|$, and $\beta_T\left(\frac{\delta}{8}\right)$ is defined in 19.

Proof. The proof is the same as that of Lemma 13 in (Abbasi-Yadkori & Szepesvári, 2011). □

4.4. Bound on R_4

Theorem 4.5. On the event $E_1 \cap E_2$,

$$R_4 \le \frac{\sqrt{2}}{\alpha_0(\sqrt{2}-1)} \left(\beta_T \left(\frac{\delta}{4}\right) + \lambda c^2\right) \sqrt{T}.$$

Proof. See Appendix B.

Now that we have established upper bounds on the terms R_1, R_2, R_3 and R_4 , we can use these in conjunction with the decomposition result of Lemma 4.1 in order to bound the regret of RBMLE as follows.

Theorem 4.6. For any $\delta \in (0,1)$ and T > 0, the regret of the RBMLE Algorithm is upper-bounded with a probability at least $1 - \delta$ as follows:

$$R(T) \le \mathcal{O}\left(\sqrt{T\log\frac{1}{\delta}}\right).$$
 (25)

where, problem dependant constants and terms logarithmic in T are hidden.

Proof. See Appendix C

5. Empirical Performance

In this section, we evaluate the empirical performance of RBMLE and compare it with the existing popular learning algorithms such as OFU (Abbasi-Yadkori & Szepesvári, 2011) and non-Bayesian Thompson Sampling (Abeille & Lazaric, 2017).

Our experiment setup is as follows: We initialize the system state as x(0) = 0 and use the first 10 time-steps with randomly generated inputs to initialize the estimates.

We ensure that all the algorithms utilize the same realization of initial random inputs, and the same external noise w(t) at each time t. More details on implementation of OFU, TS can be found in (Dean et al., 2018). OFU is implemented using a heuristic projected gradient descent approach. Note that the RBMLE algorithm differs from OFU only in that it optimizes a slightly different objective function, $\alpha(t)J^*(\theta)$ implementation is similar.

We plot the averaged regrets along with the standard deviation for a time horizon of $2000\ (T=2000)$ steps. Each experiment is performed over 200 iterations. We carry out simulation studies for the following systems, starting with a simple example in which the system state and control input are both scalars. In Figures 1 and 2, we compare the performance of RBMLE with OFU and TS for this simple example. It is evident that RBMLE has much lower average regret compared to OFU and TS.

1. **Unstable Laplacian System** This system represents a marginally unstable Laplacian dynamics, and has been previously studied in (Dean et al., 2018; Abbasi-Yadkori et al., 2019; Dean et al., 2020b; Tu & Recht, 2018). The system matrices are given as follows.

$$\bar{A} = \begin{bmatrix} 1.01 & 0.01 & 0 \\ 0.01 & 1.01 & 0.01 \\ 0 & 0.01 & 1.01 \end{bmatrix}, \bar{B} = I_3, Q = 10I_3, R = I_3$$

 Chained Integrator Dynamics: In this example, we consider a chained integrator system with 2dimensional states and 2-dimensional input.

$$\bar{A} = \begin{bmatrix} 1 & 0.1 \\ 0 & 1 \end{bmatrix}, \bar{B} = I_2, Q = 10I_2, R = I_2$$
 (26)

6. Concluding Remarks

We proposed the RBMLE algorithm for solving the adaptive linear quadratic control problem. It is an alternative to the OFU approach of (Abbasi-Yadkori & Szepesvári, 2011),

Figure 1. Unstable Laplacian System (Regret Comparision)

Figure 2. Chained Integrator Dynamics (Regret Comparision)

and generates a reward biased estimate of the unknown parameter by optimizing an objective function which is a modification of the log-likelihood function, one in which a bias term is added to give a higher preference for those parameter values that generate higher average rewards. The key difference between RBMLE and OFU is that they optimize different objective functions while generating an estimate of the underlying system parameter. OFU optimizes the objective function $J^*(\theta)$, while RBMLE additionally includes a term $V_t(\theta)$ that is representative of the log-likelihood of making the observations given that θ is the true parameter value. This difference is responsible for a better empirical performance of the RBMLE algorithm, and it remains to be seen in future works whether this additional term yields a better regret bound for the RBMLE over the OFU or Thompson Sampling.

We establish bounds on its regret, and show that it is competitive with OFU. We show, via extensive simulations performed for a broad range of real-world systems, that the empirical performance of RBMLE is much better than OFU and Thompson Sampling. Along with recent works on RBMLE for MDPs (Mete et al., 2021), stochastic Multi-

Armed Bandits (Liu et al., 2020) and Contextual bandits (Hung et al., 2020), this work on LQG substantiates the case of RBMLE as a promising alternative to the much celebrated Upper Confidence Bound and Thompson Sampling for model based RL problems. Hence, an important topic for future research is analyzing RBMLE for important settings such as that of RL for constrained MDPs (Altman, 1999), RL for continuous spaces (Ortner & Ryabko, 2013) and Bayesian Optimization. Developing efficient computational procedures for RBMLE for MDPs is another challenging open problem.

A. Proof of Lemma 4.1

Proof. The Bellman optimality equation for LQ problem can be written as:

$$J^{\star}(\theta_t) + x(t)^T P(\theta_t) x(t) = \min_{u} \left(x^T(t) Q x(t) + u^T R u + \mathbb{E} \left[x'_{u}^T(t+1) P(\theta_t) x'_{u}(t+1) | \mathcal{F}_t \right] \right),$$

where $x_u'(t+1) = A_t x(t) + B_t u + w(t+1)$. Also note that $x(t+1) = \bar{A}x(t) + \bar{B}u(t) + w(t+1)$.

$$J^{\star}(\theta_{t}) + x(t)^{T} P(\theta_{t}) x(t) = x(t)^{T} Q x(t)$$

$$+ u(t)^{T} R u(t) + \mathbb{E} \left[x'_{u(t)}^{T} (t+1) P(\theta_{t}) x'_{u(t)} (t+1) | \mathcal{F}_{t} \right].$$
(28)

Substituting $\tilde{x}_{u(t)}(t+1)$, x(t+1) and then using the martinangle property of noise (Assumption 2), we get

$$\sum_{t=0}^{T} \left\{ x(t)^{T} Q x(t) + u(t)^{T} R u(t) - J^{\star}(\theta_{t}) \right\}$$

$$= R_{2} + R_{3} + R_{4}.$$
(30)

Subtracting $TJ^{\star}(\bar{\theta})$ from both sides, we get,

$$R(T) = R_1 + R_2 + R_3 + R_4.$$

B. Proof of Theorem 4.5

Proof. Let t_k be the time of the beginning of episode k. Then the RBMLE algorithm implements the policy

$$u(t) = K(\theta_{t_k})x(t) \ \forall \ t_k \le t < t_{k+1}.$$
 (31)

Note that $t_k=2^k$. Therefore Using Lemma 4.1, we have

$$\begin{split} R_4 &= \sum_{t=0}^T \left(J(\theta_t) - J(\bar{\theta})\right) \\ &\leq \sum_{k=1}^{\lceil \log_2 T \rceil} 2^k \left(J(\theta_{t_k}) - J(\bar{\theta})\right) \\ &\leq \sum_{k=1}^{\lceil \log_2 T \rceil} \frac{2^k}{\alpha_0 \sqrt{2}^k} \left(V_{t_k}(\bar{\theta}) - V_{t_k}(\theta_{t_k})\right) \\ &\leq \sum_{k=1}^{\lceil \log_2 T \rceil} \frac{\sqrt{2}^k}{\alpha_0} \left(V_{t_k}(\bar{\theta}) - V_{t_k}(\hat{\theta_k}) + V_{t_k}(\hat{\theta_k}) - V_{t_k}(\theta_{t_k})\right) \\ &\leq \sum_{k=1}^{\lceil \log_2 T \rceil} \frac{\sqrt{2}^k}{\alpha_0} \left(E_{t_k}(\bar{\theta}) - E_{t_k}(\hat{\theta_k}) + \lambda S^2\right) \\ &\leq \sum_{k=1}^{\lceil \log_2 T \rceil} \frac{\sqrt{2}^k}{\alpha_0} \left(||(\bar{\theta} - \hat{\theta_k})^T Z(t_k)||_2^2\right) + \lambda c^2\right) \\ &\leq \sum_{k=1}^{\lceil \log_2 T \rceil} \frac{\sqrt{2}^k}{\alpha_0} \left(\beta_{t_k}(\delta/4)\right) + \lambda c^2\right) \\ &\leq \frac{\sqrt{2}}{\alpha_0(\sqrt{2} - 1)} \left(\beta_T(\delta/4)\right) + \lambda c^2\right) \sqrt{T}. \end{split}$$

C. Proof of Theorem 4.6

Proof. As shown in Lemma 4.1, the regret R(T) is given by:

$$R(T) = R_1 + R_2 + R_3 + R_4 (32)$$

On the event $E_1 \cap E_2$, we substitute the individual bounds on R_1, R_2, R_3 and R_4 to get following bound on R(T):

$$\begin{split} R(T) \leq & 2DW^2 \sqrt{2T\log\frac{8}{\delta}} + n\sqrt{B_\delta} \\ & + 2DX_T^2\log_2 T \\ & + \frac{8X_T^2SD(1+C^2)}{\sqrt{\lambda}} \sqrt{T\beta_T\left(\frac{\delta}{8}\right)\log\frac{det(Z_T)}{det(\lambda I)}} \\ & + \frac{\sqrt{2}}{\alpha_0(\sqrt{2}-1)} \left(\beta_T(\delta)\right) + \lambda c^2\right)\sqrt{T}. \end{split}$$

Since $E_1 \cap E_2$ occurs with probability at least $1 - \delta$ (Lemma 2.1), we get the desired result.
