Abstract

Blockchain network deployment and evaluation have become prevalent due to the demand for private blockchains by enterprises, governments, and edge computing systems. Whilst a blockchain network’s deployment and evaluation are driven by its architecture, practitioners still need to learn and carry out many repetitive and error-prone activities to transform architecture into an operational blockchain network and evaluate it. Greater efficiency could be gained if practitioners focus solely on the architecture design, a valuable and hard-to-automate activity, and leave the implementation steps to an automation framework.

This paper proposes an automation framework called NVAL (Network Deployment and Evaluation Framework), which can deploy and evaluate blockchain networks based on their architecture specifications. The key idea of NVAL is reusing and combining the existing automation scripts and utilities of various blockchain types to deploy and evaluate incoming blockchain network architectures. We propose a novel meta-model to capture blockchain network architectures as computer-readable artefacts and employ a state-space search approach to plan and conduct their deployment and evaluation. An evaluative case study shows that NVAL successfully combines seven deployment and evaluation procedures to deploy 65 networks with 12 different architectures and generate 295 evaluation datasets whilst incurring a negligible processing time overhead.

Keywords: Blockchain, Distributed Ledger, Deployment, Evaluation, Automation, Framework

1. Introduction

A blockchain network is a peer-to-peer software system maintained and operated by mutually-distrusting participants \[1, 2\]. This system stores a secure database, also known as a blockchain or a distributed ledger \[3, 4, 5\]. A blockchain network also acts as a secure replicated state machine \[6\] that runs distributed software programs known as smart contracts. Traditionally, blockchain networks such as Bitcoin \[7\] and Ethereum \[6\] are public entities that emerge from the voluntary participation of global Internet users without premeditated design and deployment. However, recent years have witnessed the rise of the private blockchain networks \[8\] in response to the demand by enterprises, governments, and IoT use cases \[9\], such as supply chains, central bank digital currency (CBDC) \[10\], and peer-to-peer resource trading in a smart electricity grid \[11\]. Unlike public blockchain networks, private networks have architectures that participating organisations can design to refine the networks’ performance, resource consumption, and security \[1\]. These architectures capture design decisions such as whether a network is segmented into logical channels, how those channels are configured, where blockchain nodes are deployed, and who control those blockchain nodes \[12\]. As blockchain network architectures exist, deploying and evaluating blockchain networks based on architecture specifications have become feasible and prevalent.

Blockchain network deployment denotes transforming a blockchain network architecture into an operational blockchain network. For instance, to deploy an Ethereum blockchain channel\[1\] practi-
tioners must acquire or build Ethereum software clients compatible with the targeted infrastructure described in the architectural specification. The placement of Ethereum clients on hardware nodes also follows the network architecture. Practitioners must also configure clients to form logical channels amongst the right nodes and run a correct protocol according to the architecture. The successful deployment also requires practitioners to know the unique pitfalls and workarounds of blockchain implementations. For example, Go-Ethereum (Geth) clients cannot discover peers automatically without the support of special nodes called bootnodes. As can be seen, blockchain network deployment essentially transforms an architectural specification into concrete instructions and configurations and carries them out. Mistakes in any step can result in an inoperational or non-compliant blockchain network.

Blockchain network evaluation assesses quality attributes of a blockchain network, such as performance, resource consumption, and security. This process can happen before the deployment by leveraging simulations or after the deployment by leveraging benchmark suites such as Hyperledger Caliper and Blockbench. Simulations consume blockchain network architectures as inputs directly, whilst benchmarks work on the blockchain networks resulting from the deployment of architectures. Both evaluation forms introduce an additional layer of complexity, requiring practitioners to learn the operation and configuration of benchmark suites or simulators.

The above discussions highlight that deployment and evaluation are time-consuming, error-prone, and knowledge-intensive processes that are tightly coupled to blockchain network architectures. Thus, practitioners and researchers would benefit from an automation approach that works directly with context-rich architectural specifications of blockchain networks. A recent survey on the state-of-practice of blockchain-oriented software engineering highlights such automation as a highly demanded tool because it offers practitioners with “one-click” blockchain network deployment for development and testing. Such an automation framework would maximise the value of practitioners’ time by enabling them to focus on hard-to-automate activities (designing architecture) and mitigating implementation errors.

In addition to the generic IT automation tools (Ansible, Terraform), some blockchain-specific frameworks (e.g., PlaTIBART, Hyperledger Bevel, Hyperledger Composer, MixBytes Tank, Puppeth) and cloud services have been proposed to automate blockchain network deployment. The generic IT automation tools fail to enable an architecture-driven automation approach. Practitioners still need to manually transform blockchain network architectures into instructions and configurations, as generic IT automation tools require specific instructions or specifications to deploy and evaluate a blockchain network. Whilst blockchain-specific automation frameworks and services abstract implementation details better than generic IT automation tools, most of them either require low-level and technology-specific (Bevel, PlaTIBART) or overly-simplified specifications. Moreover, most blockchain deployment frameworks and services do not support heterogeneous multi-channel blockchain networks, an emerging blockchain network type that employs multiple blockchain protocols within a network for optimisation purposes. Another drawback of the existing solutions is that they support only a few types of blockchain networks, and practitioners have little control over the scope of these tools. Due to the changing landscape of blockchain technologies, this limited extensibility limits the longevity of these automation tools.

This paper proposes NVAL (Network Deployment and Evaluation framework), an architecture-driven and extensible automation framework for blockchain network deployment and evaluation. Architecture-driven means NVAL accepts high-level and expressive architecture specifications as input rather than low-level and technology-specific specifications such as host addresses and protocol configurations. NVAL specifically targets the described heterogeneous, multi-channel blockchain networks. Being extensible means NVAL is designed such that end users can extend the functional scope of the framework, such as the type of blockchain technology and hardware infrastructure it supports, without relying on a central authority such as a project owner or service provider.

Synthesising instructions and configurations for
deploying and evaluating blockchain networks is challenging due to the rapid advance of blockchain technologies. Fortunately, the open-source community has developed many automation scripts for blockchains. As of February 2022, there exist 52 open-source GitHub repositories on automated blockchain network deployment using Ansible, 67 repositories using Terraform, and 35 repositories using other scripting languages. Many blockchain implementations’ official documentation also provides instructions for deploying private networks. NVAL’s main idea is to transform these valuable materials into interoperable software services and compose them automatically at runtime to respond to incoming architectural specifications. For instance, a request for a blockchain network consisting of two Ethereum channels and one Fabric channel can be realised by an Ethereum deployment service, a Fabric deployment service, and a benchmark service that wraps around the Caliper benchmark suite. These services can be contributed directly by end-users and reused via an inner-source or open-source mechanism. With a diverse pool of services, the framework would be able to deploy and evaluate an asymmetrically larger set of architectures.

Realising NVAL requires addressing the following challenges. Their solutions form the contribution of this paper.

- **Modelling of blockchain network architecture:** Describing blockchain network architectures in a machine-understandable format is a prerequisite for architecture-driven automation. We propose a novel meta-model called Blockchain Network Design (BND) that describes blockchain network architectures from three perspectives simultaneously: organisational structure, deployment structure, and logical topology. Section 4 presents this meta-model in detail.

- **Capturing automation logic as self-contained software services:** Functional scope, metadata scheme, and development support framework are necessary for refactoring and packaging the existing deployment and evaluation procedures for reuse. We propose the concept and architecture of self-contained software services called Actions, which package automation logic as reusable units. Section 5 presents the concept, functional scope, and architecture of NVAL’s actions.

- **Constructing execution plan for a given blockchain network architecture:** NVAL needs a mechanism to match actions with a given blockchain network architecture and construct a suitable action sequence to deploy and evaluate a network. We propose to apply a state-space search approach to solving the action planning problem. Section 6 presents the formalisation and constructs necessary for constructing execution plans with a state-space search approach.

We conducted a case study to evaluate NVAL’s effectiveness in a real-world scenario. The chosen case for the study is a research project that requires deploying and empirically evaluating various types of blockchain network architectures on an edge-fog-cloud infrastructure. A prototype of NVAL was employed to automate the deployment and evaluation. The results show that NVAL correctly combines seven actions to deploy 65 networks with 12 different architectures and generate 295 evaluation datasets whilst incurring a negligible processing time overhead. Section 7 presents the case study in detail.

2. Preliminaries

2.1. Blockchain and Blockchain Network

A blockchain is a share-write database and a secure computing engine operated by mutually-distrusting parties [3, 5]. Its operation is based on the consensus between participants rather than a central authority [2]. Every participant hosts and controls some blockchain nodes, which are computers running a software implementation of a blockchain protocol. Blockchain nodes form a peer-to-peer system called a blockchain network to operate and secure a blockchain. Interactions between blockchain nodes follow a blockchain consensus protocol. Cachin and Vukolic [3] provide a survey of prominent consensus protocols private blockchain networks use.

Figure 1a depicts a physical view of a blockchain network and a logical view of its software stack. As shown in the architecture, blockchain nodes can assume different roles in a blockchain network [1].

- **Full Nodes** hold complete blockchain replicas. They can verify transactions and execute software scripts embedded in transactions, also known as smart contracts.
(a) Anatomy of a blockchain network. Adapted from [1].

(b) An exemplary multi-channel blockchain network featuring five blockchain channels

Figure 1: Anatomy of a blockchain network and example of a multi-channel blockchain network

- **Mining Nodes** participate in a consensus protocol to process and append transactions. Mining nodes are usually full nodes, but not the other way around.

- **Lightweight Nodes** hold only ledger metadata and must rely on trusted full nodes to verify transactions. They trade security and independence for reduced resource consumption.

- **Remote Nodes** are end-user clients responsible for crafting and signing transactions on behalf of human or machine users. They are also known as wallets.

- **Network Interfaces** offer APIs for remote nodes to interact with a blockchain.

Private blockchain networks can be segmented into channels [12]. Each channel connects a subset of blockchain nodes and maintains a separate ledger. Channels in the same network might use different blockchain consensus protocols to satisfy performance requirements and hardware constraints. Channel segmentation also provides confidentiality because participants generally cannot access channels to which they do not belong. Figure [11] depicts an exemplary multi-channel blockchain network running on an edge-fog-cloud infrastructure.
This network contains three in-cluster channels that bridge devices within an edge cluster, one cross-cluster channel connecting cluster heads, and one cross-cluster channel running on a remote cloud.

2.2. Architecture and Design Decisions of a Blockchain Network

A blockchain network architecture embodies design decisions, such as channel segmentation and protocol configuration. Tran et al. defined a design space of blockchain network with 19 types of decisions [11]. These decisions can be organised into four types:

- **Topological design decisions** capture the overall shape of a blockchain network. They include how a network is segmented into channels and the number of blockchain nodes per channel.

- **Organisational design decisions** capture the assignment of blockchain nodes to participants. This assignment reflects participants’ governance power and authorisation level in the network.

- **Consensus design decisions** capture the type and configuration of the consensus protocols used by blockchain channels in the network.

- **Deployment design decisions** capture the mapping between blockchain nodes and targeted hardware infrastructure.

An architectural specification documents the above design decisions such that computers can understand and implement them. The language for writing such a specification can be considered a meta-model of blockchain network architecture.

2.3. Blockchain network design, deployment, and evaluation

Private blockchain networks can be established by software engineers or IT operators from participating organisations or a third-party service provider. We denote these practitioners as blockchain network operators (operators).

The establishment of a private blockchain network starts from requirement elicitation and design. Operators gather requirements from organisations regarding the processes they wish to implement on a blockchain, how they want to govern it, what computing infrastructure they want to use for hosting it. Operators design a blockchain network architecture based on the requirements and understanding of different blockchain protocols.

The blockchain network deployment process transforms high-level architecture into technical details, such as network addresses and configurations. Based on these technical details, a series of activities are carried out to provision infrastructure, generate cryptography artefacts, build, deploy, and configure blockchain clients. When these clients are online and connected, a blockchain network architecture has been deployed successfully.

The deployed network can undergo a blockchain network evaluation process where its quality attributes are assessed using benchmark suites, simulations, or other analytical techniques.

3. Overview of NVAL Framework

NVAL sits between blockchain network operators and hardware infrastructures. The framework can be deployed locally by operators or offered by a cloud provider as a service. Operators interact with the framework as either end-users or contributors. Figure 2 presents the interaction flows between operators and the key components of the framework.

As end-users, operators use NVAL to deploy and evaluate blockchain networks. This interaction flow contains four steps:

- **Specifying** a blockchain network architecture and the quality attributes to be measured from the deployed network via a user interface

- **Transforming** the given blockchain network architecture into a digital artefact: The user interface leverages the BND meta-model proposed in section 4 to model and serialise the given architecture as a JSON document.

- **Planning** for deployment and evaluation: The planner component matches the accumulated automation logic with a given architecture to create an execution plan. This plan describes an execution sequence of automation logic and the inputs for each step. NVAL employs a state-space search approach to create execution plans (Section 6).

- **Executing** the plan: The orchestrator component carries out the execution plan on targeted hardware infrastructure and monitor the results of each step to deploy and evaluate a
blockchain network. If the execution is successful, NVAL returns URLs to access the deployed blockchain network and download the datasets containing the requested quality attributes.

As contributors, operators provide NVAL with the automation logic necessary for deploying and evaluating blockchain networks. We denote these automation logic fragments as actions because they represent different ways NVAL can act on targeted hardware infrastructures. Actions are either developed from scratch for NVAL or refactored from the existing bash scripts, custom programs, or instructions for IT automation tools. The interaction flow between NVAL and contributors also has four steps:

- **Retrieving** architecture and kernel for implementing actions: The framework provides pre-built service interfaces called kernels to help contributors build interoperable actions. Section 5 presents more details of the action’s interface and kernel-based architecture.

- **Contributing** actions to NVAL’s action pool: Every contributed action is packaged together with its dependencies to form a software container. The kernel supplied by NVAL also provides templates and instructions to help contributors with containerisation.

- **Informing** the planning process: The planner component references the descriptions of action pool items to match actions with channels of a blockchain network architecture.

- **Applying** to the hardware infrastructure: The orchestrator component invokes actions with relevant input extracted from the deployment and evaluation requests to deploy and evaluate a blockchain network, according to the execution plan.

4. Blockchain Network Design Meta-model

A prerequisite of architecture-driven automation is capturing the abstract and implicit input architectures as concrete models that computers can understand and process. The development and comprehension of these architectural models require a meta-model that defines the utilised concepts and relationships. Whilst the existing view models (4+1 [23]) and notations (Unified Modelling Language (UML)) can model blockchain network architectures, they suffer several drawbacks:

- **Generic models and notations lack a standardised way to describe blockchain network architectures**, leading to ambiguity in both their construction and parsing. For instance, blockchain channels and configurations can be captured in deployment diagrams, component diagrams, or even class diagrams depending on the abstraction level that an architect considers. Without a common understanding of how the blockchain network’s entities are represented, readers might misunderstand the blockchain network’s architectural model.

- **The existing view model can scatter design decisions of a blockchain network across multiple views**, complicating both the specification and the comprehension of design decisions. For
instance, assigning a new blockchain node to a participant requires modifying separated architectural views that describe the network’s topology and the mapping between participants and blockchain nodes.

We address the above drawbacks with a domain-specific meta-model for describing blockchain network architectures called Blockchain Network Design (BND). This meta-model defines concepts, relations, and architectural structures for constructing concrete BND models that describe specific blockchain network architectures. To avoid the fragmentation of blockchain network architecture specification, every BND model simultaneously describes three aspects of a blockchain network: organisational, physical, and logical. Figure 3 presents an exemplary BND model of a two-channel blockchain network, showing three architectural structures. Organisational and physical structures describe a blockchain network’s requirements regarding the power dynamics between participants and the hardware constraints. The logical structure of a blockchain network captures its design decisions, such as logical topology, assignment of blockchain nodes to participants and deployment of blockchain nodes on hardware infrastructure.

The BND meta-model defines six vertices and five edges to describe blockchain network architectures. The vertices represent entities in a blockchain network architecture, including blockchain nodes, blockchain channels, participants, processes, computing nodes, and computer networks. Various types of edges capture relationships between entities. For example, an in-channel edge shows a blockchain node participates in a blockchain channel. Semantically related vertices and edges form the architectural structures described above. Table 4 describes vertices, edges, and architectural structures defined by the BND meta-model.

4.1. Modelling Blockchain Network Architecture with BND

Before designing a blockchain network, operators need to define the network’s context and constraints by constructing organisational and physical structures. This step can be done during the requirement engineering phase.

Operators use BND to describe the design decisions introduced in Section 2.2 as follows:

- Topological design decisions describe how a blockchain network is segmented into channels and the number of blockchain nodes per channel. Operators specify these decisions by (1) adding blockchain nodes, (2) adding channels, and (3) adding In-Channel edges between nodes and their channels.

- Organisational design decisions capture the assignment of blockchain nodes to participants. The type of the assigned blockchain node reflects a participant’s authorisation level. Operators specify these decisions by (1) adding Control-BNode edges between participants and blockchain nodes, and (2) specifying the type of blockchain nodes by setting the Node Type property of blockchain nodes.

- Consensus design decisions capture the type and configuration of the consensus protocol used by blockchain channels in the network. Operators specify these decisions by setting the Consensus Protocol property of channels.

- Deployment design decisions capture how blockchain nodes are deployed on targeted hardware infrastructure. Operators specify these decisions by adding Deploy-on-Node edges between blockchain nodes and computing nodes.

Operators make the above decisions based on the requirements, characteristics of blockchain implementations, and previous experiences encoded as patterns and tactics. The completed BND model can be serialised as an XML or a JSON document and used as an input for automated network deployment.

4.2. Parsing Blockchain Network Architecture with BND

BND models enable automation frameworks like NVAL to divide and process multi-channel blockchain networks channel-by-channel. By following a channel’s In-Channel and Deploy-on-Node edges, NVAL can identify its blockchain nodes and where they are deployed. Properties embedded in blockchain node and channel vertices tell NVAL how to deploy and configure them. Properties embedded in the computing node vertices tell NVAL the hardware and OS on which a blockchain channel operates. A channel’s hardware type and consensus protocol represent a channel’s requirements for deployment. NVAL can use these requirements to match channels with the existing deployment logic.
All information about a channel extracted from a BND model can be packaged as an input to the deployment logic.

Architecture validation is another feature enabled by BND models. Syntactic validation can be done by validating the XML or JSON document containing a BND model against a schema constructed from the meta-model. Semantic problems such as misconfigurations can be identified with heuristic or formal analyses on the design decisions encoded in a BND model. For instance, assume that a blockchain network contains a Proof-of-Work mining node running on a resource-constrained computer like a Raspberry Pi. A rule-based analyser can be built to detect and raise alerts about conflicts between resource-constrained hardware (Raspberry Pi computing node) and the resource-intensive design (mining node of a Proof-of-Work blockchain channel).

5. Composable Actions for Deployment and Evaluation

NVAL deploys and evaluates a given blockchain network architecture by composing the existing automation logic fragments, denoted as actions, which operators contribute via an open-source or inner-source mechanism. This section proposes action’s scope and architecture to facilitate the development and utilisation of these composable actions.

5.1. Action Scope

NVAL requires the contributed actions to adhere to a set of predefined interfaces to be understandable and usable. These interfaces capture actions’ functional scopes by defining their inputs, outputs, and description features (Table 1). NVAL defines three interfaces that represent three types of actions: verifier, deployer, and evaluator. These action types represent three types of activities conducted by the framework, including verifying a given blockchain network architecture, deploying...
individual channels, and evaluating each deployed channels.

5.1.1. Example

Operators can refactor existing automation scripts into composable actions by following the described action scopes. Let us consider an overly-large and specific automation script, which deploys a 3-channel network (one Fabric channel and two Ethereum channels) and evaluates every channel using the Caliper benchmark suite. The proposed action types allow us to refactor it into the following reusable actions:

- **Deployer 1** specialises in Fabric. Assuming that it only works with computers running an X86-64 processor, for the sake of demonstration, we can denote this deployer as \( \text{Depl}(_{\text{Fabric}})X86-64\).

- **Deployer 2** specialises in Ethereum. Assuming that it can deploy on both ARMv7 and X86-64 hosts, we denote this deployer as \( \text{Depl}(_{\text{Eth}})_{\text{ARMv7}}X86-64\).

- **Evaluator 1** specialises in measuring performance metrics such as latency and throughput from Ethereum or Fabric channels using the Caliper benchmark suite. We denote this evaluator as \( \text{Eval}(_{\text{Perf}}\text{Eth}\text{Fab})\).

NVAL can combine these actions to handle incoming requests. For example, consider the following request: deploy a 2-channel network (one Ethereum channel running on an edge infrastructure with ARMv7 and X86-64 computers (ch1), one Ethereum channel running solely on X86-64 hosts (ch2)), and evaluate the performance of the edge channel (ch1). NVAL can handle the request with the following action sequence:

1. \( \text{Depl}(_{\text{Eth}})_{\text{ARMv7}}X86-64\text{True}(ch1) \)
2. \( \text{Depl}(_{\text{Eth}})_{\text{ARMv7}}X86-64\text{True}(ch2) \)
3. \( \text{Eval}(_{\text{Perf}}\text{Eth}\text{Fab})\text{True}(ch1) \)

NVAL can determine that \( \text{Depl}(_{\text{Fabric}})X86-64\) is not suitable because the deployer’s capability does not match any channel. If NVAL does not have enough actions to handle every request’s element, then the request is considered unsatisfiable. In this

case, operators need to develop or acquire the missing actions from others.

5.1.2. Rationale
When defining the scope and designing the interface of NVAL’s actions, we aimed to achieve an optimal balance between reusability and abstraction. Our design is informed by our observations and experiences in developing automation scripts for blockchain networks as follows:

1. **Overly large action scopes hamper reuse:** For instance, we cannot reuse the automation script described in the above example to deploy and evaluate Ethereum channels in a different blockchain network directly because its ability to deploy Ethereum channels is tightly coupled with deploying Fabric channels and running Caliper benchmarks.

2. **Overly small scopes hamper abstraction:** For instance, if we narrow down actions to specific technical steps such as building and deploying an Ethereum client, operators would need an in-depth understanding of Ethereum to use these actions. In other words, we lose the abstraction of implementation details, which is NVAL’s primary goal.

3. **Deploying and evaluating channels are atomic activities.** From an operator’s perspective, deployment and evaluation are either successful or failed. In other words, it does not matter to them whether the failure happens at the first compilation step or the last provisioning step. Therefore, the scope of actions must cover an entire deployment or evaluation step to preserve their abstraction.

4. **Channels divide the work on a multi-channel blockchain network into independent units.** For instance, we can break the deployment and evaluation of a three-channel blockchain network into three parts; each deploys and evaluates one channel. The same procedure can be used for all channels if they employ similar blockchain technology and request the same evaluation metrics.

5. **Actions can be distinguished by what channels they can act on and how they do so.** For instance, a deployment action might be able to build and deploy Ethereum nodes only on computers with an ARMv7 processor. This information helps NVAL match this action with blockchain network architectures that feature Ethereum protocol and low-power computers running ARMv7 chips.

The observations (1) to (3) show that deployment and evaluation of individual channels are atomic activities for handling heterogeneous multi-channel blockchain networks. We match actions’ functional scopes with the identified atomic activities by classifying actions into deployers, evaluators, and verifiers. We include architectural verification as an action type because it can be partially automated if a blockchain network architecture is captured explicitly as a BND model. The observation (4) informed us to reduce action’s scope to work with individual blockchain network channels rather than an entire network at once. Finally, observation (5) helps us identify the description features of different action types.

5.2. Action Architecture
How to ensure NVAL can understand and execute actions, regardless of their underlying technology, whilst minimising the complexity and implementation effort facing contributors? We address this challenge by designing NVAL actions as microservices and adopting a kernel-based architecture to abstract the complexity from contributors.
We choose microservice for NVAL actions because this architectural style turns actions into self-contained software units that NVAL can acquire and utilise without managing additional dependencies. The interfaces of these microservices adhere to defined action interfaces (Table 1), allowing NVAL to understand and invoke them. The kernel-based architecture offsets the increased complexity of a microservice architecture by providing contributors with pre-implemented service interfaces, enabling them to focus on developing automation logic.

Figure 5 presents the architecture of a NVAL action. Every NVAL action is a self-contained black box accessible only via a predefined interface (Table 1). This black box is packaged and delivered with all dependencies as a software container. NVAL provides contributors with software packages called kernel, which contains a pre-implemented service interface and some abstract classes (Figure 6) for developing bridging modules between interface and the contributed automation logic.

5.2.1. Action Development Process
From a contributor’s perspective, the development process of action is as follows:

1. Determining the type of action to develop based on Table 1
2. Refactoring or developing automation logic according to the defined scope
3. Acquiring the kernel
4. Developing a bridging module by implementing abstract functions (e.g., deployHandler(), teardownHandler()) of a suitable abstract module (DeplCore, EvaluatorCore, VerifierCore). At runtime, NVAL calls these functions though the service interface to reach the automation logic. By implementing these functions, contributors control how NVAL uses their automation logic.
5. Filling in the action metadata in the bridging module
6. Packaging the service interface, the bridging module, the automation logic, and necessary utilities into a container. The kernel can provide a template for conducting this step.

Let us consider an example of developing an Eval_{Perf,Eth\land Fabric} evaluator. A contributor can write a shell script to capture the automation logic of preparing and running performance benchmarks with the Caliper suite. As this action is an evaluator, the contributor uses the EvaluatorCore to build a bridging module. In the evaluateHandler() function, they write the code for invoking the shell script and feeding it the input from NVAL. In the attributes of the bridging module, the contributor specifies the supporting metrics of their evaluator as performance and the support platforms as Ethereum and Fabric. Finally, they pack the action and the Caliper benchmark suite in a container and make it available to others. This containerisation step ensures that any NVAL instance can run the action without deploying the benchmark suite themselves.

6. Action Planning with State Space Search
Action planning denotes the process of finding a suitable sequence of action calls to deploy and
evaluate a requested blockchain network architecture. This section presents an automated planning approach that leverages state-space search to match composable actions with user requests and construct action sequences.

6.1. Problem Formulation

We regard the action planning for a request as a search task on its implicit state-space with the goal state being the successful deployment and evaluation of a requested blockchain network. This decision stems from the following observations:

- **Every request has a state**, reflecting whether (1) it has been verified, (2) its channels have been deployed, and (3) its requested metrics have been measured.

- **Suitable function calls to actions transit requests between states.** These function calls receive fragments of requests, such as architectural specifications of blockchain channels, as inputs. The suitability of these calls depend on whether the functions can process the inputs and whether a request is at a state where such calls are required. For instance, if a requested blockchain network has not been deployed, it is too early to invoke evaluation actions.

- **The execution plan of a request is, therefore, a sequence of suitable action calls that leads to a goal state.**

- **A request’s state space is implicit** because it depends on NVAL’s action pool when it starts to plan for a request. If the state-space of a request is exhausted before reaching a goal state, then the request is unsatisfiable with the current action pool.

We define formalise the state-space search problem for action planning as follows.

**Definition 6.1 (Request).** A request \((R)\) from an operator contains the description of a blockchain network to deploy and a list of quality attributes to measure from the deployed network. Every request has a state, denoted as \(S_R\).

**Definition 6.2 (Request Components).** A request consists of multiple request components that can be tracked and resolved separately: \(R = (D, E)\). A deployment request component \((D)\) contains a BND fragment that describes a channel within a requested blockchain network. An evaluation request component \((E)\) lists the types of metrics to measure from a channel. Every request contains \(n\) deployment request components and \(m\) evaluation request components.
Definition 6.3 (Action). An action is a function that (1) receives a request component, (2) carries out a corresponding task, and (3) returns a new request state. Actions’ interfaces and description features are defined in section 5. NVAL contains three action types: verifier (ver), deployers (depl), and evaluators (eval).

Definition 6.4 (Action Pool). An action pool is the set of actions (A) that NVAL can access to plan and resolve a request (Eq. (1)).

\[ A = \{ Ver, Depl, Eval \} \]  

Ver = \{ ver|ver : R \rightarrow B \}  

Depl = \{ depl|depl : D \rightarrow S_R \}  

Eval = \{ eval|eval : E \rightarrow S_R \}  

Definition 6.5 (Action Planning). The action planning problem can be formalised as follows: given a request \( R \), generate an action sequence \( \Lambda_R = ((a, input)|a \in A, input \in R) \) such that \( S_R \) is a goal state.

6.2. Approach

Our approach is built upon the state-space search approach [25], which is an effective planning approach when an agent (NVAL) has full observability over the states, has a set of actions with deterministic effects, and can determine whether a state satisfies the goal. Noted that actions are deterministic only in the planning phase. A plan might still fail due to runtime exceptions such as hardware failures. Operators can choose to fix the exception or re-plan without the impacted actions.

The main idea of state-space search is employing a search algorithm to systematically traverse the state space to find a goal state. The path taken by the search algorithms becomes the execution plan. Unlike the traditional search problem, a search algorithm simultaneously finds a goal state and maps the state-space as it is undefined at the beginning of a search. The state-space mapping activity requires a state model and a set of state transition functions. To solve the action planning problem with state-space search, we need to define these models and functions in terms of NVAL’s concepts. Afterward, any search algorithm can employ these models and functions to solve the action planning problem.

6.2.1. Request’s State Model

Following [25], we model a request’s state space as a tree whose nodes represent the request’s states and edges represent action calls \((a, input)\). Figure 7a depicts an exemplary state space of a request. The request’s state stored in every node is a tuple with \( 3 + n + m \) elements, denoted as \( S_R \) (Eq. (5)).

The first three elements of a state tuple \((v, d, e)\) capture the overall status of a request, showing whether it has been verified, deployed and evaluated. The remaining \( n + m \) elements of the tuple capture the status of individual request components, including failed (-1), in-progress (0), and successful (1). The initial state of every request is an all-zero tuple. Its goal state is an all-one tuple. Figure 7a depicts an exemplary state tree of a request with eight components (Table 7b).

\[ S_R = (v, d, e, req) \]  

\( req \in \{-1, 0, 1\}^{n+m} \)  

\( v \in \mathbb{B} \)  

\( d, e \in \{-1, 0, 1\} \)  

6.2.2. State Transition Functions

State transition functions control the traversal of a search algorithm through a state space. We define the four following state transition functions based on [25]:

\( \text{ACTIONS}(s) \) determines the possible out-going edges for each state. Each out-going edge represents an action call \((a, input)\). By controlling the outgoing edges, we control the order at which a search algorithm traverses the state space. The function returns action calls according to the following rules:

- If \( v \) is 0, return all verifiers (Ver)
- If \( d \) is 0, return all deployers (Depl) with deployment request components as their input. For instance, if a given blockchain network architecture contains two channels (ch1,ch2), and NVAL has two deployers (PoW(), PoA()), then \( \text{ACTION}(s) \) returns four actions: PoW(ch1), PoW(ch2), PoA(ch1), PoA(ch2).
- If \( d \) is 1 and \( e \) is 0, return all evaluators (Eval) with evaluation request components as their input, similarly to the above example with deployers.
RESULT($s$, $a$) determines the destination of an out-going edge. In other words, it returns a new state that captures the results of applying an action $a$ to an initial state $s$. It should be noted that $a$ denotes action and input ($\text{PoW}(\text{ch1})$, $\text{PoW}(\text{ch2})$, $\text{PoA}(\text{ch1})$, $\text{PoA}(\text{ch2})$). The results of this function are according to the following rules:

- If $a \in \text{Ver}$, the verification state $v$ is set to 1 to indicate that the verification has been planned.
• If \( a \in Depl \), the new state depends on whether the deployer in \( a \) (e.g., PoW) can handle a given request component (e.g., \( ch1 \)). This assessment is done by matching the deployer’s metadata with the channel’s characteristics, such as its protocol and the type of hardware hosting it. If a deployer can handle a given deployment request component, then its status in the \( reg \) part of the tuple \( S^p_R \) is set to 1. If all \( reg \) components related to deployment are 1, the overall deployment state \( d \) is also updated to 1.

• If \( a \in Eval \), the new state depends on whether the evaluator can handle a given evaluation request component. If it can, then the status of the relevant request component in \( reg \) is set to 1. If all \( reg \) components related to evaluation become 1, the overall evaluation state \( e \) would also be updated to 1.

\text{STEP-COST}(s, a)\) returns the cost of applying an action \( a \) on a state \( s \). This cost can represent an action’s resource consumption (CPU time, memory, network bandwidth), time delay, reliability, or financial costs. For the sake of simplicity, we set the \text{STEP-COST} uniformly to be 1 in this approach, which means the total cost of an execution plan is the number of actions taken. Future works could explore other \text{STEP-COST} to improve the efficiency of the state space search.

\text{IS-GOAL}(s)\) determines whether a given state \( s \) is the goal state. It returns true if all values of a state tuple \( S^p_R \) is 1. If the state space is exhausted before \text{IS-GOAL}(s)\) returns true, the request is deemed unsatisfiable.

Figure 8 depicts how the state transition functions are utilised by a breadth-first search to plan for actions. The \text{node} object represents a node in the state tree, which contains a state vector (\( s \)) and a set of \text{actions} leading to it. The \text{POP()}\) removes and returns the last item from an array.

6.3. Exemplary Run of the Approach

We describe an exemplary action planning run in detail to demonstrate the proposed approach.

\text{Context:} This example shows how NVAL plans to deploy and evaluate a three-channel blockchain network running on two edge clusters and a cloud-based virtual machine (Figure 9). The first channel (\( ch1 \)) uses a Proof-of-Work (PoW) variant of Ethereum to connect cluster heads with the cloud node. The other two channels (\( ch2 \) and \( ch3 \)) use a Proof-of-Authority (PoA) variant of Ethereum to connect cluster heads with low-power computers within each cluster. Operators require performance metrics (latency and throughput) from all three channels. They also require the resource consumption metrics at edge nodes by channel \( ch2 \) and \( ch3 \). Table 7b presents the three deployment request components and five evaluation request components. Table 7c presents the action pool that NIVAL uses to plan for the experiment in this example.

\text{Procedure: Figure 7a} depicts the state tree and the search process. The state tuple of the sample request consists of 11 components (three general states \( (v, d, e) \), three deployment requests, and five evaluation requests). The request is initially assigned with an all-zero state tuple \( (0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0) \).

The planning procedure repeatedly applies the state transition functions to expand nodes. Let’s consider the expansion of the initial state as an example.

1. \text{IS-GOAL}(s)\) is applied on the initial state. It returns false, allowing the search to continue.
2. \text{ACTIONS}(s)\) is applied on the initial state to identify all available actions. Because \( v \) is 0, all verifiers are returned as possible actions.
3. \text{RESULT}(s, a)\) is applied on the starting state and the verifier action. It returns a new state \( (1, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0) \), reflecting that verification has been planned.
4. STEP-COST(s, a) assigns the cost of the verification to be 1, indicating that one action has been planned.

The order of expanding nodes depends on the search algorithm. This example uses a breadth-first search algorithm. We present only expansions that lead to the goal state in the figure for brevity. All actions leading to that state becomes the experiment plan for the given request.

7. Evaluation

We assessed NVAL in a real-world use case by conducting a case study that is designed to answer the following research questions:

RQ1 (Effectiveness) How effective is NVAL at orchestrating actions for deploying and evaluating diverse blockchain network architectures? Can the framework accurately plan and conduct experiments based on its action pool and incoming requests?

RQ2 (Efficiency) What is the degree to which NVAL can reuse actions across requests?

RQ3 (Efficiency) What is the overheads of NVAL in terms of processing time? In other words, what is the portion of a request’s processing time spent on NVAL rather than deploying and evaluating blockchain networks?

We employed a case study approach because it is a powerful and flexible technique to investigate contemporary phenomena in their context [26, 27]. The chosen case for our study is a research project on blockchain network architecture, in which a proof-of-concept of NVAL was employed. This project presents a suitable real-world context for assessing NVAL because it requires rapid deployment and evaluation of multiple blockchain networks on a testbed infrastructure featuring diverse hardware nodes (Figure 9). The deployed blockchain networks feature heterogeneous, multi-channel architectures (Table 3), which are the type of blockchain network architecture targeted by NVAL.

7.1. Case Study Settings

7.1.1. NVAL Prototype Implementation and Deployment

We developed and deployed a NVAL prototype to conduct the case study. Figure 10 depicts the deployment structure of a NVAL instance:

- **NVAL Server** hosts the framework’s software components. It exposes functionality as Web services via a RESTful API. We used the Open API Specification version 3.0 to model the API and employed the Swagger Codegen utility to generate the service interface automatically from the specification. Javascript and NodeJS runtime environment were used to implement NVAL’s components.

- **Operator’s Computer** hosts the client-facing software for creating BND models, submitting requests to NVAL and monitoring the experiments (i.e., deployment and evaluation of a blockchain network). We developed the web application with ReactJS and react-digraph libraries.

- **Target hardware infrastructures** consist of computers and networks used for deploying and evaluating blockchain networks (Figure 9). NVAL server can reach these computers via SSH.

Both the NVAL server and the client-facing software are deployed on a mobile workstation equipped with a quad-core processor and 16GB of memory.

7.1.2. Action Pool

The prototype contains four deployers, two evaluators, and one verifier (Table 2). All deployers were implemented as Ansible playbooks, which contain instructions for an IT automation engine called Ansible. The bridging modules of these deployers transform deployment request components from NVAL into playbooks’ prerequisites such as hardware lists and cryptographic keys.

We developed DeplPoA by refactoring an existing playbook, which resembles the counterexample described in Section 5. We refined and extended the scope of this action to support more blockchain platforms (Go-Ethereum Proof of Work) and hardware architecture (ARMv7), creating DeplPoA_x64_ARM and DeplPoW_x64_ARM.

EvalPerformanceEthereum benchmarks a blockchain network’s performance and measures the underlying hardware’s resource consumption throughout the benchmark. The evaluator sends three

---

https://github.com/uber/react-digraph
sets of blockchain transactions to create smart contracts, query contracts' values, and update random contract pairs. Every transaction is tracked to determine a blockchain network’s latency (seconds) and throughput (transactions per second). The evaluator also measures disk write rate, network sent rate, network receive rate, memory usage, and processor usage of underlying computing nodes throughout the benchmarks. We employed Hyperledger Caliper benchmark suite and Prometheus to implement these functionalities.

The action pool of NVAL also contains DeplBaseline and EvalBaseline, which are special deployer and evaluator for determining the baseline resource consumption level of experiment hardware infrastructures. The baseline deployer deploys blockchain channels called “baseline”, which do not contain any active blockchain node. The baseline evaluator only works with “baseline” channels. It measures the resource consumption metrics of nodes underlying these channels over a long period.

7.1.3. Experimented Architecture

Twelve blockchain network architectures were deployed and evaluated in the case study (Table 3). The architecture D4 to D6 has only one channel that connects every node in the experiment hardware infrastructure. D1 to D3 and D7 to D12 are multi-channel blockchain works. Channels in D1 to

7.2. Data Collection and Processing

We collected data for the case study from the prototype's source code and experiment results stored in a Git repository. The following data was collected for RQ1 and RQ2: (1) all requests submitted to NVAL, (2) source code of all actions, (3) NVAL-generated experiment plans of all requests, and (4) experiment outcomes. For RQ3, we collected operation logs of all requests, which contain the timestamps of their life cycle events. Figure 11 presents a log's snippet.

Figure 11: Snippet of a log file generated by NVAL framework

RQ1 Calculate the experiment success rate. An experiment is successful if the deployed blockchain network matches the architecture and all the requested metrics are captured in a dataset.

RQ2 Calculate the ratio of experiments in which each action in the pool is involved. Higher ratios indicate a higher level of reuse.

RQ3 Calculate the portion of processing time consumed by NVAL-specific activities. This ratio represents NVAL’s overheads. Calculating these overheads involves three steps: (1) extracting activity time from individual logs, (2) compiling the extracted activity time into a dataset, (3) analyzing the descriptive statistics of the dataset.

7.3. Results

7.3.1. RQ1: The Effectiveness of NVAL

NVAL framework successfully planned and conducted five rounds of 13 experiments (twelve architecture and one baseline), leading to the deployment and evaluation of 150 blockchain channels, constituting 65 blockchain networks. All evaluation datasets were usable and free of anomaly. We also did not observe any false-negative from the planning mechanism as the action pool was adequate to satisfy all the given requests. Given these observations, we reached the following conclusion for RQ1:
RQ1: Given an adequate action pool, NVAL plan and conduct experiments accurately for 100% of the given experiment requests.

7.3.2. RQ2: The Reuse Rates of NVAL
The case’s action pool served 365 invocations spreading across five rounds of 13 experiments. We quantify the utilisation level of all actions in two ways: (1) the number of experiments that use an action and (2) the number of calls that action receives. Higher figures indicate a higher utilisation level.

Table 12 presents both utilisation metrics. Actions with higher utilisation levels are critical ones with few or no alternatives, such as the Verifier action, and the flexible ones with a larger scope. For instance, 92% of the experiments rely on EvalPerformanceEthereum because it supports both performance benchmarking and resource consumption measurement. Actions in low demand, such as DeplBaseline and EvalBaseline, have low utilisation levels.

An interesting observation can be drawn from three deployers, which are in the middle in terms of utilisation levels. Individually, they cover only 23% to 38% of the experiments. However, together, they can deploy all of the requested blockchain network architecture. Based on the described results, we reach the following conclusion for RQ2:

RQ2: NVAL can reuse an action pool to deploy and evaluate new blockchain networks. It can orchestrate a small set of actions to serve a substantially larger set of requests.

7.3.3. RQ3: Processing Time Overheads
Figure 13 presents the durations of various activities conducted by NVAL. The framework’s overheads are the time spent on internal activities rather than verifying, deploying, and evaluating blockchain networks.

We classify the overheads into bootstrap overheads and experiment overheads. NVAL instance incurs bootstrap overheads once when it first boots up due to preparation activities. Loading NVAL-Module components incurs the most significant bootstrap overheads, taking around half a second (441 ms) on average.

NVAL incurs experiment overheads for every experiment it conducts. Each experiment’s total overheads are around a tenth of a second (95.5 ms). They are minuscule compared to the actual runtime of experiments, which ranges from 7 to 14 minutes. Based on these results, we reach the following conclusion for RQ3:

RQ3: NVAL’s overheads are negligible compared to the time required to deploy and evaluate blockchain networks.

8. Discussions

8.1. Benefits and Usage Scenario
The NVAL framework provides practitioners and researchers with the ability to rapidly deploy and evaluate heterogeneous multi-channel blockchain networks. By leveraging BND meta-model, composable actions, and state-space search, the framework can deploy and evaluate blockchain network directly based on their architecture whilst abstracting procedural details and low-level configurations from users. This architecture-driven automation approach benefits practitioners and researchers by allowing them to focus on designing blockchain network architecture, a valuable and hard-to-automate activity. Automation of implementation and configuration steps also prevent errors such as missing steps and misconfigurations, reducing time and effort in blockchain network deployment and evaluation. Another benefit of NVAL is the capturing and sharing of procedural knowledge regarding deployment and evaluation activities. By capturing this knowledge explicitly as software artefacts (composable actions) rather than documents, practitioners and researchers can version control, test, refine, and employ the knowledge rapidly across multiple organisations. Finally, by enabling practitioners to rapidly deploy and evaluate their blockchain network architectures, NVAL can shorten the feedback loop and enable practitioners to conduct more design iterations, which ultimately lead to better architectures [28].

Unlike existing blockchain automation framework and services, NVAL offers practitioners complete control and transparency over the framework’s capability. NVAL is designed such that it can be deployed and operated by individual practitioners on consumer hardware, as demonstrated in the case study. These practitioners maintain a complete control over the capability of their NVAL instances as they can choose the actions making up the action pool of their instances. The kernel-based approach employed in these composable actions facilitate the

development and sharing of new NVAL’s capabilities, without relying on permission or approval from any central authority such as service providers or project maintainers. These mechanisms together enable NVAL to keep up with the ever changing landscape of blockchain technology, increasing its transparency and longevity.

8.2. NVAL and Beyond

The case study has shown NVAL’s effectiveness in reusing and composing a small pool of automation logic to deploy and evaluate diverse and complex blockchain network architectures. However, our approach and the current implementation still have some drawbacks. This section analyses these drawbacks and presents some potential solutions, constituting future research.

Firstly, because NVAL reuses existing automation logic to deploy and evaluate blockchain networks, its capability is limited by the breadth of actions it can access. Therefore, the prime challenge of NVAL is ensuring a steady supply of composable actions for both existing and emerging blockchain technologies. The interfaces and the kernel-based architecture proposed in Section ?? lay a foundation for practitioners to capture and share their procedural knowledge as composable actions. Future research could focus on the automated transformation of the existing automation scripts and natural language instructions into composable actions. As of February 2022, there exist 52 open-source repositories on automated blockchain network deployment with Ansible, 67 repositories with Terraform, and 35 repositories with other scripting languages. The official documentation of many blockchain implementations also provide instructions for deploying private networks\[7\]. These scripts and documents represent raw materials for NVAL’s actions.

Secondly, the current version of NVAL does not feature extensive verifications of the contributed actions beyond manual inspections by practitioners. The rationale of this design is the assumption that actions primarily come from trusted inner-sources, and the community verifies open-source actions before they reach an end-user. This model might not scale when NVAL’s actions proliferate and increasingly become targets of malicious actors who want to leverage them as an attack vector to infrastructures. Future research could develop a resilient and

Figure 13: Durations of NVAL activities and the framework’s overheads.

decentralised registry for discovering and reporting malicious actions. The \textsc{STEP-COST()} function could leverage the ratings from this registry to adjust the planning procedure.

Thirdly, the current version of NVAL only employs Unicode strings and a substring detection mechanism to describe and match actions with architectural specifications written in BND. This approach has been shown to be effective in the case study. However, it might not scale to the complexity that presents when NVAL actions proliferate. Future research could integrate semantic description schemes to actions and BND models and employ more sophisticated semantic matching techniques. These semantic descriptions can replace or complement the current description features defined for each action type. The semantic matching mechanism can be implemented in the \textsc{ACTION()} function of the action planning procedure.

Finally, NVAL currently does not automatically feed the execution phase’s output to the planning phase. Practitioners must inspect the logs manually when a deployment fails and determine whether the failure is due to an exception or an action’s failure. If they detect that a composable action is the root cause, they need to remove it from the pool manually. Future research could explore techniques from self-adaptive software systems, such as MAPE-K feedback loops [29] to enable NVAL to observe and update its action pool automatically.

8.3. Threats to Validity

8.3.1. Construct validity

Construct validity concerns whether our case study design successfully assesses NVAL’s effectiveness and efficiency in real-world usage. We mitigated this threat by following an established guideline [27], which requires that case selection and data collection follow research objectives.

The selected case supports our research objectives because (1) it is a real-world use case of NVAL, (2) it requires the rapid deployment and evaluation of many blockchain networks, and (3) these blockchain networks have diverse and complex multi-channel architectures.

The data collection process was also driven by the objectives of assessing NVAL’s effectiveness and efficiency. We chose success and failure rates to quantify NVAL’s effectiveness because these metrics reflect the framework’s ability to correctly use an existing action pool to deploy and evaluate blockchain networks. We chose time overheads to quantify NVAL’s efficiency because time is the most tangible and significant resource that NVAL consumes, given that it is not computing-intensive.

8.3.2. External validity

External validity concerns whether the effectiveness and efficiency that NVAL shows in the case study can be generalized. Whilst the case study method does not aim to provide statistically significant conclusions [27], we attempted to broaden the generalization of our results by choosing a case
that features diverse blockchain network architectures extracted from the literature. The variety of network topology and the inclusion of edge devices and fog nodes expand our generalization scope beyond enterprise blockchain use cases, covering the emerging use cases in cyber-physical systems and edge computing.

8.3.3. Reliability

Reliability concerns whether case study results depend on the researchers carrying out the study. We mitigated threats to reliability by the following strategies. Firstly, we avoided subjective data such as NVAL’s usability and focused on objective data gathered from the source code and runtime logs. Secondly, we only employed commodity hardware for NVAL and the experiment infrastructure to prevent skewing the efficiency results due to exclusive, high-performing computers.

9. Related Work

This paper addresses the problem of automating blockchain network deployment and evaluation, which contributes to the Blockchain Oriented Software Engineering (BOSE) research [30, 31, 32] and aligns with three research areas: blockchain network architecture, blockchain network deployment, and evaluation.

9.1. Blockchain Network Deployment

Automated blockchain network deployment has been investigated by both academia [22, 20, 19, 13] and industry [33, 34, 35, 36] to abstract the time-consuming [20], and error-prone deployment process [19], allowing practitioners to focus on application development instead of learning networks and protocols [13]. Automation has also been sought to make blockchain network deployment repeatable to support regression tests [22].

Hyperledger Composer [33] is amongst the first tools that recognise and address the complexity of establishing a private blockchain. It helps practitioners implement organisational design decisions by providing them with models and tools to deploy business abstractions such as assets and participants on an existing Hyperledger Fabric network. The Composer was deprecated in 2021.

The automation tools released after Composer have shifted their focus to blockchain networks’ logical and physical design decisions. Many of these tools feature some form of domain-specific languages to capture the topology and configurations of the requested blockchain networks. The PlaTIBART platform [22] is among the first to tackle blockchain network deployment, focusing on Ethereum. It proposes a domain-specific language to describe Ethereum’s configurations, such as network ID and mining difficulty level. A Python-based network manager uses the configuration files to deploy Ethereum networks on connected computers. Hyperledger Bevel [34], formerly known as the Blockchain Automation Framework, is a state-of-the-art tool for rapidly deploying production-ready blockchain networks, supporting Fabric, Corda, Indy, and Quorum blockchain protocols. It uses Ansible, Helm, and Kubernetes to rapidly provision containerised blockchain networks on any Kubernetes cluster. Bevel’s inputs are low-level and technology-specific configurations such as consensus types, network addresses and ports. Malik et al. [20] bypassed blockchain network configuration files by proposing a shell script that practitioners manually place on targeted computers and invoke to deploy blockchain nodes.

Many Blockchain-as-a-Service (BaaS) platforms such as uBaaS [19], NutBaaS [13], AWS Managed Blockchain, Azure BaaS, and IBM Blockchain Platform also provide deployment automation as a prominent feature. They generally provide a “one-click deployment” utility for spawning a blockchain network across cloud-based virtual machines. This deployment utility is generally vendor-locked in terms of the supported blockchain technologies and computing nodes [19]. Few offer any form of extensibility besides promised first-party extensions.

A few blockchain benchmark tools also support blockchain network deployment. For instance, MixBytes Tank [35] helps practitioners deploy a private Polkadot or Haya blockchain on private clouds before running a benchmark. MADT [36] is a Python-based network simulator that allows practitioners to deploy a private blockchain on the simulated network for development and evaluation.

NVAL shares the core approach with PlaTIBART and Bevel, which involves capturing blockchain network architectures as digital artefacts and employing a centralised network manager to realise the requested blockchain networks. NVAL also supports blockchain network evaluation, similarly to MixBytes Tank. The framework improves upon the state-of-the-art in three ways. Firstly, it works with complex and expressive architectural models

rather than technical configurations or a simplified form of architectural specification. Secondly, it supports multi-channel, heterogeneous blockchain networks. Thirdly, it enables end-users to control and extend the framework’s capability without relying on a project owner or service provider. Table 4 compares NVAL with the existing work.

9.2. Blockchain Network Architecture

This paper also contributes to the architectural research of blockchain applications and networks. This line of research started from the recognition of blockchain as a software connector type that bridges software components across organisations in a decentralised and trustless manner [37, 38]. Recent research on the software architecture aspects of blockchains has focused on architectural tactics [39] and patterns [40] to design on-blockchain smart contracts and the software systems surrounding them.

Whilst blockchain networks are also software systems, research on blockchain network architectures have received less focus. Xu et al. [5] proposed a taxonomy of blockchain networks to support practitioners in choosing a blockchain for their use cases.

Tran et al. [11] was amongst the first to investigate the possible design decisions in establishing a blockchain network. Recent research has identified design patterns of blockchain networks for edge computing use cases, highlighting the prevalence of multi-channel heterogeneous blockchain networks [12].

This paper advances the research on blockchain network architecture by proposing a meta-model for capturing blockchain network architectures as computer-understandable artefacts. This meta-model is based on the design decisions identified by Tran et al. [11]. Future research, such as formal verification and recommendation of blockchain network architecture, can leverage the proposed meta-model.

9.3. Blockchain Network Evaluation

Blockchain network evaluation can be classified into benchmark and simulation. Benchmarks assess a blockchain network’s quality after deployment by subjecting the network to standardised workloads and measuring quality attributes of interest. Benchmarks can be conducted manually as
demonstrated on the Quorum [11] and Red Belly [12], and Fabric [13] blockchain platforms. As proprietary benchmarks can be difficult to compare, researchers and industry have developed blockchain benchmark suites. BLOCK BENCH [18] is among the earliest benchmark automation suites. It provides workloads for benchmarking both end-to-end performance and individual layers such as consensus and processing. Pongnumkui et al. [44] extended the idea of BLOCK BENCH but emphasised the impact of workload size on the computing layer of blockchain nodes. Zheng et al. [45] proposed an alternative monitoring framework that analyses the logs generated by Ethereum clients to infer their performance in real-time. Beyond performance, researchers have also applied benchmarks to assess the correlation between CPU consumption and blockchain’s rewards [16], and bandwidth requirement for real-time use cases [17]. A survey of blockchain benchmark suites is available in [15].

Simulations assess the qualities of a blockchain network before deployment. They are helpful in scenarios where deploying a blockchain network prototype is impractical. The existing simulators [14] [15] [16] [17] vary broadly in simulation parameters and predicted indicators. However, their inputs are primarily reflections of the architectures of blockchain networks that they need to simulate.

NVAL does not offer new simulators or benchmarks. However, it offers a platform for integrating and employing simulators and benchmark suites. Specifically, simulators and benchmark suites can be encapsulated as composable actions and integrated into NVAL’s action pool. The bridging modules of these actions can transform architectural specifications (BND fragments) into the input expected by the enclosed simulators or benchmark suites.

10. Conclusion

This paper introduces NVAL, a software framework that automatically deploys and evaluates blockchain networks based on architectural specifications. This framework enables practitioners and researchers to focus on designing blockchain networks and reduces the time and effort consumed by implementation mistakes and misconfigurations. NVAL operates by breaking down complex multi-channel blockchain networks into logical channels and leveraging the existing automation logic contributed by practitioners to deploy and evaluate these channels individually. We propose a novel meta-model to capture blockchain network architectures, a novel concept and architecture to capture automation logic, and a state-space search approach to match architectures with actions and construct execution plans automatically. A real-world case study with 65 blockchain networks featuring 12 diverse architectures shows that NVAL can accurately deploy and evaluate blockchain networks with negligible time overheads.

We plan to extend NVAL by introducing semantic descriptions to actions and BND models to enable more sophisticated semantic-based matching between actions and architectures. We also aim to explore AI-based techniques to build actions automatically from the existing open-source deployment scripts and natural language instructions. These solutions aim to further improve the longevity and effectiveness of NVAL as an all-in-one solution for researchers and practitioners to deploy and evaluate complex blockchain networks.
