EXPLORING THE DYNAMICS OF THE CIRCUMCENTER MAP

NICHOLAS MCDONALD, RONALDO GARCIA, AND DAN REZNİK

Abstract. Using experimental techniques, we study properties of the “circumcenter map”, which sends a polygon to a scaled and rotated copy of itself. We also explore the topology of area-expanding and area-contracting regions induced by this map.

1. Introduction

Using simulation and visualization techniques, we explore rather interesting plane curves implied by a certain map applied to a generic polygon. For a preview of the graphical results, see Figures 12 and 13. Let us first define this map, called here the “circumcenter map”. Referring to Figures 1 and 2:

Definition 1 (Circumcenter Map). Given a point \( M \) in the plane of a polygon \( P = P_1, \ldots, P_n \), the circumcenter map \( C_M(P) \) yields a new polygon \( P' \) whose vertices are the circumcenters of \( MP_1P_2, MP_2P_3, \ldots, MP_nP_1 \), respectively.

In Section 2 we review classical results that underpin the phenomena studied herein, namely: (i) \( C_M(P) \) yields the (half-sized) \( M \)-antipedal polygon\(^1\); (ii) as a consequence of a result proved in [8], \( n \) consecutive applications of this map, i.e., \( C^n_M(P) \) yields a new polygon which is the image of \( P \) under a rigid rotation about \( M \) by \( \alpha \), followed by a scaling of \( s \) with respect to \( M \); (iii) subsequent \( n \) applications of the map result in a transformation with identical parameters \( \alpha \) and \( s \).

Given a starting polygon \( P \), we will study the locus of \( M \) such that after \( n \) applications of the map \( s = 1 \) (resp. \( \alpha = 0 \)), i.e., the resulting polygon has the same area (resp. orientation) as the original one. Experiment reveals curious structure and symmetry on such curves.

Main results. The claims below were initially evidenced by simulation. Most are proved with a computer algebra system (CAS) and their proofs will be omitted.

- We explicitly derive the locus of \( M \) such that \( s = 1 \), when \( P \) is an equilateral triangle (resp. a square). This results in a 6-degree (resp. 8-degree) polynomial on the coordinates of \( M \).
- If \( P \) is a regular \( n \)-gon, the locus of \( M \) such that \( \alpha = 0 \) is the union of \( n \) lines through the centroid of \( P \), rotated about each other by \( \pi/n \).
- In all cases there is a discrete set of locations such that both \( s = 1 \) and \( \alpha = 0 \).

We study the map with \( P \) an equilateral triangle, showing that if \( M \) is on any of these locations the map is 3-periodic. If \( M \) is at the centroid of the equilateral, the map is 2-periodic.

\(^1\)The \( M \)-antipedal \( P' \) of a polygon \( P \) is such that \( P' \) is its \( M \)-pedal.

N. McDonald, ETHZ, Lausanne, Switzerland. nicholasmcdonald40@gmail.com.
D. Reznik*, Data Science Consulting, Rio de Janeiro, Brazil. dreznik@gmail.com.
Figure 1. Given a point $M$, the circumcenter map sends a triangle $T = ABC$ to $T' = A'B'C'$ with vertices at the circumcenters of $MBC$, $MCA$, $MAB$, respectively. Also shown are the vertices $a'', b'', c''$ of the $M$-pedal of $T'$ which is a half-sized version of $T$.

Figure 2. If $P = \{P_i\}$ is a 5-gon (red), $C_M(P)$ sends it to another 5-gon (green) which is a half-sized version of the $M$-antipedal of $P$ (magenta). Also shown is the construction for $P_1'$ which is the center of circle $MP_1P_{i+1}$ (dashed gray).

- Based on compactified visualizations of the $s = 1$ boundary, we conjecture that for all $n$: (i) there is only one connected region such that $s > 1$, and (ii) if $n$ is odd (resp. even), the number of connected regions such that $s < 1$ is given by $1 + n(n + 1)/2$ (resp. $1 + n^2/2$), i.e., in both cases it is of $O(n^2)$.
We show that the $s = 1$ boundary may change in topology upon simple affine stretching of an initial polygon, though a more in-depth study is still lacking.

**Related Work.** In [9], properties of the “central” sub-triangle defined by a four-fold subdivision of a reference triangle (using cevians) are studied. A map based on the 2nd isodynamic point of a polygon’s subtriangles is described in [6].

**Article Organization.** In Section 2 we review classical results that show that $n$ applications of the circumcenter map are a similarity transform with parameters $s$ and $\alpha$ which only depend on $M$. In Section 3 we describe properties of the map for the initial polygon a triangle or a square. In Section 4 we extend the analysis for regular polygons of any number of sides. Conclusions and suggestions for further exploration appear in Section 5. To facilitate reproducibility, explicit expressions for the circumcenter map appear in Appendix A.

## 2. Review: Stewart’s Result

Note: this section can be skipped (and returned to later) if the reader is mostly interested in simulation results.

Recall that (i) the $M$-pedal polygon of a reference polygon $P$ has vertices at the intersections of perpendiculars dropped from $M$ onto the sides of $P$; (ii) the $M$-antipedal polygon of $P$ is such that $P$ is its $M$-pedal. Finally, the $M$-reflection polygon of $P$ has vertices at the reflections of $M$ about the vertices of $P$. Clearly:

**Remark 1.** the $M$-reflection polygon of $P$ is the twice-sized $M$-pedal polygon of $P$, with $M$ as the homothety center.

Let $C_M(P)$ denote the circumcenter map as in Section 1.

**Lemma 1.** The image of $C_M^{-1}(P)$ is the $M$-reflection polygon $P$.

**Proof.** By definition, vertex $P_i'$ (resp. $P_{i+1}'$) of $P'$ is the center of a circle $K_i$ passing through $M, P_i, P_{i+1}$ (resp. $K_{i+1}$ passing through $M, P_{i+1}, P_{i+2}$). The inverse circumcenter map $P = \{P_i\}$ comprises the non-$M$ intersections between consecutive
circles $\mathcal{K}_i$ and $\mathcal{K}_{i+1}$. For each such pair the intersections $M, P_i$ are symmetric about $P_i'P_{i+1}'$. □

Using Remark 1 and Lemma 1, the following property is illustrated in Figure 2:

**Corollary 1.** $C_M(\mathcal{P})$ is homothetic to the $M$-antipedal of $\mathcal{P}$, with ratio 1/2 and homothety center $M$.

Recall a well-known result by Johnson [2, Theorem 2c]:

**Result (Johnson, 1918).** If two polygons $\mathcal{F}$ and $\mathcal{F}'$ with no parallel sides are similar, there exists a point $M$, called the self-homologous point, such that $\mathcal{F}'$ is a rigid rotation of $\mathcal{F}$ about $M$ followed by uniform scaling about the same point.

Using a definition in [8, Construction 1]:

**Definition 2 (Miquel Map).** Given a point $M$ and an angle $\theta$, let $\mathcal{M}$ denote a map that sends a polygon $\mathcal{P} = \{P_i\}$, to a new polygon $\mathcal{P}'$ (known as the Miquel polygon) with each vertex $P_i'$ on line $P_iP_{i+1}$, and such that $\angle P_iP_i'M = \theta$, for $i = 1, \ldots, n$.

Let $\mathcal{M}^k$ denote $k$ successive applications of the map. The following key result was proved in [8, Theorem 2]:

**Theorem (Stewart, 1940).** Let $\mathcal{P}$ be a polygon with $n$ sides. $\mathcal{M}^n(\mathcal{P})$ is similar to $\mathcal{P}$ with $M$ as the self-homologous point. If follows that if $\mathcal{M}^i(\mathcal{P})$ is similar to $\mathcal{M}^j(\mathcal{P})$, then if $i = j \pmod{n}$.

Let $\mathcal{M}_\perp$ denote the case when $\theta = \pi/2$. Definition 2 implies that $\mathcal{M}_\perp(\mathcal{P})$ is the pedal polygon of $\mathcal{P}$ with respect to $M$. Referring to Figure 4:

**Corollary 2.** $\mathcal{M}_\perp^n(\mathcal{P})$ is self-homologous to $\mathcal{P}$, i.e., it is an image under rigid rotation and uniform scaling of $\mathcal{P}$ about $M$.

The inverse map $\mathcal{M}_\perp^{-1}(\mathcal{P})$ yields the $M$-antipedal polygon of $\mathcal{P}$. Referring to Corollary 1:

**Remark 2.** $C_M(\mathcal{P})$ is a half-sized homothety of $\mathcal{M}_\perp^{-1}(\mathcal{P})$ with respect to $M$.

Since the pedal transformation has an inverse, $\mathcal{M}_\perp^{-n}(\mathcal{P})$ will be similar to $\mathcal{P}$. Referring to Figure 4, and noting that the scaling in Corollary 1 scaling does not affect similarity:

**Corollary 3.** $C_M^n(\mathcal{P})$ is similar to $\mathcal{P}$.

Let $\mathcal{P}' = C_M^n(\mathcal{P})$, and $\mathcal{P}'' = C_M^{2n}(\mathcal{P}')$. Express these as $P' = T.M$, and $P'' = T'.P'$, where $T$, $T'$ are similarity transforms (rotation+scaling about $M$).

**Proposition 1.** $T = T'$.

**Proof.** Since $P' = T.P$, then $C_M^n(TP) = C_M^n(TP)$. By definition (see Section 1), the circumcenter map is based on the circumcenters of subtriangles of a given triangle. Since circumcenters are triangle centers (see [3]), they are equivariant over similarity transforms, therefore, $C_M^n(TP) = TC_M^n(P) = T^2.P$, i.e., $C_M^n(P') = T.P'$. □

In Figures 5 and 6, we illustrate a statement by Stewart in [8], namely, that intermediate applications of the map produce polygons “as diverse in shape as is imaginable”.
3. The $n = 3$ and $n = 4$ cases

In this section we study the curves prescribed by area preservation ($s = 1$) of the $n$-times applied circumcenter map where the starting polygon is a triangle or quadrilateral.

Let $P = ABC$ be a triangle, and $P'$ result from 3 consecutive applications of the circumcenter map, i.e., $P' = C^3_M(P)$. Let $A(Q)$ denote the area of a polygon $Q$. Via CAS, obtain:
Proposition 2. The ratio of sides of \( P' = A'B'C' \) and \( P \) is given by:

\[
\frac{|A' - B'|}{|A - B|} = \frac{|A' - C'|}{|A - C|} = \frac{|B' - C'|}{|B - C|} = \frac{l_a l_b l_c m_a m_b m_c}{8 A(ABM)A(BCM)A(ACM)}
\]

where \( l_a = |B - C|, l_b = |C - A|, l_c = |A - B|, m_a = |A - M|, m_b = |B - M|, m_c = |C - M|.

Proposition 3. Let \( \alpha \) denote the rotation of \( P' \) with respect to \( P \). Then:

\[
\cos \alpha = \frac{m_c^2 (m_a^2 + m_b^2)A(ABM) + m_b^2 (m_a^2 + m_c^2)A(ACM) + m_a^2 (m_b^2 + m_c^2)A(BCM)}{l_a l_b l_c m_a m_b m_c}
\]

The case of the equilateral. Let \( R = ABC \) be an equilateral triangle with vertices \( A = (1, 0) \), \( B = (-1, \sqrt{3})/2 \), \( C = (-1, -\sqrt{3})/2 \). Let \( R' = C_3^{\dagger}(R) \) with \( M = (x_m, y_m) \). Let \( s = A(R')/A(R) \). Via CAS obtain:

Proposition 4. Departing from an equilateral \( R \), one obtains \( s = 1 \) when \( M = (x_m, y_m) \) satisfies:

\[
3 x_m^6 - y_m^6 - 12 x_m^5 + 9 y_m^4 + (-27 y_m^2 + 9) x_m^4 + (24 y_m^2 + 6) x_m^3 + (33 y_m^4 + 18 y_m^2 - 6) x_m^2 + (36 y_m^4 - 18 y_m^2) x_m - 6 y_m^2 = 0
\]

Figure 6. Diverse intermediate shapes (with scale and rotation removed) obtained from the first \( n \) applications of the circumcenter map. Each sequence departs from a regular 4-, 5-, and 6-gon, with the rightmost vertex \( P_1 = (1, 0) \), and \( M = (2, 0) \).
Figure 7. **Left:** Nine iterations of the circumcenter map departing from an equilateral (solid red) centered on $O$. $M$ is placed in an area-shrinkage zone (green). A new, smaller equilateral (red) is produced every 3 applications of the map. **Right:** with $M$ on the area-expansion zone (green), the area expands upon every 3 applications of the map.

Figure 8. With $M$ on the boundary between the expansion (red) and contraction (green) regions, triangles 3 generations apart are rigid rotations of each other (no net expansion nor contraction).

Figures 7 and 8, illustrate sequential applications of the circumcenter map for the cases of $M$ in an area-contracting, area-expanding, and the boundary in between them defined in Proposition 4.

**Proposition 5.** The rotation $\alpha$ of $\mathcal{R}'$ with respect to $\mathcal{R}$ is zero when $y_m(y_m^2 - 3x_m^2) = 0$.

As shown in Figure 9, the topology of the boundary between expansion and contraction regions is highly dependent on the shape of the starting triangle.
As the equilateral (red, left) is stretched along the horizontal direction, the boundary of $C_{\Delta}^3$ regions of area expansion (red) and contraction (green) change in topology.

Referring to Figure 10:

**Proposition 6.** There are six points on Proposition 4 such that $\alpha = 0$. These are: $K_1 = (1 + \sqrt{3}, 0)$, $K_2 = (1 - \sqrt{3}, 0)$, and their rotations by $\pm 2\pi/3$.

Let $R_i = A_iB_iC_i$ denote the image of $R$ under $i$ iterations of the circumcenter map. As shown above $R_3$ is similar to $R$. Referring to Figure 10(left):

**Proposition 7.** If $M = K_1$, $R_3 = R$ and:

\[
A_1 = (1, 0), \quad B_1 = (1 + \frac{\sqrt{3}}{2}, \frac{3}{2} + \sqrt{3}), \quad C_1 = (1 + \frac{\sqrt{3}}{2}, -\frac{3}{2} - \sqrt{3})
\]

\[
A_2 = (-2 - \sqrt{3}, 0), \quad B_2 = (1 + \frac{\sqrt{3}}{2}, \frac{3}{2}), \quad C_2 = (1 + \frac{\sqrt{3}}{2}, -\frac{3}{2}).
\]

$R_1$ (resp. $R_2$) has internal angles $30^\circ, 75^\circ, 75^\circ$ (resp. $150^\circ, 15^\circ, 15^\circ$).

Referring to Figure 10(right):

**Proposition 8.** If $M = K_2$, $R_3 = R$ and:

\[
A_1 = (1, 0), \quad B_1 = (1 - \frac{\sqrt{3}}{2}, -\frac{3}{2} + \sqrt{3}), \quad C_1 = (1 - \frac{\sqrt{3}}{2}, \frac{3}{2} - \sqrt{3})
\]

\[
A_2 = (\sqrt{3} - 2, 0), \quad B_2 = (1 - \frac{\sqrt{3}}{2}, \frac{3}{2}), \quad C_2 = (1 - \frac{\sqrt{3}}{2}, -\frac{3}{2}).
\]

$R_1$ (resp. $R_2$) has internal angles $30^\circ, 75^\circ, 75^\circ$ (resp. $150^\circ, 15^\circ, 15^\circ$).

Referring to Figure 11, it can be shown that:

**Proposition 9.** When $M$ is the centroid of $R$, repeated applications of the circumcenter are 2-periodic, where the first triangle is $R$ and the second one is a reflection of $R$ about said centroid.

The case of the square. Let $Q = ABCD$ be a square with with vertices $A = (1, 0), B = (0, 1), C = (-1, 0), D = (0, -1)$. Let $Q' = C_{\Delta}^4(Q)$, with $M = (x_m, y_m)$. Via CAS obtain:

**Proposition 10.** Departing from the square $Q$, $s = 1$ occurs when $M = (x_m, y_m)$ satisfies:

\[
15x_m^8 - 68x_m^6y_m^2 + 90x_m^4y_m^4 - 68x_m^2y_m^6 + 15y_m^8 - 64x_m^6 + 64x_m^4y_m^2 + 64x_m^2y_m^4 - 64y_m^6 + 98x_m^4 + 52x_m^2y_m^2 + 98y_m^4 - 64x_m^2 - 64y_m^2 + 15 = 0
\]
Figure 10. Left: departing from an equilateral $ABC$, when $M$ is at the critical point $K^+ = (1 + \sqrt{3}, 0)$, repeated applications of the circumcenter map will cycle indefinitely through the 3 canonical triangles shown (red, green, blue). Right: With $M = K^- = (1 - \sqrt{3}, 0)$, the sequence is also 3-periodic, and the canonical triangles obtained are as shown.

Figure 11. Left: 36 iterations of the circumcenter map with $M$ close to the centroid $O$ of the starting equilateral. A slightly expanding sequence is shown. Right: If $M = O$, the sequence becomes 2-periodic, the original $ABC$ (blue) and its reflection about $O$ (green).

4. Conjectures for all $n$

Let $P$ be a regular $n$-gon, $n \geq 3$, with centroid $O = (0, 0)$ and a first vertex at $(1, 0)$. Figure 12 illustrates the partitioning of the plane into area-contracting and area-expanding regions by $n$ applications of the map, for $n = 3, 4, 5, 6$.

Let $P' = C^n_M(P)$. Let $\alpha$ be the angle of rotation of the similarity that takes $P$ to $P'$.

**Conjecture 1.** The locus of $M$ such that $\alpha = 0$ is the union of $n$ lines along directions $k\pi/n$, $k = 0, \ldots, n - 1$.

To facilitate region counting, in Figure 13 the plane is compactified into a single hemisphere. Table 1 shows the counts of area-contracting regions. This pattern suggests:
Conjecture 2. For all $n$ there a single connected area-expanding connected region. Let $k$ denote the number of area-contracting contiguous regions. Then:

$$k = \begin{cases} r^* + n(n+1)/2, & \text{odd } n \\ 1 + n^2/2, & \text{even } n \end{cases}$$

where $r^* = 0$ if $n = 3$, and 1 otherwise.

Conjecture 3. $s$ approaches infinity as $M$ approaches a side of $P$ (or an extension thereof).
Table 1. Region count according to Figure 13.

**Figure 13.** Area-expansion (red) and area-contraction (green) regions for regular $n$-gons, compactified (via stereographic projection) to a single hemisphere; the south pole (center) is “infinity”. From top-to-bottom, left-to-right, $N = 3, \ldots, 11$. 
5. CONCLUSION

An video walk-through of our experiments appears in [5].

The circumcenter map can be generalized to the $X_k$-map, where $X_k$ is some triangle center (see [3]). For example, the $X_2$-map sends a polygon to one with vertices at the barycenters of $MP_iP_{i+1}$ of vertices of a given polygon. In such a case, an iteration produces a sequence of ever-shrinking polygons which converges to $M$. If the starting polygon is a triangle, a few notable cases include: (i) the $X_4$-map (orthocenter) is area preserving for all $M$, and the sequence of triangles tends to an infinite line; (ii) the $X_{16}$-map (2nd isodynamic point) induces regions of the plane such that 3 applications of the map are the identity (no rotation and no scaling), see [6]. A question not addressed here, is whether a certain $X_k$-map is integrable in the sense of [1, 4].

We would like to thank Sergei Tabachnikov, and Richard Schwartz for their encouragement during the early experimental results, and Darij Grinberg for contributing a proof to Corollary 3; we thank Mark Helman for relating this phenomenon with a 1940 result by Stewart [8]. We are indebted to Wolfram Communities for inviting us to post a short description of our experimental results, see [7].

**Appendix A. Explicit Circumcenter Map**

Consider a generic polygon with vertices $(x_i, y_i)$, $i = 1, \ldots, n$, and a point $M = (x_m, y_m)$. The $M$-circumcenter map is a new polygon with vertices $(p_i, q_i)$ given by:

$$p_i = \frac{r'_i x_m + 2(y_{i+1} - y_i)(x_{i+1} - x_i)y_m + 2(y_{i+1} - y_i)(x_iy_{i+1} - x_{i+1}y_i)}{r_i}$$

$$q_i = -\frac{-r'_i y_m + 2(y_{i+1} - y_i)(x_{i+1} - x_i)x_m - 2(x_{i+1} - x_i)(x_iy_{i+1} - x_{i+1}y_i)}{r_i}$$

where $r_i = (x_{i+1} - x_i)^2 + (y_{i+1} - y_i)^2$, and $r'_i = (x_{i+1} - x_i)^2 - (y_{i+1} - y_i)^2$.
