Abstract

A natural procedure for assigning students to classes in the beginning of the school-year is to let each student write down a list of \( d \) other students with whom she/he wants to be in the same class (typically \( d = 3 \)). The teachers then gather all the lists and try to assign the students to classes in a way that each student is assigned to the same class with at least one student from her/his list. We refer to such partitions as friendly. In realistic scenarios, the teachers may also consider other constraints when picking the friendly partition: e.g. there may be a group of students whom the teachers wish to avoid assigning to the same class; alternatively, there may be two close friends whom the teachers want to put together; etc.

Inspired by such challenges, we explore questions concerning the expressiveness of friendly partitions. For example: Does there always exist a friendly partition? More generally, how many friendly partitions are there? Can every student \( u \) be separated from any other student \( v \)? Does there exist a student \( u \) that can be separated from any other student \( v \)?

We show that when \( d \geq 3 \) there always exist at least 2 friendly partitions and when \( d \geq 15 \) there always exists a student \( u \) which can be separated from any other student \( v \). The question regarding separability of each pair of students is left open, but we give a positive answer under the additional assumption that each student appears in at most roughly \( \exp(d) \) lists. We further suggest several open questions and present some preliminary findings towards resolving them.

1 Introduction

In many schools the following procedure is used to assign students to classes: each student \( u \) writes down a list \( L(u) \) of \( d \) other students with whom he or she wants to be in the same class. The goal is to find a partition of the students to classes so that each student is in the same class with at least \( r \leq d \) students from \( L(u) \). In realistic cases, \( r = 1 \) and \( d \) is a small constant, say \( d = 3 \). Of course, there may also be various other constraints the partition needs to satisfy such

*This work is a part of a project (including COSP REU 2020) that has received funding from the European Union’s Horizon 2020 research and innovation programme under the Marie Skłodowska-Curie grant agreement No. 823748. M.S. was also supported by GACR grant 22-19073S.
as that the number of classes needs to be some parameter $k$ and that all $k$ classes need to have roughly the same size, or constraints regarding certain groups of students which should/should not be put together, etc.

One can naturally model this problem in the language of graph-theory: define the preferences graph $G = (V,E)$ to be a directed graph where $V$ is the set of students and $u \rightarrow v \in E$ if and only if $v \in L(u)$. So, the out-degree of every vertex in $G$ is $d$. The goal is then to find a partition of $V$ such that the subdigraph induced by each part has minimum out-degree $\geq r$. We will refer to such partitions as $r$-friendly partitions. Note that the trivial partition where all vertices are in the same part is $d$-friendly.

1.1 Existence

Perhaps the most basic question is whether non-trivial $r$-friendly partitions exist. Consider the case of $r = d = 1$, and let $G = C_n$ be a directed cycle on $n$ vertices. See Figure 1

Clearly, in this case, the only $r$-friendly partition is the trivial one. Thus, in order to guarantee the existence of non-trivial 1-friendly partitions, $d$ has to be larger than 1. Next, assume $d = 2, r = 1$. Also here there are digraphs for which only the trivial partition is $r$-friendly. A simple example for such a digraph is the complete directed graph on 3 vertices. See Figure 2

Alon showed in [Alo20] that for $d \geq 3, r = 1$ there always exist a non-trivial friendly partition. The argument hinges on the following classical result due to Thomassen:

Figure 1: A directed cycle on 6 vertices. In any friendly partition, each vertex has to be in the same part with its unique out-neighbor. Hence, by transitivity, only the trivial partition is friendly.

Figure 2: The complete directed graph on 3 vertices. Any non-trivial partition will leave one of the vertices alone in its part, and hence cannot be friendly.
Theorem 1 ([Tho83]). Each directed graph with minimum out-degree 3 contains two disjoint cycles.

Indeed, given two disjoint cycles $C_1, C_2$ one can extend them into a 1-friendly partition as follows. One part consists of the cycle $C_1$ and of all vertices from which there is a path to $C_1$ which does not intersect $C_2$, and the second part consists of all other vertices. It is easy to verify that this partition is indeed 1-friendly. This argument leads to the following useful lemma which we will use throughout the article:

Lemma 2. Let $G = (V, E)$ be a digraph with minimal out-degree $\geq 1$, and let $U, W \subseteq V$ be disjoint sets which are friendly in the following sense: each vertex in $U$ (resp. $W$) has an out-neighbor in $U$ (resp. $W$). Then, there exists a 1-friendly partition in $G$ with one part containing $U$ and the other part containing $W$.

For $r > 1$ the existence of non-trivial $r$-friendly partitions remain open:

Question 3 (see [Alo06]). Let $r > 1$ be an integer, does there exist an integer $d = d(r)$ such that in every digraph $G$ whose minimal out-degree is at least $d(r)$ there exists an $r$-friendly partition?

We make a brief remark regarding this question in Section 7 (see Proposition 33).

Unless stated otherwise, for the remainder of this manuscript we focus on the case $r = 1$, and refer to 1-friendly partitions simply by friendly partitions. As discussed above, in order to guarantee the existence of (non-trivial) friendly partitions, $d$ must be at least 3.

Let us go back to the setting of assigning students for classes. In this context, it would be useful to have many friendly partitions with diverse properties that can be efficiently found. This raises a host of questions: How many friendly partitions are there: what is the minimal number $t(d,n)$ of friendly partitions a digraph with $n$ vertices and out-degree $d$ can have? By Theorem 1 and Lemma 2, we have $t(3,n) \geq 1$ for all $n$. Is it the case that $\lim_{n \to \infty} t(3,n) = \infty$? Is it the case that $\lim_{n \to \infty} t(d,n) = \infty$ for some fixed $d$? How well does the family of friendly partitions separate the vertices: can every pair of vertices be separated by some friendly partition (provided that $d$ is a sufficiently large constant)? Can most pairs be separated? In the following subsections, we address these questions as well as other related questions in more detail.

1.2 How Well Do Friendly Partitions Separate the Vertices?

Imagine that there is a small group $S \subseteq V$ of $s = 5$ students that can control the preferences of all other kids. Can the students in $S$ devise lists $L(u)$ for every student $u$ such that the teachers will have to assign all students in $S$ together to the same class? This suggests the following definition: Let $G = (V, E)$ be a digraph, let $S \subseteq V$. We say that $S$ is separable if there exists a friendly partition $V = U \cup W$ such that both $U \cap S \neq \emptyset$ and $W \cap S \neq \emptyset$. The above motivation question amounts to the following:

Question 4 (Separability). Does there exist a choice of $d$ and $s$ such that in any digraph $G = (V, E)$ with out-degree $d$, every $S \subseteq V$ of size $k$ is separable? How about the case where $d = 3$ and $s = 2$: can every pair of vertices be separated if all out-degrees are at least 3?

We present the following partial result that it is sufficient to consider strongly connected digraphs; that is, digraphs in which there is an oriented path from every vertex to every other vertex.
Proposition 5. Let \( d \geq 3 \). If every strongly connected digraph with minimum out-degree at least \( d \) satisfies that each pair of vertices in it is separable, then every digraph with minimum out-degree at least \( d \) satisfies this property.

While we do not know an answer to Question 4, our main technical result yields that if \( d \geq 15 \) then there exists a vertex which can be separated from all other vertices:

**Theorem 6** (A Separable Vertex Exists). Let \( G = (V,E) \) be a digraph with minimum out-degree at least 15. Then, there exists \( u \in V \) such that for all \( w \in V \setminus \{u\} \) there exists a friendly partition that separates \( u \) and \( w \).

We prove this theorem in Section 2. Our proof follows by contradiction by considering a counter-example \( G \) of minimal size. We show that since the minimum out-degree of \( G \) is \( \geq 15 \), it must contain 3 cycles \( C_1, C_2, C_3 \) such that \( C_1 \) and \( C_2 \) intersect, but \( C_3 \) is disjoint from them. Then, by exploiting the minimality of \( G \), we show that one of the vertices on \( C_1 \cup C_2 \) is separable, which is a contradiction. The existence of such three cycles hinges on a result by Thomassen [Tho83] which asserts that every digraph with minimal out-degree at least 15 contains 3 disjoint cycles. Thomassen also conjectures that a minimal degree of 5 is sufficient. If true, this would imply that one can improve Theorem 6 by replacing 15 by 5.

1.3 How Many Friendly Partitions Are There?

In the previous section we interpreted “richness” of a family of partitions in terms of the ability to separate sets of vertices. An alternative, perhaps more simplistic, interpretation of “richness” is obtained by counting: i.e. bigger families are richer. How large must the family of friendly partition in a digraph with out-degree \( d \geq 3 \) be? Theorem 1 implies that there is at least one such partition. Is this tight? Are there arbitrarily large digraphs with out-degree 3 all of which have only \( O(1) \) many friendly partitions? In Section 3 we strengthen Theorem 1 and show that when \( d = 3 \) there must be at least 2 friendly partitions:

**Theorem 7.** In every digraph with minimum out-degree at least 3 there are at least 2 distinct friendly partitions.

1.3.1 Counting versus Separating

The number of friendly partitions and their separation capabilities are linked. For example, assume every pair of vertices in a digraph \( G = (V,E) \) can be separated by a friendly partition, and let \( k \) denote the number of friendly partitions in \( G \). We claim that \( k \geq \log(n) \), where \( n \) is the number of vertices. To see this, assign to every vertex \( v \) a binary string \( b_v \) of length \( k \), such that \( b_v(i) = 0 \) if and only if \( v \) belongs to the left part of the \( i \)-th friendly partition. Since every pair of vertices \( u, v \) are separable by some friendly partition, it follows that \( b_v \neq b_u \). Thus, all binary strings are different and \( 2^k \geq n \) as claimed.

The next theorem implies a statement in the opposite direction: if the number of friendly partitions tends to infinity with \( n \) then the family of friendly partitions must separate all subsets of some fixed size (independent of \( n \)).

Recall that \( t(d,n) \) denotes the minimum number of friendly partitions that exist in any digraph with \( n \) vertices and out-degree \( d \), and that a subset \( S \subseteq V \) is called separable if there exists a friendly partition \( V = V_1 \cup V_2 \) such that both \( V_1 \cap S \neq \emptyset \) and \( V_2 \cap S \neq \emptyset \).
Theorem 8. Fix \( d \in \mathbb{N} \) then the following statements are equivalent:

1. There exists \( s \in \mathbb{N} \) such that in every digraph with minimum out-degree at least \( d \), every subset of \( s \) vertices is separable.

2. In every digraph with minimum out-degree at least \( d \), every subset of \( s = d - 1 \) vertices is separable.

3. The function \( t(d,n) \) is unbounded (as a function of \( n \)).

4. \( t(d,n) \geq \log(n) - \log(d - 2) \).

Theorem 8 is proved in Section 3. Note that this theorem implies that either \( t(3,n) \) is bounded by a constant for every \( n \), or else it must be the case that each pair of vertices must be separable. Thus, to prove that each pair of vertices is separable in every digraph with out-degree 3, it suffices to show that the number of friendly partitions is unbounded.

Another corollary of Theorem 8 is a dichotomy for \( t(d,n) \): for every fixed \( d \), the function \( t(d,n) \) is either upper bounded by a constant, or it tends to infinity at a rate of at least \( \Theta(\log n) \). (E.g., it is impossible that \( t(d,n) \in \Theta(\sqrt{\log n}) \).)

The equivalence between items 1 and 2 implies that if there exists some \( s \in \mathbb{N} \) such that every subset of \( s \) vertices is separable, then this already holds for \( s = d - 1 \). The next result asserts that in this case it holds that every pair of vertices is separable in every digraph with minimum out-degree at least \( d + 1 \):

Theorem 9. Let \( d \in \mathbb{N} \). If \( t(d,n) \) is unbounded as a function of \( n \), then in every digraph with minimum out-degree at least \( d + 1 \), each pair of vertices is separable.

1.4 Special Digraphs

It is natural to explore the above questions under additional assumptions on the preference digraph. For example, it seems reasonable to assume that the in-degrees of the vertices are not too large. (I.e. that each student is listed by a bounded number of their school-mates.) Under such an assumption, a standard application of Lovász local lemma yields an affirmative answer to Question 4:

Theorem 10. Let \( G = (V,E) \) be a directed graph with minimum out-degree \( \geq d \) and maximum in-degree \( \delta \leq \frac{d^2 - 1}{cd} \). Then, for every pair of distinct vertices \( v_1, v_2 \in V \) there exists a friendly partition which separates it.

Proof. It will be convenient to assume that all out-degrees are exactly \( d \). This is without loss of generality because we can always remove edges until this is satisfied. (Notice that the maximum in-degree can not increase when removing edges.)

Let \( v_1, v_2 \in V \) be distinct vertices. Draw a random partition of \( V \) into two parts \( V_1, V_2 \) which separates \( v_1, v_2 \) as follows: \( v_1 \) is assigned to \( V_1 \), \( v_2 \) is assigned to \( V_2 \), and the part of every other vertex is chosen independently with probability \( \frac{1}{2} \). For \( w \in V \), let \( A_w \) denote the event that every out-neighbor of \( w \) is on a different part than \( w \). Notice that the probability of each \( A_w \) is at most \( \frac{1}{2} d^{-1} \).

\(^1\)Lovász local lemma (symmetric version, see \([EL73]\)): Let \( A_1, \ldots, A_n \) be events such that each \( A_i \) occurs with the probability at most \( p \) and each \( A_i \) is independent of all but at most \( d \) other \( A_j \). Then, \( \Pr \left[ \bigcap_{i=1}^{n} \overline{A_i} \right] > 0 \) provided that \( e \cdot p \cdot (d + 1) \leq 1 \).
We prove that with a positive probability such a random partition is friendly. Note that a partition is friendly if and only if it does not belong to any of the events $A_w$. Thus, it suffices to prove that with a positive probability none of the events $A_w$ holds. Towards this end we use the Lovász Local Lemma: fix $w \in V$ and note that $A_w$ is independent of all events $A_u$ such that $u$ is not an out-neighbor of $w$ and $w$ and $u$ have no common out-neighbor; there are $d + d(\delta - 1) = d\delta$ such events $A_u$. Thus, every $A_w$ is independent of all but at most $d\delta$ events $A_u$. Therefore, by the Lovász Local Lemma there exists a friendly partition separating $v_1$ and $v_2$, provided that

$$e \left( \frac{1}{2} \right)^{d-1} (\delta d + 1) \leq 1,$$

which is equivalent to $\delta \leq \frac{2^{d-1} - \varepsilon}{ed}$.

Similarly, using the multiplicative form of Chernoff bound\(^2\) one can separate each pair of vertices by an $r$-friendly-partition for $r = (1 - \varepsilon) \frac{d\delta - 1}{2} + 1$ if $d$ is sufficiently large and the maximum in-degree is bounded. E.g. for $\varepsilon = \frac{1}{5}$ we get the following.

**Theorem 11.** Let $G = (V, E)$ be a directed graph with minimum out-degree $\geq d$ and maximum in-degree $\leq e \frac{d\delta - 1}{2} d$. For every pair of distinct vertices $v_1, v_2 \in V$ there exists an $r$-friendly partition which separates $v_1$ and $v_2$.

**Proof.** The proof is essentially same as the proof of Theorem 10. Again, without lost of generality we assume that all out-degrees are exactly $d$. We choose $v_1, v_2 \in V$ and draw a random partition of $V$ into $V_1$ and $V_2$ such that $v_1 \in V_1$ and $v_2 \in V_2$ and the part for of every other vertices is chose independently with probability $\frac{1}{2}$. Now, we need to bound the probability of an event $A_w$ representing that there are $\leq \frac{d\delta - 1}{2}$ out-neighbors of $w$ being in the same part as $w$. This can be bounded by $e^{-\frac{d\delta - 1}{2}}$ by Chernoff bound. As in the previous case, each event $A_w$ is independent of all but $d\delta$ events $A_u$. Therefore, if $\delta \leq e \frac{d\delta - 1}{2} d$ Lovász Local Lemma guarantees there is a $(\frac{d\delta - 1}{2} + 1)$-friendly partition separating $v_1$ and $v_2$.

**Vertex-Transitive Digraphs.** Theorem 6, which asserts the existence of a vertex which is separable from all other vertices in digraphs with minimum out-degree at least 15, also answers Question 4 in the affirmative for vertex-transitive digraphs with the same minimum out-degree. Indeed, recall that vertex-transitive digraphs are digraphs such that for every pair of vertices $u, v$ there exists an automorphism of the digraph $\tau$ such that $\tau(u) = v$. Now, since for every friendly partition $\{V_1, V_2\}$ of $V$ it holds that also $\{\tau(V_1), \tau(V_2)\}$ is a friendly partition, we get that the existence of a single vertex which is separable from any other vertex implies that all vertices have this property.

However, for vertex-transitive digraphs we can use Theorem 10 to obtain better bounds. Indeed, Theorem 10 applies to any digraph in which all vertices have the same out-degree and in-degree. In particular, regular digraphs with out-degree (and thus also with in-degree) equal 9 fulfill the condition of Theorem 10 and thus the following holds:

**Corollary 12.** Let $G$ be a regular digraph with degree at least $d = 9$. Then, every pair of vertices in $G$ is separable.

\(^2\)(Multiplicative) Chernoff bound (see [AS00]): Let $n \in \mathbb{N}, p \in [0, 1]$ and let $B = B(n, p)$ denote a binomial random variable. Then, $\Pr [B \leq (1 - \varepsilon) \mu] \leq \exp \left(-\frac{\varepsilon^2 \mu}{2} \right)$, for every $\varepsilon > 0$ where $\mu = np$ is the expectation of $B$. 
Can one further improve this bound for vertex-transitive digraphs: is \( d = 9 \) tight? We conjecture that \( d = 3 \) (which is clearly a lower bound, as witnessed by the triangle, see Figure 2), is the tight bound for vertex-transitive digraphs. In Section 5 we prove some partial results towards proving this conjecture:

**Proposition 13.** If the number of vertices in a vertex-transitive digraph with degree at least 3 is prime then each pair of vertices is separable.

**Proposition 14.** Let \( \sim \) denote the following equivalence relation on the set of vertices of a digraph \( G \).

\[
\text{“} u \sim v \iff u \text{ cannot be separated from } v \text{ by a friendly partition.} \text{”}
\]

Then, if \( G \) is vertex-transitive with degree \( d \geq 3 \) then each equivalence class of \( \sim \) is an independent set. Moreover, each vertex has its out-neighbors in at least 3 different classes.

Curiously, Proposition 14 implies that if there are two vertices which cannot be separable in a vertex transitive digraph of out-degree \( d \geq 3 \) then there is no edge between them, which seems somewhat counter-intuitive.

**Infinite Digraphs.** It is also interesting to explore the properties of friendly partitions in infinite digraphs: in the last section (Section 6), we generalize the existence of friendly partitions to infinite digraphs with minimum out-degree 3.

**Proposition 15.** Let \( G \) be a (possibly infinite) digraph with minimum out-degree at least 3. Then, there exists a friendly partition in \( G \).

Perhaps surprisingly, the proof we found for Proposition 15 is more complex then one might expect. In particular, we could not find a reduction to the finite case using standard arguments such as compactness.

1.5 Organization

The article is organized as follows. In Section 2 we prove our main result. That is, in each digraph of minimum out-degree at least 15 there is a vertex separable from each other vertices (Theorem 6).

In Section 3, we prove Theorem 8 and Theorem 9 connecting the function \( t(d, n) \) and separability of \( k \)-tuples. In this section we also prove the existence of at least 2 friendly partitions in each digraph of minimum out-degree 3 (Theorem 7).

In Section 4, we prove Proposition 5 showing that it suffices to only consider strongly regular graphs to show that any digraph with sufficiently large out-degrees, satisfies that each pair of vertices in it is separable.

In Section 5 we prove our partial result for vertex transitive digraphs. Namely, if there is a pair of unseparable vertices in vertex transitive digraph of minimum out-degree 3, then the number of its vertices is not a prime number (Proposition 13) and such unseparable vertices are not connected by an oriented edge (Proposition 14).

In the last section, Section 6, we prove the existence of friendly partition for infinite digraphs with minimum out-degree at least 3 (Proposition 15).
Figure 3: A dominated edge $uv$.

Figure 4: A picture showing how to contract a non-dominated edge $uv$ which is not part of a two-cycle while preserving the minimum out-degree in the graph.

2 Existence of a Separable Vertex

In this section we prove Theorem 6. We begin by recalling a useful definition introduced by Thomassen ([Tho83]).

**Definition 16.** Let $G = (V, E)$ be a digraph. An edge $u \rightarrow v \in E$ is called dominated if $u, v$ have a common in-neighbor. (See Figure 3.)

Thomassen used a process which, given a digraph $G = (V, E)$, produces a “compressed” digraph $G' = (V', E')$ such that every edge $e' \in E'$ is either dominated, or a part of a 2-cycle. The digraph $G = (V', E')$ is produced as follows: as long as there exists an edge $u \rightarrow v$ which is not dominated nor a part of 2-cycle, delete all the edges going out from $u$ and identify vertices $u$ and $v$. Let us call this procedure contraction of non-dominated edge. See Figure 4. Crucially, notice that every friendly partition of $G'$ is naturally “decompressed” to a friendly partition of $G$ by putting identified vertices in the same part. The compressed digraph $G'$ satisfies the following useful property.

**Lemma 17 ([Tho83]).** Let $G = (V, E)$ be a digraph such that each edge in it is either dominated or a part of a 2-cycle, and let $v \in V$ be a vertex which is not part of a 2-cycle. Then, there exists a cycle in the in-neighborhood of $v$.

Indeed, this lemma follows because every vertex $u$ in the digraph induced by the in-neighborhood of $v$ has a positive in-degree (because the edge $u \rightarrow v$ is dominated).

Another theorem due to Thomassen which will be useful in our proof is the following.

**Theorem 18 ([Tho83]).** Each digraph with minimum out-degree 15 contains three disjoint cycles.

Now, we continue with three lemmas which, combined with Theorem 18 imply Theorem 6.
Lemma 19. If $G$ is a digraph with minimum out-degree at least 2 then it contains two intersecting cycles.

Proof. Let $\mathcal{C} = \{C_1, \ldots, C_k\}$ be a maximal family of disjoint cycles. Note that $\mathcal{C} \neq \emptyset$ since the minimum out-degree is at least 2 and thus, $G$ contains a cycle. Now, let us delete all edges of $C_1, \ldots, C_k$ and denote the resulting digraph as $G'$. Since $C_1, \ldots, C_k$ are disjoint, the minimum out-degree of $G'$ is at least 1. Therefore, $G'$ contains a cycle which intersect at least one cycle from $\mathcal{C}$ by maximality of $\mathcal{C}$.

Lemma 20. Let $d$ be the minimum integer such that every digraph with minimal out-degree $\geq d$ must contain three disjoint cycles. Then, $G$ contains two intersecting cycles and one cycle disjoint from them.

Before we prove this lemma, note that $d$ must be $> 4$ since, for example, the complete directed graph on 5 vertices has minimum out-degree 4 but cannot contain three disjoint cycles. See Figure 5.

Proof of Lemma 20. We prove by contradiction: let $G = (V, E)$ be a smallest counterexample. Every edge of $G$ must be dominated or a part of a 2-cycle, otherwise we can contract this edge and get a smaller counterexample. If $G$ contains a 2-cycle $C$ then $G$ without $C$ has minimum out-degree at least 2. Therefore, by Lemma 19 it contains two intersecting cycles. Such cycles are disjoint from $C$ in $G$; a contradiction.

Thus, $G$ does not contain a 2-cycle and each edge in $E$ is dominated. Therefore, by Lemma 17 the in-neighborhood of each vertex $v \in V$ contains a cycle.

Let $I_v$ denote a cycle in the in-neighborhood of vertex $v$, let $\mathcal{C} = \{C_1, \ldots, C_k\}$ be a maximal family of disjoint cycles (by the assumption on $d$ we know that $k \geq 3$), and let $V_C = \bigcup_{i=1}^{k} V(C_i)$ be the set of all their vertices. By maximality of $\mathcal{C}$, for each $v \in V$ the cycle $I_v$ must intersect some $C_i \in \mathcal{C}$. Consider the following cases.

- Case 1: The in-neighborhood cycle $I_v$ of every vertex $v$ from $V_C$ is $C_i$ for some $i \in \{1, \ldots, k\}$. Define a digraph $H$ whose vertices are cycles $C_i$ and its edges are all the edges

---

3By Theorem 18, $d \leq 15$.

4Indeed, two intersecting cycles and a third cycle disjoint from them in the contracted digraph are naturally lifted to three cycles with the same properties in the original digraph.
Figure 6: A picture showing how to find two intersecting cycles and one another cycle disjoint from them in the proof of Lemma 20 in the case where $H$ is a cycle.

$C_i \rightarrow C_j$ such that there exists $v \in C_j$ such that $I_v = C_i$. By the assumption, every vertex in $H$ has in-degree at least one. Thus $H$ has to contain a cycle. If $H$ is a cycle then every two neighboring $C_i, C_j$ in it are fully connected in $G$: that is, for each vertex $v$ of $C_i$ there is an edge to every vertex of the following cycle $C_j$. (Indeed, else the in-degree of $C_j$ in $H$ would be at least 2, contradicting the assumption that $H$ is a cycle.) Now, since each $C_i$ contains at least 3 vertices, one can find two intersecting cycles and a cycle disjoint from them as well. (See Figure 6.)

Else, $H$ is not a cycle and hence, there must exist a cycle in $H$ which does not contain all vertices in $H$. In such a case one can also find two intersecting cycles and a cycle disjoint from them. (See Figure 7.)

• Case 2: There exists $v \in V_C$ such that $I_v \neq C_i$ for all $i \leq k$. Without loss of generality, assume $v \in V(C_1)$. If there exists $C_i$ for some $i \in \{1, \ldots, k\}$ such that $I_v$ and $C_i$ are disjoint then we can find the two intersecting cycles and a cycle disjoint from them as follows: by maximality of $C$, $I_v$ intersects $C_j$ for some $j \neq i$, and the cycle $C_i$ is disjoint from both of them.

We are left with the case that $I_v$ intersects every $C_i$. Here, we can find the two intersecting cycles and a cycle disjoint from them as follows (see Figure 8): let $u \in I_v \cap C_1$ and let $w \in I_v$ be the first vertex in cycle $I_v$ after $u$. Then the set $V(C_1) \cup \{w\}$ induces two intersecting cycles. For the disjoint cycle, pick any $C_{l}, l \neq 1$ such that $w \notin C_l$. (Such $C_l$ exists because $k \geq 3$.)

This is in contradiction to $G$ being a counterexample. \hfill \Box

**Lemma 21.** Let $d \geq 3$ be a sufficiently large integer such that every digraph with minimal out-degree $\geq d$ must contain two intersecting cycles and another cycle disjoint from them. Then,\footnote{By Lemma 20, $d \leq 15$.}
Figure 7: A picture showing how we can choose two intersecting cycles and one another cycle disjoint from them in the proof of Lemma 20 in the case when there is a cycle in $H$ which does not contain all of its vertices.

Figure 8: The two intersecting cycles induced by $V(C_1) \cup w$ and the cycle $C_l$ disjoint from them from the proof of Lemma 20.
every digraph $G$ with minimal out-degree $\geq d$ contains a vertex which is separable from every other vertex.

**Proof.** We prove by contradiction: let $G = (V, E)$ be a smallest counterexample. Consider three cycles $C_1, C_2, C_3$ as guaranteed by the premise: let $I$ denote the set of vertices in the two intersecting cycles $C_1, C_2$ and let $J$ denote the set of vertices of the remaining cycle $C_3$. (Thus, $I \cap J = \emptyset$.)

Let $\{V_1, V_2\}$ be a friendly partition of $V$ such that $I \subset V_1, J \subset V_2$ and $|V_1|$ is minimal. The idea of the proof is to find a vertex $v \in V_1$ such that the partition $\{V_1 \setminus \{v\}, V_2 \cup \{v\}\}$ is also friendly. Note that this implies that $v$ is separable and yields the desired contradiction. Note that $\{V_1 \setminus \{v\}, V_2 \cup \{v\}\}$ is friendly if and only if $v$ has at least one out-neighbor in $V_2$ and every in-neighbor of $v$ in $V_1$ has at least one additional out-neighbor in $V_1$.

By the minimality of $\{V_1, V_2\}$ it follows that if $v \in V_1 \setminus I$ then all out-neighbors of $v$ are in $V_1$. Notice that at least one vertex $v_0 \in I \subseteq V_1$ has an out-neighbor in $V_2$, because otherwise the digraph induced by $V_1$ would be a smaller counterexample: indeed, if there exists $v \in V_1$ which is separable from any other vertex $u \in V_1$ then $v$ is also separable from any other vertex in $V$ (because $\{V_1, V_2\}$ is friendly.) Next, since $v_0$ is not separable, there must exist $v_1 \in V_1$ such that:

(i) $v_0$ is the only out-neighbor of $v_1$ in $V_1$: because otherwise the partition $V = \{V_1 \setminus \{v_0\}, V_2 \cup \{v_0\}\}$ is also friendly, which implies that $v_0$ is a separable vertex and therefore, yields a contradiction.

(ii) $v_1 \rightarrow v_0$ is an edge of one of the cycles $C_1$ or $C_2$: indeed, all vertices in $V_1 \setminus I$ have all their out-neighbors in $V_1$. Thus, $v_0 \in I$; now, since $v_0$ is the only out-neighbor of $v_1$ in $V_1$, it follows that $v_1 \rightarrow v_0$ is a cycle-edge.

Similarly, there must exist $v_2 \in V_1$ with analogous properties (i.e. $v_1$ is the only out-neighbor of $v_2$ in $V_1$, and $v_2 \rightarrow v_1$ is an edge of one the cycles $C_1$ or $C_2$). Continuing in this way we construct an endless sequence $v_0, v_1, v_2, \ldots \in V_1$ such that for each $i \geq 0$, $v_i$ is the unique out-neighbor of $v_{i+1}$ in $V_1$, and $v_{i+1} \rightarrow v_i$ is an edge on $C_1$ or $C_2$. In particular, at some point $i > 0$, we must encounter a vertex $v_i$ which is in the intersection of the cycles $C_1, C_2$. This is a contradiction because such a vertex has at least 2 out-neighbors in $I \subseteq V_1$. (See Figure 9) \hfill $\Box$

Theorem 8 also implies the following.

**Corollary 22.** Let $G$ be a digraph with minimum out-degree at least $15 + k$, then $G$ contains at least $k$ vertices separable from all the other vertices.

**Proof.** It easily follows from Theorem 8. We simply delete the vertex separable from all other vertices and apply the corollary again. \hfill $\Box$

## 3 The Number of Friendly Partitions

In this section we prove Theorems 7, 8, and 9. We begin by proving Theorem 8.

**Theorem 8 (Restatement).** Fix $d \in \mathbb{N}$ then the following statements are equivalent:

1. There exists $s \in \mathbb{N}$ such that in every digraph with minimum out-degree at least $d$, every subset of $s$ vertices is separable.
2. In every digraph with minimum out-degree at least \( d \), every subset of \( s = d - 1 \) vertices is separable.

3. The function \( t(d, n) \) is unbounded (as a function of \( n \)).

4. \( t(d, n) \geq \log(n) - \log(d - 2) \).

Proof. The implication “4 \( \Rightarrow \) 3” is trivial. Therefore, it is sufficient to show “1 \( \Rightarrow \) 2”, “2 \( \Rightarrow \) 4”, and “3 \( \Rightarrow \) 1” since then we get

\[
1 \Rightarrow 2 \Rightarrow 4 \Rightarrow 3 \Rightarrow 1.
\]

1 \( \Rightarrow \) 2: let \( G = (V, E) \) be a digraph with minimum out-degree \( d \) and let \( D_- \subset V \) be a \((d - 1)\)-tuple of vertices we want to separate. We modify \( G \) by adding a cycle \( S \) to it of size \( s \) and a directed edge from each vertex in \( S \) to each vertex in \( D_- \). See Figure 10. Note that the minimum out-degree in the modified digraph remains \( d \). Thus, by the assumption in Item 1, there exists a friendly partition \( \{W, U\} \) that separates \( S \). We claim that this partition must separate \( D_- \): indeed, otherwise all vertices in \( D_- \) are in the same part, say \( D_- \subseteq W \). However, there must be \( s_0 \in S \) such that \( s_0 \in U \); thus, since \( S \) is a cycle, the unique out-neighbor of \( s_0 \) in \( S \), denoted by \( s_1 \), must also be in \( U \). Similarly, the out-neighbor of \( s_1 \) in \( S \) must also be in \( U \). Continuing in this way, we conclude that all vertices of \( S \) are in \( U \) which contradicts the assumption that \( S \) is separated by \( \{W, U\} \). Thus, \( D_- \) must be separable by \( \{U, V\} \) as required.

2 \( \Rightarrow \) 4: assume every subset of \( d - 1 \) vertices in a digraph \( G = (V, E) \) can be separated by a friendly partition, and let \( k \) denote the number of friendly partitions in \( G \). We claim that

\[ \text{Recall that } t(d, n) \text{ denotes the minimum number of friendly partitions that exist in any digraph with } n \text{ vertices and out-degree } d \]
Figure 10: A picture of the digraph $G$ together with the cycle of size $s$ showing how we proceed in the proof of Theorem 8. In this example, we suppose $d = 3$ and every 4-tuple is separable.

$k \geq \log(n) - \log(d - 2)$, where $n$ is the number of vertices. To see this, assign to every vertex $v$ a binary string $b_v$ of length $k$, such that $b_v(i) = 0$ if and only if $v$ belongs to the left part of the $i$-th friendly partition. Note that $b_u = b_v$ if and only if $v$ and $u$ cannot be separated by a friendly partition. In other words, $b_u = b_v$ if and only if $u,v$ belong to the same equivalence class under the relation 

“$x \sim y \iff x$ cannot be separated from $y$ by a friendly partition.”

By the assumption in Item 2, each equivalence class is of size $\leq d - 2$, and therefore, the number of equivalence classes is at least $\frac{n}{d - 2}$. Hence, also the number of distinct binary vectors in the set $\{b_v : v \in V\}$ is at least $\frac{n}{d - 2}$, and since each vector $b_v$ has length $k$, it follows that $k \geq \log(\frac{n}{d - 2})$ as required.

3 $\implies$ 1: we prove the contrapositive $\neg 1 \implies \neg 3$. Assume that for each $s \geq 2$ there is a digraph with minimum out-degree at least $d$ containing an unseparable $s$-tuple. Pick such digraph $G = (V,E)$ for $s = d$ and denote the unseparable $d$-tuple by $D$.

For every $n > |V|$ consider the digraph $G_n$ on $n$ vertices which is obtained by adding $n - |V|$ vertices to $G$ and connect them with an out-going edge only to $D$ (i.e. the new vertices have in-degree 0). The digraph $G_n$ has minimum out-degree $d$ as well and has the same number of friendly partitions as $G$ since each new vertex has to be in the same part as $D$. The digraphs $G_n$ witness that $t(d,n)$ is bounded.

This completes the proof of Theorem 8. $\square$

**Theorem 9** (Restatement). Let $d \in \mathbb{N}$. If $t(d,n)$ is unbounded as a function of $n$, then in every digraph with minimum out-degree at least $d + 1$, each pair of vertices is separable.

**Proof.** By Theorem 8 if $t(d,n)$ is unbounded then every $(d - 1)$-tuple of vertices is separable in every digraph with minimum out-degree at least $d$.

Let $u,v$ be vertices in a directed graph $G$ with all out-degrees being at least $d + 1$. By deleting $u$ we obtain a digraph $G'$ with all out-degrees being at least $d$. Now, take a friendly partition of $G'$ separating the out-neighborhood of $u$. (Such a partition is guaranteed to exist by the assumption.) Then we can extend such friendly partition of $G'$ to a friendly partition of $G$ by adding $u$ to any of the at least 2 parts which contain an out-neighbor of $u$. By picking a part which does not contain $v$, we get a friendly partition that separates $u$ from $v$. $\square$
In the rest of this section, we prove Theorem 7 which asserts that every digraph with minimum out-degree at least 3 has at least 2 friendly partitions. This generalizes Thomassen’s result (Theorem 1 and Lemma 2) which amounts to the existence of at least 1 friendly partition.

Recall from the beginning of Section 2 that an edge is dominated if both its vertices have a common in-neighbor. Our strategy is at first to prove the desired result for digraphs in which each edge is dominated or a part of a 2-cycle. Then, we use Thomassen’s reduction which implies this result to general digraphs.

We begin with a couple of lemmas which characterize the structure of digraphs with out-degree 3 in which each edge is dominated and there are no 2-cycles. In a nutshell, these lemmas imply that such digraphs are closed under reversing the edges. (I.e. the digraph obtained by reversing all the edges is of the same kind.)

**Lemma 23.** Let $G$ be a digraph without 2-cycles such that all edges of $G$ are dominated and all vertices have out-degree 3. Then, all vertices in $G$ have in-degree 3.

**Proof.** Since all vertices have out-degree 3, the average in-degree is 3. Assume towards contradiction that there is a vertex with in-degree greater than 3. So, there has to be a vertex of in-degree less than 3. However, by Lemma 17, its in-neighbors form a cycle which has to be of length 2. This contradicts the assumption that $G$ does not contain 2-cycles.

**Lemma 24.** Let $G$ be a digraph without 2-cycles such that all edges of $G$ are dominated and all vertices have out-degree 3, and let $u \to v$ be an edge in $G$. Then, $u$ and $v$ have a common out-neighbor.

**Proof.** By Lemma 23 also all the in-degrees in $G$ are 3. Let $i, j$ denote the 2 other in-neighbors of $v$, apart from $u$, and let $o, p, q$ denote the 3 out-neighbors of $v$. (See Figure 11.) By assumption, each of the edges $v \to o, v \to p, v \to q$ is dominated, and the only vertices that can dominate these edges are the 3 in-neighbors $u, i, j$ of $v$. Since $u, i, j$ form a cycle in $G$ (as the in-neighborhood of $v$) and because the out-degrees in $G$ are 3, it follows that each of $u, i, j$ dominates exactly one edge from $v \to o, v \to p, v \to q$. Thus, one edge, say $v \to o$, has to be dominated by $u$, and consequently, $o$ is a common out-neighbor of $u$ and $v$. 

![](image.png)

**Figure 11:** A neighborhood of the vertex $v$ illustrating the situation of Lemma 24.
**Corollary 25.** Let $G$ be a digraph without 2-cycles such that all edges of $G$ are dominated and all vertices have out-degree 3, then the out-neighbors of each vertex in $G$ form a cycle.

**Proof.** By reversing the orientation of each edge we obtain a digraph in which all vertices has out-degree 3 by Lemma 23 and all edges are dominated by Lemma 24. Then, we can use Lemma 17. □

**Lemma 26.** Up to isomorphism, there are exactly two non-empty digraphs $G$ satisfying the following properties:

1. Each vertex in $G$ has out-degree 3.
2. Every edge in $G$ is dominated.
3. $G$ does not contain a 2-cycle.
4. The undirected graph underlying $G$ is connected.

**Proof.** Consider such a digraph $G$ and pick any vertex $v$ in $G$. By Lemma 23 also the in-degree of every vertex in $G$ is 3. Let $w_1, w_2, w_3$ be $v$’s out-neighbors and $u_1, u_2, u_3$ be $v$’s in-neighbors (see Figure 12).

Lemma 17 and Corollary 25 imply that each of the triplets $w_1, w_2, w_3$ and $u_1, u_2, u_3$ form an oriented cycle in $G$. Let $C_{in}$ denote the cycle formed by $w_1, w_2, w_3$ and $C_{out}$ denote the cycle formed by $u_1, u_2, u_3$. Without loss of generality, assume that $u_2$ is the out-neighbor of $w_1$ in $C_{in}$, and that $u_2$ is the out-neighbor of $u_1$ in $C_{out}$. In addition, each of the edges $v \to w_i$ is dominated by one of the $u_j$’s, and therefore, $G$ contains a matching of the form $w_i \to u_{\pi(i)}$ for some permutation $\pi : [3] \to [3]$. Without loss of generality, assume that $\pi(1) = 1$; there are two cases:

- $\pi(2) = 2$ (and therefore, $\pi(3) = 3$),
- $\pi(2) = 3$ (and therefore, $\pi(3) = 2$).

In other words, with respect to the correspondence induced by $\pi$, either $C_{in}$ and $C_{out}$ are oriented the same (when $\pi(2) = 2$) or oppositely (when $\pi(2) = 3$).

By Corollary 25 the out-neighborhood of each vertex forms a cycle (triangle). One can verify that in each of the above cases there is a unique way of connecting edges from $C_{out}$ to $C_{in}$ so that the out-neighborhoods of each vertex from $C_{in}$ form a cycle: for example $u_1 \in C_{in}$ has out neighbors $v, u_2, w_1$, and since $u_2v$ and $vw_1$ exist as edges, it follows that $w_1u_2$ must also be an edge, in order to form a cycle (see Figure 13).

By Lemma 17 the in-neighborhoods of each vertex from $C_{out}$ forms a cycle as well. If the orientations of $C_{in}$ and $C_{out}$ are not the same (i.e. $\pi(2) = 3$), then there is a unique way of adding edges from $C_{in}$ to $C_{out}$ so that the in-neighborhoods of each vertex from $C_{out}$ form a cycle (see the right picture of Figure 14). The resulting digraph satisfies all the conditions from the statement, and in particular all vertices in it have out-degree 3. Thus, when $\pi(2) = 3$, this is the unique digraph satisfying the conditions in the lemma.

In the remaining case, when the orientations of $C_{in}$ and $C_{out}$ are the same (i.e. $\pi(2) = 2$), then the in-neighbors of each vertex from $C_{out}$ form a cycle as well (see Figure 13). However, the partial digraph considered thus far still does not satisfy the required conditions, as the out-degrees of the vertices in $C_{out}$ and in-degrees of the vertices in $C_{in}$ are only 2.
Figure 12: The two possible neighborhoods of the vertex $v$ from the proof of Lemma 26. On the left, $C_{in}$ and $C_{out}$ are oriented the same ($\pi(2) = 2$), and on the right oppositely ($\pi(2) = 3$).

Figure 13: The two possible neighborhoods of the vertex $v$ from the proof of Lemma 26. The dashed edges connect $C_{in}$ and $C_{out}$ so that the out-neighbors of each vertex from $C_{in}$ form a cycle.
Consider the vertex $w_1$ in $C_{out}$; it already has two out-neighbors $w_2$ and $u_2$. We claim that its third out-neighbor, denoted by $x$, must be a new vertex $x \notin \{v, u_1, u_2, u_3, w_1, w_2, w_3\}$: clearly $x \notin \{w_2, u_2\}$ as it is the third out-neighbor of $w_1$; also, $x \notin \{v, w_3, u_1\}$ since $G$ has no 2-cycles; lastly, $x \neq u_3$ since $u_3$ is the out-neighbor of both $u_2, w_2$ and hence cannot form a cycle with them, which would contradict Corollary 25 with respect to the out-neighbors of $w_1$.

Thus, $x$ must be a new vertex. Now, we use the fact that each two consecutive vertices have common out-neighbor (Lemma 24) and thus, the vertex $x$ has to be an out-neighbor of $w_2$ and $w_3$ as well. This fixes the out-degree of the vertices of $C_{out}$. We claim that the out-neighbors of $x$ must be $u_1, u_2, u_3$; by Lemma 24 the vertices $x$ and $w_1$ have a common out-neighbor, and therefore either $w_2$ or $u_2$ must be an out-neighbor of $x$. However, $w_2$ is excluded as there is no 2-cycle in $G$. Thus, $u_2$ is an out-neighbor of $x$ Repeating the same argument for the pairs $x, w_2$ and $x, w_3$, implies that the new vertex $x$ is an in-neighbor of $u_1, u_2, u_3$. The obtained digraph satisfies all the conditions in the lemma and is therefore the unique solution in the case when $\pi(2) = 3$ (see the left picture of Figure 14).

Lemma 26 will be used to show that digraphs with out-degrees $\geq 3$ that do not contain 2-cycles have at least 2 friendly partitions. How about digraphs that do contain 2-cycles? If a digraph with out-degrees $\geq 3$ has at least two 2-cycles then it has more than one friendly
partition as well. Indeed, a 2-cycle itself as one part and the rest of the digraph as the other part form a friendly partition. The next lemma is the key to handle digraphs which contain precisely one 2-cycle.

**Lemma 27.** Let $G$ be a digraph with all edges dominated, with all vertices of out-degree 3, and with exactly one 2-cycle. Then, $G$ has at least two friendly partitions.

*Proof.* We prove by contradiction: assume $G = (V, E)$ is a counterexample with the smallest number of vertices, and let $C_1 = \{u, v\}$ be the unique 2-cycle in $G$. Thus, $C_1$ is one part of the unique friendly partition of $G$.

The second part $V_G \setminus C_1$ must contain a cycle $C_2$ (because the minimal out-degree in the digraph induced by it is $\geq 1$). Pick $C_2$ to be a cycle with fewest vertices in the second part, and let $A = V \setminus (C_1 \cup C_2)$ denote the set of remaining vertices. Note that the subdigraph induced by $A$ is acyclic (or else it would contain a cycle $C_3$ which is disjoint from $C_2$ and Lemma 2 would imply the existence of another friendly partition, namely the one separating $C_2$ and $C_3$). Also note that there are no edges from $A$ to $C_1$—or else we could move such a vertex to the part of $C_1$ and obtain another friendly partition.

Let $C_A$ be the set of vertices in $C_2$ that have an out-neighbor in $A$, and let $C_B$ be the set of vertices in $C_2$ that have an out-neighbor in $C_1$. Note that: (i) $C_A \cup C_B = C_2$ (by minimality of $C_2$), and (ii) $C_B \neq \emptyset$ (or else the subdigraph induced by $A \cup C_2$ would be itself of minimum out-degree 3, and therefore, $G$ would have more than one friendly partition). We consider two cases:

- **Case 1:** The set $C_A$ is nonempty. Let $c \in C_A$ be a vertex whose outneighbor $b$ on $C_2$ is in $C_B$. Let $a$ be an out-neighbor of $c$ from $A$. (See Figure 15)

  We claim that there are paths from $a$ to at least 3 distinct vertices in $C_2$. Indeed, this follows by taking a vertex $a' \in A$ which is reachable from $a$ and that has no out-neighbor in $A$ (such $a'$ exists since $A$ is acyclic); now, since there are no edges from $A$ to $C_1$, it follows that the 3 out-neighbors of $a'$ must be in $C_2$, and are all reachable from $a$. Hence, at least one of these vertices is neither $b$ nor $c$. Denote such a vertex by $w$.

  Consider the cycle $C_3$ which starts at $c$, and continues via $a$ and $a'$ to $w$, and then continues together with $C_2$ until it reaches back $c$ (see Figure 15). Notice that $b \notin C_3$.

  Now, by Lemma 2 one can obtain an additional friendly partition whose one part contains $C_1 \cup \{b\}$ and the other contains $C_3$, which is a contradiction.

- **Case 2:** The set $C_A$ is empty. In other words, each vertex in $C_2$ has out-going edges to the two vertices $u, v$ in $C_1$. We consider two subcases.

  - There is an edge from some vertex in $C_1$, say $v$, to some vertex $w \in C_2$. Thus, $\{v, w\}$ is a 2-cycle distinct from $C_1$. However, by the assumption $G$ has exactly one 2-cycle. A contradiction.

  - There is no such edge. Therefore, each of $u, v$ has its two out-neighbors in $A$. Let $a$ be a vertex from $A$. Since $a$ does not lie in a 2-cycle, Lemma 17 implies there is a cycle $K$ formed by the in-neighbors of $a$. We claim that $K = C_1$: there is no vertex from $C_2$ in $K$, since there is no edge from $C_2$ to $A$. Since $A$ is acyclic, $K$ cannot contain vertices only from $A$. Since there are no edges from $A$ to $C_1$, the cycle $K$ cannot contain vertices from both $A$ and $C_1$. 

19
Figure 15: A picture illustrating the case when the set $C_A$ from the proof of Lemma 27 is non-empty.

The only candidate for $K$ is thus $C_1$ which implies that $A$ contains only two vertices $a_1$ and $a_2$.
Let $w_1$ be an out-neighbor of $a_1$ from $C_2$ and $w_2$ be an out-neighbor of $a_2$ from $C_2$ different from $w_1$. Such $w_1$ and $w_2$ exist since there is no edge from $A$ to $C_1$. Recall that $u, v \in C_1$ are both out-neighbors of $w_1$ and $w_2$. Whence, $\{a_1, w_1, v\}$ and $\{a_2, w_2, u\}$ are two disjoint cycles different from $C_1$ witnessing (by Lemma 2) there is another friendly partition; a contradiction. (See Figure 16.)

Proof of Theorem 7. First of all, we delete edges so that all vertices have out-degree exactly 3. Then, we contract edges so that in the resulting digraph $G$, all edges are dominated or a part of 2-cycle. This procedure preserves the out-degree of 3.
If $G$ contains no 2-cycle, then it is isomorphic to one of the two digraphs from Lemma 26. Both these digraphs have more than one friendly partition.
If $G$ contains exactly one 2-cycle then it has more than one friendly partition as well by Lemma 27.
Finally, if $G$ contains at least two 2-cycles, say $C_1, C_2$, then $(C_1, V_G \setminus C_1), (C_2, V_G \setminus C_2)$ are two distinct friendly partitions by Lemma 2.
As discussed in the beginning of Section 2 these friendly partitions of $G$ induce (distinct) friendly partitions in the original digraph.

4 Strongly Connected Digraphs

In this section we prove Proposition 5 which says that in order to show that every pair of vertices can separated by a friendly partition in any digraph $G$ with minimum out-degree $d$, it suffices to only consider strongly connected digraphs $G$: 
Proposition \(5\) (Restatement). Let \(d \geq 3\). If every strongly connected digraph with minimum out-degree at least \(d\) satisfies that each pair of vertices in it is separable, then every digraph with minimum out-degree at least \(d\) satisfies this property.

Proof. Suppose we can separate each pair of vertices in strongly connected digraphs with out-degrees \(\geq d\). Consider a digraph \(G = (V,E)\) and its strongly connected components. Let us contract each strongly connected component to one vertex and denote the resulting digraph \(A\). Note that \(A\) is acyclic. Let \(S\) be the set of vertices of \(G\) that are contracted to vertices of out-degree 0 in \(A\), let \(G_S\) denote the subdigraph of \(G\) induced by \(S\), and let \(u, v\) be a pair of vertices from \(G\). We need to show that \(u, v\) are separable; we consider three cases:

- Case 1: \(u, v \in S\). By the assumption, they are separable in \(G_S\) since it is a disjoint union of strongly connected digraphs with minimum out-degree at least \(d\). This partition can be extended to a friendly partition of the entire digraph \(G\) by Lemma 2. Thus, in this case \(u, v\) are separable in \(G\).

- Case 2: \(u \in V \setminus S, v \in S\). We distinguish two subcases:
  - There is a path \(P\) from \(u\) to \(S\) such that the \(P \cap S = \{w\} \neq \{v\}\). Again, by the assumption \(v\) and \(w\) are separable in \(G_S\). Now, it is sufficient to extend the partition of \(G_S\) to a partition of \(G\) placing \(P\) to the part of \(w\).
  - There is no such path. Let \(V_u\) denote the set of vertices from \(V \setminus S\) which are reachable from \(u\). Then \(v\) is the only out-neighbor of \(V_u\) in \(S\) and thus, \(V_u\) induces a subdigraph \(G_u\) which is of minimum out-degree at least \(d - 1 \geq 2\). Also \(S\) induces a subdigraph \(G_S\) in which all out-degrees are \(d \geq 2\). Thus, we can extend the disjoint pair \(\{V_u, S\}\) to a friendly partition of the entire digraph \(G\) by Lemma 2. Such partition separates \(u, v\).

- Case 3: \(u, v \in V \setminus S\). We distinguish two subcases:
There are vertex-disjoint paths $P_u$ from $u$ to some $s_u \in S$ and $P_v$ from $v$ to some $s_v \in S$. We can assume that $P_u \cap S = \{s_u\}$ and $P_v \cap S = \{s_v\}$. (Otherwise, replace $P_u, P_v$ by prefixes $P'_u, P'_v$ which satisfy this.) Since $s_u$ and $s_v$ are separable in $G_S$ we can extend such partition to $G$ so that $P_u$ is in the part of $s_u$ and $P_v$ in the part of $s_v$.

There are no such paths. Then, by Menger’s Theorem\footnote{Menger’s theorem for (possibly infinite) digraphs: let $A$ and $B$ be two sets of vertices in a possibly infinite digraph. Then there exist a family $P$ of disjoint $A \rightarrow B$ paths, and a set $S$ of vertices separating $A$ from $B$, such that $S$ consists of a choice of precisely one vertex from each path in $P$.} there exists $t \in V \setminus S$ which separates the pair $\{u, v\}$ from $S$. Now, delete all outgoing edges from $t$ and add edges $tu, tv$ and edges from $t$ to some other $d-2$ out-neighbors of $u, v$ which are different from $t$. (In the special case when $t \in \{u, v\}$, say $t = u$, add an edge $tv$ and another $d-1$ edges from $t$ to $d-1$ out-neighbors of $v$ which are different from $u$.)

Let us denote the resulting digraph $G'$. Consider the subdigraph $G''$ of $G'$ which is induced by all vertices which are reachable from $u$ or from $v$. We claim that $G''$ is strongly connected with minimum out-degree at least $d$: indeed, to see that its minimum out-degree is at least $d$, observe that we only modified the out-neighborhood of $t$ and we connected it with $d$ vertices which are reachable from $u$ or $v$. To see that $G''$ is strongly connected, let $x, y \in G''$ be a pair of vertices. Since $t$ separates $\{u, v\}$ from $S$ in $G$, and $x$ is reachable from $u$ or from $v$, it follows that there must be a path from $x$ to $t$. (Or else, any path from $u$ to $V$ via $x$ would reach $t$ before it reaches $x$, which implies that $x \notin V(G'')$, which is a contradiction to the definition of $x$.) Since there is an edge from $t$ to both $u$ and $v$ and since $y$ is also reachable from $u$ or $v$ there is a walk from $x$ to $y$ through $t$.

Therefore, $G''$ is strongly connected of minimum out-degree at least $d$ and by the assumption there is a friendly partition of $G''$ separating $u, v$. The vertices $u, v$ can also be separated in $G$: indeed, we use the partition of $G''$ and add $S$ along with a path from $t$ to $S$ to the same part as $t$. This gives us a partial friendly partition separating $u, v$ that can be extended to the entire digraph $G$ by Lemma\footnote{Menger’s theorem for (possibly infinite) digraphs: let $A$ and $B$ be two sets of vertices in a possibly infinite digraph. Then there exist a family $P$ of disjoint $A \rightarrow B$ paths, and a set $S$ of vertices separating $A$ from $B$, such that $S$ consists of a choice of precisely one vertex from each path in $P$.}

In all three cases, vertices $u, v$ are separable in $G$. This finishes our proof.

\section{Vertex-Transitive Digraphs}

In this section, we prove our partial results for vertex-transitive digraphs. First of all, recall the equivalence relation “being unseparable” denoted by $\sim$ on the vertex set of a digraph:

$$u \sim v \iff u \text{ cannot be separated from } v \text{ by a friendly partition.}$$

Observe that that for a vertex-transitive digraph $G = (V, E)$ each class of $\sim$ has the same number of vertices: indeed, let $u, v \in V$ be an arbitrary pair of vertices of $G$ and let $\tau$ be an automorphism of $G$ mapping $u$ to $v$. If $u$ is separable from some vertex $s_u$ by a friendly partition $\{V_1, V_2\}$ then $v$ is separable from the vertex $\tau(s_u)$ by $\{\tau(V_1), \tau(V_2)\}$ (since $\{V_1, V_2\}$ is a friendly partition if and only if $\{\tau(V_1), \tau(V_2)\}$ is a friendly partition). Conversely, if $u$ is separable from some vertex $s_v$ by a friendly partition $\{V_1, V_2\}$ then $v$ is separable from the vertex $\tau^{-1}(s_v)$ by $\{\tau^{-1}(V_1), \tau^{-1}(V_2)\}$ since $\{V_1, V_2\}$ is a friendly partition if and only if $\{\tau^{-1}(V_1), \tau^{-1}(V_2)\}$ is a
friendly partition. Therefore, each two vertices have the same number of vertices from which they can be separated by a friendly partition. This observation implies Proposition 13:

**Proposition 13** (Restatement). If the number of vertices in a vertex-transitive digraph with degree at least 3 is prime then each pair of vertices is separable.

Indeed, consider a transitive digraph $G$ with out-degrees $\geq 3$ and with a prime number $n$ of vertices. Then, since $G$ has a non-trivial friendly partition it follows that all equivalence classes with respect to $\sim$ have size $<n$. Thus, since all equivalence classes have the same size it follows that each equivalence class is a singleton, and consequently that each pair of vertices is separable.

We continue with several lemmas which lead to the proof of Proposition 14.

**Proposition 14** (Restatement). Let $\sim$ denote the following equivalence relation on the set of vertices of a digraph $G$.

$$u \sim v \iff u \text{ cannot be separated from } v \text{ by a friendly partition.}$$

Then, if $G$ is vertex-transitive with degree $d \geq 3$ then each equivalence class of $\sim$ is an independent set. Moreover, each vertex has its out-neighbors in at least 3 different classes.

**Lemma 28.** Let $G = (V,E)$ be a digraph with all vertices of out-degree $\geq 3$. If there is a friendly partition $\{V_1,V_2\}$ such that there exists $v_0 \in V_1$ with at least two out-neighbors in $V_1$ and at least one out-neighbor in $V_2$, then there is an equivalence class of size 1.

**Proof.** Let us call an in-neighbor $u$ of a vertex $v \in V_1$ **critical in-neighbor** if $u \in V_1$ and $v$ is the only out-neighbor of $u$ in $V_1$. If the vertex $v$ has at least one out-neighbor in $V_2$ and no critical in-neighbors, then its equivalence class under $\sim$ is $\{v\}$ (in other words, it can be separated from any other vertex): indeed, this implies that the partition $\{V_1 \setminus \{v\}, V_2 \cup \{v\}\}$ is friendly, and so every vertex in $V \setminus \{v\}$ is separated from $v$ by $\{V_1, V_2\}$ or by $\{V_1 \setminus \{v\}, V_2 \cup \{v\}\}$.

Suppose for contradiction that there is no equivalence class of size 1. Since $v_0$ has at least one out-neighbor in $V_2$ and it is not a singleton, there must exist a critical in-neighbor of $v_0$ by the observation above. Let us denote it $v_1$. Analogously there must be a critical in-neighbor of $v_1$ etc. Therefore, there is a sequence $\sigma = (v_0, v_1, v_2, \ldots)$ of vertices from $V_1$ such that $v_i+1$ is a critical in-neighbor of $v_i$. This sequence must be infinite, otherwise the last element would be singleton. We consider two cases and we show that both lead to a contradiction:

- **Case 1:** The first repeated vertex of $\sigma$ is $v_0$. That means $v_0$ is a critical in-neighbor of $v_i$ for some $i > 0$. This is a contradiction since $v_0$ has more than one out-neighbor in $V_1$ by the assumption and thus, it cannot be a critical in-neighbor.

- **Case 2:** The first repeated vertex of $\sigma$ is $v_i$ for $i > 0$. In other words, there exist $0 < i < j$ such that $v_i = v_j$. That means $v_i = v_j$ must have at least 2 out-neighbors, $v_{i-1}$ and $v_{j-1}$, in $V_1$. (The vertex $v_{i-1}$ must be different from $v_{j-1}$, or else $v_i$ would not be the first repeated vertex.) However, the only vertex from the sequence $\sigma$ having more than one out-neighbor in $V_1$ is $v_0$; a contradiction.

Note that Lemma 28 holds in general, not only for vertex-transitive digraphs. However, it implies the following corollary for vertex-transitive digraphs since in such digraphs all classes of the equivalence $\sim$ have the same size.
We prove by contradiction: consider a vertex-transitive graph $G$. Proof.

**Corollary 29.** Let $G = (V, E)$ be a vertex-transitive digraph of out-degree $\geq 3$. If there is a partition $V \equiv \{V_1, V_2\}$ such that there is a vertex from $V_1$ with at least two out-neighbors in $V_1$ and at least one out-neighbor in $V_2$, then all pairs of vertices of $G$ are separable.

Now, we show that each equivalence class of $\sim$ for vertex-transitive digraphs with all vertices of out-degree at least 3 is an independent set. First of all, we show that each class is a cycle or an independent set (Lemma 30). Then, we show that it cannot be a cycle (Lemma 31).

**Lemma 30.** If an equivalence class of $\sim$ in a vertex transitive digraph whose out-degrees are $d \geq 3$ contains an edge, then each equivalence class is a cycle.

Proof. Let us fix an arbitrary equivalence class $K$ and let $G_K$ denote the subdigraph induced by $K$. For the rest of the classes the result follows from vertex-transitivity since $G_K \cong \tau(G_K)$ for each automorphism $\tau$ of $G$.

First of all, note that $G_K$ is vertex-transitive, and in particular all vertices in $G_K$ have the same out-degree $g \geq 1$; indeed, let $u, v$ be arbitrary pair of vertices of $G_K$ and let $\sigma$ be an automorphism of $G$ mapping $u$ to $v$. Since $u, v \in K$ are from the same equivalence class, we have $K = \tau(K)$, and therefore $\tau|_K$ is an automorphism of $G_K$ mapping $u$ to $v$.

Observe that if $g \geq 3$ then $G_K$ itself can be partitioned in a friendly manner by Theorem 1 and Lemma 2. This is impossible since all pairs of vertices of $K$ are not separable.

Now, assume $g = 2$. Pick an arbitrary vertex $v$ from $K$. Then, the subdigraph induced by $K \setminus \{v\}$ has all vertices of out-degree at least 1. Therefore, it contains a cycle $C_1$. Let $u$ be an out-neighbor of $v$ which is not in $K$, and let $K_u$ denote the equivalence class of $u$. By vertex-transitivity, the out-degree of all vertices in the subdigraph induced by $K_u$ is 2 as well and thus, it must contain a cycle $C_2$ and a path $P \subseteq K_u$ connecting $u$ with $C_2$ (possibly consisting only of $u$, when $u$ is in $C_2$). Hence, there are two disjoint cycles $C_1 \subseteq K, C_2 \subseteq K_u$ and the path $\{v\} \cup P$ connecting $v$ and $C_2$. Moreover, $C_1$ does not contain $v$, which means that $v \in K$ is separable from $C_1 \subseteq K$ by some partition extending $C_1, C_2 \cup P \cup \{v\}$ by Lemma 2, a contradiction.

The only remaining possibility is $g = 1$. In this case, since $G_K$ is vertex-transitive, it must be a union of disjoint cycles. Notice however that there can only be one cycle in $G_K$: indeed, by Lemma 2 disjoint cycles can be separated by a friendly partition.

**Lemma 31.** An equivalence class of $\sim$ in a vertex transitive digraph $G$ whose out-degrees are $d \geq 3$ cannot be a cycle.

Proof. We prove by contradiction: consider a vertex-transitive graph $G$ with out-degrees $d \geq 3$ in which some equivalence class is a cycle. Further assume that $G$ has the minimum number of vertices among all such graphs. Notice that by vertex-transitivity all equivalence classes in $G$ are cycles. Let $G_c$ be the digraph whose vertex set consists of the equivalence classes of $G$ and there is an edge from class $K$ to class $L$ in $G_c$ if and only if there are $v_K \in K$ and $v_L \in L$ forming an edge $v_K \to v_L$ in $G$. We consider two cases:

- **Case 1:** There is a vertex in $G_c$, corresponding to an equivalence class $K$ from $G$, whose out-degree is $\geq 2$. Thus, there are $u, v \in K$ such that $u \neq v$ (recall that $K$ has at least two vertices since it is a cycle) and classes $K_u \neq K_v$ different from $K$ such that $u$ has an out-neighbor in class $K_u$ and $v$ has an out-neighbor in class $K_v$ (because each vertex in $K$ has $d - 1 \geq 2$ out-neighbours outside $K$). Now, we can easily separate vertices $u$ and $v$ by Lemma 2 since the classes $K_u$ and $K_v$ are cycles. This contradicts unseparability of the vertices $u$ and $v$ from the same class $K$.

24
• Case 2: All out-degrees in $G_\sim$ are 1. Thus, $G_\sim$ contains a cycle $C$ with no edge going outside from it. Consider a subdigraph $G_C$ of $G$ induced by the vertices from the unions of classes in $C$. Note that all out-degrees in $G_C$ are $d$ since there is no outgoing edge from $C$ in $G_\sim$. We claim that also all in-degrees in $G_C$ are $d$. Indeed, $G$ is transitive and hence all in-degrees in it are $d$. Therefore, since all out-degrees in $G_C$ are $d$, and no vertex in $G_C$ can have in-degree greater than $d$, it follows that all in-degrees in $G_C$ must be $d$.

We first claim that the cycle $C$ must contain more than 2 vertices: indeed, otherwise we reach a contradiction since Theorem\textsuperscript{7}\footnote{A bipartite graph $G$ with parts $X, Y$ of the same size has a perfect matching in $G$ if and only if for every $W \subseteq X$, $|W| \leq |N_G(W)|$. Moreover, each $d$-regular bipartite graph satisfies this condition: indeed, let $E_W$ be a set of edges between $W$ and $N_G(W)$. Then, $d |W| = |E_W| \leq d |N_G(W)| \implies |W| \leq |N_G(W)|.$} implies that $G_C$ has at least two friendly partitions: one partition being $\{C_1, C_2\}$ but every other partition has to separate vertices from $C_1$. By Lemma\textsuperscript{2}\footnote{From the viewpoint of $G_\sim$, this corresponds to a contraction of one edge of the cycle $C.$} this partition extends to a friendly partition of $G$, which separates vertices from the same equivalence class which is a contradiction.

Thus, we can assume that the cycle $C$ from $G_\sim$ contains at least 3 vertices. Pick classes $K, L$ such that $K \rightarrow L$ is an edge in $C$. By Hall’s marriage theorem\textsuperscript{8}\footnote{\textsuperscript{8}From Theorem of Hall.}, there exists a perfect matching $M$ between $K$ and $L$ which consists of edges from $K$ to $L$ in $G_C$: indeed, this follows by applying Hall’s Theorem to the graph whose sides are the classes $K, L$ and whose edges are the edges between $K$ and $L$, without their orientation. This graph is $(d-1)$-regular and hence contains a perfect matching, because $d-1 > 0$.

Now, remove the edges between $K$ and $L$ which are not in $M$ as well as the edges between vertices in $K$. Thus, each vertex in $K$ now has in-degree $d-1$ and out-degree 1 while each vertex in $L$ has out-degree $d$ and in-degree 1. Next, contract the edges of $M$ and note that both out-degree and in-degree of each vertex is again $d$ in the resulting graph. Further, the number of equivalence classes is decreased by 1 since the vertices from $K$ are identified with the vertices of $L$\textsuperscript{9} (See Figure 17). Moreover, every friendly partition of the resulting digraph can be extended to a friendly partition of $G$ by putting identified vertices in the same part. Thus, the resulting graph has fewer vertices than $G$, and still satisfies that at least one of its equivalence classes is a cycle. This contradicts the minimality of $G$.

We are now ready to wrap-up the proof of Proposition\textsuperscript{14}.

Proof of Proposition\textsuperscript{14}. By Lemma\textsuperscript{30} if there is an equivalence class contains an edge then it is a cycle, and by Lemma\textsuperscript{31} an equivalence class cannot be a cycle. Thus, each equivalence class must be an independent set.

It remains to prove that each vertex has its out-neighbors in at least 3 different classes:

• Case 1: If some vertex $v$ has all its out-neighbors in the same equivalence class $K$ then $v$ cannot be separable from its out-neighbors. This implies that $v \in K$ which is impossible since every equivalence class is an independent set.

• Case 2: If $v$ has its out-neighbors in exactly two classes $K, L$ then in one of them, say in $K$, there are at least two out-neighbors $x, y$ of $v$. Consider a friendly partition separating $v$ from some vertex $u \in L$. (Note that $v \notin L$ because $L$ is independent and $v$ has an out-neighbor in $L$.) Let $V_u$ be the part containing $v$ and $V_{\bar{u}}$ the part containing $u$. All vertices
Figure 17: A picture showing how we reduce the number of equivalence classes using a perfect matching given by Hall's marriage theorem in the proof of Lemma 31.
of $L$ must be in $V_u$ since $u$ is unseparable from them and all vertices from $K$ must be in $V_v$ (or else $v$ would have no out-neigbor in $V_v$). However, by Corollary 29 all pairs of vertices in $G$ are separable since $v$ has at least two out-neighbors, $x, y$, in its part $V_v$ and at least one neighbor, $u$, in the other part $V_u$. In other words, all classes are singletons which contradicts the fact that $x, y$ are in the same class.

Therefore, each vertex has its out-neighbors in at least 3 different classes. 

6 Infinite Digraphs

This last section consists of the proof of Proposition 15.

Proposition 15 (Restatement). Let $G$ be a (possibly infinite) digraph with minimum out-degree at least 3. Then, there exists a friendly partition in $G$.

We start with the following variant of König’s lemma [Kon27].

Lemma 32. Let $G(V,E)$ be an infinite digraph with bounded out-degree and with no cycle. If there is a vertex $v \in V$ such that there are infinitely many vertices reachable from it, then $G$ contains an infinite path.

Proof. We can construct such infinite path inductively as follows. We start with $P^{(1)} = \{v\}$ and in each step we extend the path $P^{(i)}$ to $P^{(i+1)}$ by one vertex assuming that the set of reachable vertices from the last vertex of $P^{(i)}$ is infinite (in the beginning such assumption is guaranteed by the assumption from the statement). We can always choose a next vertex preserving our assumption (by the infinite pigeonhole principle) since out-degree of each vertex is bounded. Note that no vertex is repeated since $G$ contains no cycle.

Proof of Proposition 15. It will be convenient to assume that all out-degrees are exactly 3. This is without loss of generality since by the Axiom of choice we can choose exactly three out-neighbors of each vertex and remove all of its other outgoing edges.

Let $V$ denote the vertex set of $G$. Observe that if there are disjoint sets $P_1, P_2 \subset V$ such that they induce subdigraphs of out-degree at least 1 then we can extend them to a friendly partition in the same way as we can do it for finite digraphs (Lemma 2).

Our proof strategy is to show there exist disjoint sets $P_1, P_2 \subset V$ such that for each $i \in \{1, 2\}$ either there is a directed cycle containing all vertices of $P_i$ or there is an infinite path containing all vertices of $P_i$, each of which induces a cycle or an infinite path. Both a cycle and an infinite path have out-degrees 1 and hence this guarantees the existence of a friendly partition of $G$.

For a vertex $u$ in $G$, let $R_u$ denote the set of vertices reachable from a vertex $u$. If there is a vertex $u$ such that $R_u$ is finite then $R_u$ induces a finite subdigraph whose out-degrees are all 3. By Theorem 11 this finite digraph contains two disjoint cycles and we are done.

Otherwise, pick an arbitrary pair of distinct vertices $u$ and $v$. Let $V_k \subseteq R_u \cup R_v$ denote the set of vertices with distance at-least $k \in \mathbb{N}$ from both $u$ and $v$. (So, $V_1 = R_u \cup R_v$ is the set of vertices reachable from $u$ or $v$.) Note, that for all $k$, $V_k \neq \emptyset$, because both $R_u$ and $R_v$ are infinite and because all the out-degrees are 3. We consider two cases:

- Case 1: There exists $k$ for which there do not exist two disjoint paths, one starting in $u$ and one in $v$ that end in $V_k$. Therefore, by Menger’s theorem for infinite graphs [Men27], [AB09] there exists a vertex $t$ separating $\{u, v\}$ from $V_k$. Let us delete the vertex $t$ from
and let $V_{u,v}$ denote the set of vertices reachable from $u$ or $v$ in the resulting digraph $G \setminus \{t\}$. Note that $V_{u,v}$ is finite and that it induces a subdigraph with minimum out-degree at least 2. Such subdigraph contains a cycle $C_1$.

The set $V \setminus V_{u,v}$ induces an infinite subdigraph in which there are infinitely many vertices reachable from $t$: indeed, in $G$ there are infinitely many vertices reachable from $u$ or from $v$, and $t$ separates the finite set $V_{u,v}$ containing $u$ and $v$ from the infinite set $V \setminus (V_{u,v} \cup \{t\})$ containing the remaining vertices reachable from $u$ or from $v$. Therefore, Lemma 32 implies that the subdigraph induced by $V \setminus V_{u,v}$ contains a cycle $C_2$ or an infinite path $P$.

Consequently, $C_1$ and either $C_2$ or $P$ witness the existence of a friendly partition in the original graph $G$.

• Case 2: For every $k$, there are two disjoint paths from $u$ and $v$ to $V_k$. We prove that this implies the existence of two infinite disjoint paths starting in $u$ and $v$, respectively. We construct such paths in the following way (which is similar to the proof of Lemma 32): we start with $P_u^{(1)} = \{u\}, P_v^{(1)} = \{v\}$ and in each step, we extend the paths $P_u^{(i)}, P_v^{(i)}$ to $P_u^{(i+1)}, P_v^{(i+1)}$, each by one vertex.

Let $\mathcal{P}^{(i)}$ be the set of all pairs of finite disjoint paths of the same length with prefixes $P_u^{(i)}$ and $P_v^{(i)}$, respectively. In the base-case, $\mathcal{P}^{(1)}$ is infinite by the assumption in Case 2. We construct the two disjoint paths by maintaining the invariant that $\mathcal{P}^{(i)}$ is infinite for all $i$. Indeed, assume we have done so for $i$ steps: so, $\mathcal{P}^{(i)}$ is infinite, which in particularly implies that the constructed paths $P_u^{(i)}$ and $P_v^{(i)}$ are disjoint. Now, there are only finitely (in fact, 9) possible ways to extend $P_u^{(i)}$ and $P_v^{(i)}$ since the out-degree of each vertex is 3. Therefore, since $\mathcal{P}^{(i)}$ is infinite, the infinite pigeon principle implies that there is at least one extension for which $\mathcal{P}^{(i+1)}$ is infinite. In this way, we can extend $P_u^{(i)}$ and $P_v^{(i)}$ indefinitely. This pair of disjoint paths then witnesses the existence of a friendly partition of $G$ as required.

\[\square\]

7 Appendix

Recall that Question 3 asks whether for every $r > 1$ there is a $d(r)$ such that each digraph with minimum out-degree at least $d(r)$ has a non-trivial $r$-friendly partition.

Note that an affirmative answer to this question has the following nice corollary: each digraph on $n$ vertices with minimum out-degree at least $d(r)$ contains a subdigraph with minimum out-degree $r$ on at most $\frac{n}{r}$ vertices.

While we do not know the answer to Question 3 we present a proof by Ron Holzman of the above corollary. We focus on the case $r = 2$ but the idea applies more generally.

**Proposition 33** (Ron Holzman, personal communication). If $G$ is a digraph on $n$ vertices with all out-degrees 10 then it contains a subdigraph on at most $\frac{n}{2}$ vertices with all out-degrees at least 2.

**Proof.** We select every vertex independently with probability $\frac{1}{3}$ and denote by $X$ the random set of these selected vertices. Let $Z$ be the set of vertices of $G$ having no out-neighbor in $X$, and $O$ be the set of vertices of $G$ having one out-neighbor in $X$. We create a set of vertices
Y by adding to X two out-neighbors of each vertex in Z and one out-neighbor of each vertex in O. Such Y contains at least two out-neighbors of every vertex of G. We proceed to upper bound the expected size of Y.

\[
E(|Y|) \leq E(|X|) + 2E(|Z|) + E(|O|) = n \left( \frac{1}{3} + 2 \left( \frac{2}{3} \right) ^{10} + \frac{10}{3} \left( \frac{2}{3} \right) ^{9} \right) < 0.46n.
\]

Therefore, there exists a realization of Y of size less than 0.46n < \( \frac{n}{2} \). Since Y contains at least two out-neighbors of every vertex of G it has to itself induce a subdigraph with minimum out-degree at least 2.

One can extend this result for \( r > 2 \) by choosing suitable \( d = d(r) \) so that

\[
\frac{1}{3} + \sum_{k=0}^{r} (r-k) \binom{d(r)}{k} \left( \frac{1}{3} \right)^k \left( \frac{2}{3} \right)^{d(r)-k} < \frac{1}{2}.
\]

The right hand side is bounded from above by \( 1/3 + (r+1) \cdot r \cdot d(r)^r \cdot (2/3)^{d(r)-r} \). Thus, it is sufficient to find \( d(r) \) such that

\[
(r+1) \cdot r \cdot d(r)^r \cdot \left( \frac{3}{2} \right)^r \left( \frac{2}{3} \right)^{d(r)} < 1/6
\]

which is possible since the left-hand side converges to zero as \( d(r) \to \infty \).
