ABSTRACT
Non-convex loss functions arise frequently in modern machine learning, and for the theoretical
analysis of stochastic optimization methods, the presence of non-isolated minima presents a unique
challenge that has remained under-explored. In this paper, we study the local convergence of the
stochastic gradient descent method to non-isolated global minima. Under mild assumptions, we
estimate the probability for the iterations to stay near the minima by adopting the notion of stochastic
stability. After establishing such stability, we present the lower bound complexity in terms of various
error criteria for a given error tolerance $\epsilon$ and a failure probability $\gamma$.

Keywords Stochastic Gradient Descent, Non-isolated minima, Stochastic Stability, Supermartingale Theorem,
Non-Convex optimization

1 Introduction
Stochastic gradient-based optimization methods have demonstrated tremendous success in machine-learning problems
[4]. In many applications of such methods as training algorithms, the objective function $f(x)$ has an additive form
going through a set of $M$ training data (i.e. regression, cross entropy, etc.),

$$f(x) = \frac{1}{M} \sum_{i=1}^{M} f_i(x).$$  (1)

For large data sets, $M \gg 1$, the implementation of the conventional gradient descent (GD) approach is prohibitively
expensive due to the huge number of evaluations of the loss function and its back propagated gradients. In this
context, stochastic gradient descent algorithms have emerged as a unique alternative to minimize the computational
cost. Among the various algorithms, this paper focuses on the stochastic gradient descent (SGD) [5] and the stochastic
average gradient (SAG) [37] as specific examples:

SGD: $x_{n+1} = x_n - \alpha_n \nabla f_{i_n}(x_n)$,  \hspace{1cm} (2a)

SAG: $x_{n+1} = x_n - \frac{\alpha_n}{M} \sum_{i=1}^{M} y_i^n$, \hspace{1cm} (2b)

where for simplicity we set the batch size to be 1 for SGD. Here, $\alpha_n$ is the deterministic learning rate, $i_n$ is a randomly
selected index, and the auxiliary variable $y_i^n$ is determined by the following update rule ([37]),

$$y_i^n = \begin{cases} \nabla f_i(x_n), & i = i_n, \\ y_i^{n-1}, & i \neq i_n. \end{cases}$$  (3)

Local Analysis for SGD in non-convex optimization with non-isolated local minima

Prior works (see [4,32] and references therein) on the analysis of gradient-based algorithms for convex optimizations in both deterministic and stochastic settings have provided great insight, and these results have been supported by numerical results. A remarkable observation, as demonstrated in many recent studies, is that the stochastic gradient algorithms still perform well in non-convex settings, such as the deep neural networks ([1,16,28]). This success has intrigued many theorists to explore convergence properties for non-convex optimization problems; almost sure convergence to critical points by [31,35], concentration inequalities for the difference between the loss function and its global minimum by [11]. Convergence results using the Polyak-Lojasiewicz (PL) condition by [29,30] are some important examples of such results.

As fig. 1 illustrates pictorially, an interesting feature in non-convex optimization is that the global minimum is often not isolated. For instance, in the regime of overparametrized neural networks, often observed is that the global minima can form a connected set that belongs to a submanifold of $\mathbb{R}^d$ ([6,8,12] and therein). Despite its presence in machine-learning, this important scenario has been under-explored in theoretical investigations. In addition, non-convex optimization tasks are sometimes very sensitive to the initialization, as reported in [15,39]. In these works, the empirical tests have suggested that bad initial guess or poorly chosen learning rates can lead to poor performance of stochastic gradient methods. These observations clearly demand a better understanding of the behavior of the iterations from stochastic algorithms.

This paper focuses primarily on the convergence behavior of stochastic gradient descent methods near a subset of local minima, $\mathcal{X}$, by taking into account the effect of the initial guess and the learning rate. The first obvious question is how to characterize the non-isolated set $\mathcal{X}$ using its geometric structure. This requires a new framework of local convexity. Moreover, the paper poses the following further questions: Among the trajectories associated with the iterations of stochastic optimization methods starting from an initial iterate $x_1$ near $\mathcal{X}$,

1. How likely do the iterates from SGD type methods remain close and converge to $\mathcal{X}$ in non-convex optimization?
2. What is a lower bound for the failure probability when there is the possibility of divergence from $\mathcal{X}$?
3. Can variance reduction methods, such as SAG, enhance the local convergence and improve the iteration complexity in a neighborhood of $\mathcal{X}$?

The first important focus of our work is to relax some standard assumptions. In many of previous works, assumptions for the loss function are made at the global level, e.g., for any $x, y$ in $\mathbb{R}^d$,

\begin{align}
\|\nabla f(x) - \nabla f(y)\| &\leq L\|x - y\|, \quad \text{Lipschitz continuous gradient} \\
\mathbb{E}_i\|\nabla f_i(x)\|^2 &\leq C + C_V\|\nabla f(x)\|^2, \quad \text{Quadratically bounded Variance}
\end{align}

where $i$ is the index randomly chosen and $C, C_V$ are non-negative universal constants. Under assumptions like these, many aspects of global convergence has been studied ([4,22]). In contrast, such assumptions can be relaxed for local convergence analysis, in which an event where the departure of the iterations from a neighborhood $\mathcal{N}$ of $\mathcal{X}$ can be neglected. In other words, the information on the Lipschitz condition and the bounded variance condition outside
Local Analysis for SGD in non-convex optimization with non-isolated local minima

$\mathcal{X}$, the neighborhood of interest, does not have to be assumed. Consequently, we can provide precise answers for the above questions under the local conditions near $\mathcal{X}$, e.g., locally Lipschitz continuous gradient, locally bounded variance of the stochastic gradient and a locally convex-like condition.

Besides aforementioned assumptions, part of our analysis is performed with the quasar convexity which is firstly introduced in [17] as a different term. The quasar convexity possesses interesting geometric features (more detail in [13]). Although this condition is weaker than many of convex-like conditions (e.g. the essential strong convexity (ESC), the weak strong convexity (WSC) and the restricted secant inequality (RSI) ([22])), there are still some non-convex landscapes where even this condition fails to hold. A specific example will be presented in fig. 2. To deal with such a highly non-convex landscape, we formulate a condition which describes the situation of non-isolated minima, and more importantly, generalizes the quasar convexity to an even more general framework of local convexity. Our main analysis for SGD is carried out under this generalized condition as one of the very mild conditions, which allows us to characterize the behavior of the SGD around non-isolated local minima. Thus, our framework encompasses many possible scenarios of minima, with isolated minima as one obvious and special case.

Beyond the vanilla SGD, there are several variance reduction methods, e.g., [7, 9, 19, 21, 40, 41], and the potential improvement is also of theoretical interest for non-convex problems. As an example, we consider the SAG method by [37]. We extend the analysis in [37] to local convergence to an isolated minimum, to examine the improvement of the complexity using the same notation of stochastic stability. This analysis, due to the involvement of the Lyapunov function, relies on the assumption that the loss function is locally strongly-convex at the minimum.

Summary of Our Contributions

Our primary goal is to establish local convergence and iteration complexity of SGD and SAG for non-convex optimization. Our results on SGD apply to the case of non-isolated local minima (which obviously includes non-isolated global minima since global minima are local minima as well). To be specific, we show that SGD converges to $\mathcal{X}$ with a probability that depends on the initial guess, the learning rate, the local Lipschitz constant for the gradient and the mini-batch size. More importantly, the concentration inequalities for SGD are based on standard error criteria, i.e., the expectation of $f(x_n) - f^*$ or the expectation of $\|\nabla f(x_n)\|^2$. Due to our particular focus on local convergence, the failure probability in these inequalities has a finite lower bound, which accounts for events when the iterations diverge from $\mathcal{X}$. This is a departure from the result in the global convergence analysis, in which the iterations are allowed to approach any critical point and as a result, one can choose any failure probability between 0 and 1. With the concentration inequality for the expectation of $\|x_n - x^*\|^2$, we show that the failure probability can be set exactly as the probability of divergence from the local minimum which depends on the initial guess $x_1$ and a given constant step size.

Related work

Stability in Dynamical theory. In this paper, we use the term stability in the context of the dynamical theory for stochastic processes. This is not in the context of the generalization error, roughly, but rather, how the change of an input influences that of the output. The main idea emanates from the theory of stochastic dynamical system, especially the notion of stochastic stability in [25]. In the classical dynamical theory ([27]), the notion of local stability is deterministic, i.e., trajectories starting near a stable equilibrium $x^*$ do not leave its neighborhood. This is not guaranteed for stochastic processes due to the noise which may cause a trajectory to diverge from the stable equilibrium. However, with a similar Lyapunov function approach for the stochastic processes, [26] established the notion of stability with a probability for the trajectories to remain close to $x^*$. The only mild assumption is that the Lyapunov functions are required to have supermartingale properties in a neighborhood of $x^*$. By applying the results in [24, 25] to non-convex problems, our results show that the probability of stability depends on the magnitude of the learning rate and the initial distance from the set of minima $\mathcal{X}$.

Stochastic Gradient Descent. There has been exciting recent development for the analysis on SGD in non-convex optimization. [35] proved under the weak assumption that $f$ has a locally Hölder continuous gradient, that the SGD iterations either converge to a stationary point or diverge almost surely with random initial guess. Another recent result is by [31], where they show, by assuming that the gradient is globally Lipschitz continuous and the set where the gradients with magnitude being less than some tolerance $\epsilon$ is bounded, the SGD iterations converge to stationary points almost surely with random initial guess. The convergence of SGD to local minima, which is more pertinent to the current work, has also been studied by some authors. Part of the analysis in [31] shows a local convergence of SGD with rate at most $O\left(\frac{1}{n}\right)$, with assumption that the local minimum is a regular minimizer and the initial guess is
close to the minimizer. With the existence of a certain class of stable submanifold assumed, the analysis in [11] yields concentration inequalities for the error $f(x_n) - f^*$, which is controlled by batch sizes and step sizes.

**Stochastic Average Gradient.** Convex optimization has been investigated in many applications. Many properties of the convexity and the strong convexity have been extensively studied in the monograph by [32].

In the case when a finite training set is given and under strong convexity assumption, [37] has shown the linear convergence of the SAG method to the global minimum, as well as the improved performance over the stochastic gradient descent methods in some cases.

**Iteration Complexity and Concentration Inequality.** Of our interest in this work is the iteration complexity, which is defined to be the number of iterations to compute a stochastic gradient. In global convergence analysis, the estimation of complexity is performed with standard error indicators: the loss error $E[f(x_n) - f_*]$ or the gradient estimate $E[\|\nabla f(x)\|^2]$, rather than the iterate error, $E[\|x_n - x^*\|^2]$. On the other hand, when it comes to local convergence analysis, we should consider events where the iterations diverge from the neighbor of the minima. This leads to slightly modified error criteria: $E[(f(x_n) - f_*)I_S]$ ([11],[34]) and $E[\|x_n - x^*\|^2 I_S]$ ([31]), where $I_S$ denotes the indicator function defined on the events that the iterations remain close to local optima. Our technical results, especially the concentration inequalities, are expressed in this manner. We will also show the complexity in terms of the gradient $E[\|\nabla f(x_n)\|^2 I_S]$.

2 Preliminaries

2.1 Notation

$K \subset \mathbb{R}^d$ denotes a compact set unless it is stated otherwise. $d$ represents the dimension of the parameter space. We use $\|\cdot\|$ for the $\ell_2$ norm in $\mathbb{R}^d$. $[N]$ is the set of integers $[N] := \{1, 2, \cdots, N\}$. For the complexity, we define big-$O$ notation as follows: $a_n = O(b_n)$ if $\limsup_{n} \frac{a_n}{b_n} < \infty$ and $a_n = \Theta(b_n)$ if $a_n = O(b_n)$ and $b_n = O(a_n)$.

2.2 Stochastic Stability

Here, we briefly introduce definition of stochastic stability for discrete stochastic processes. First of all, we define the term stable path.

**Definition 2.1.** With an initial iterate $x_1 \in K$, a realization $\{x_n\}_{n=2}^{\infty}$ from a stochastic algorithm is called a stable path if

$$x_n \in K \text{ for all } n \geq 2. \tag{5}$$

Since the update rule for stochastic gradient methods such as (2a) and (2b) uses the previous information, the iteration from both methods forms a discrete process with a filtration $\mathcal{F}_n = \sigma(\cup_{i=1}^{n} \mathcal{F}_n)$. Strictly, the stochastic stability is defined by the measure of the set of stable paths with respect to the $\sigma$-algebra $\mathcal{F}_{\infty} = \sigma(\cup_{n=1}^{\infty} \mathcal{F}_n)$.

**Definition 2.2.** With an initial guess $x_1 \in K$, an iteration from a stochastic algorithm is said to be stable with probability at least $1 - \eta$. Namely,

$$\mathbb{P}\{x_n \in K \text{ for all } n \geq 2 | x_1\} > 1 - \eta. \tag{6}$$

For interesting technical results relative to this notion, we refer the reader to reference [25] and therein.

2.3 Assumptions for SGD

Our regularity assumption on the loss function $f$ is that it has a locally Lipschitz gradient.

**Assumption 2.1.** The gradient of $f$ in the iteration (2a) is locally Lipschitz continuous for any compact set $K$, i.e., there exists a constant $L_K > 0$ such that,

$$\|\nabla f(x) - \nabla f(y)\| \leq L_K \|x - y\|, \text{ for all } x, y \in K.$$

The stochastic nature of the SGD method can be revealed by writing the gradient term in the iteration (2a) as,

$$\nabla f_{i_n}(x) = \nabla f(x) + \xi(x, \omega),$$

4
Local Analysis for SGD in non-convex optimization with non-isolated local minima

Figure 2: Examples of non-convex functions with isolated minima (left), or non-isolated minima (middle and right). The regions highlighted in red indicate sets of local minima. The figures in the left and middle panels are those loss functions that satisfy Assumptions 2.4 and 2.5 while the loss function shown in the right figure only satisfies Assumption 2.5.

where \( \xi(x, \omega) \) represents the noise arising at \( x \) with \( \omega \) sampled from some fixed probability space. Thus, we can interpret the iteration of SGD in (2a) as a Markov process,

\[
x_{n+1} = x_n - a_n \left( \nabla f(x_n) + \xi_n \right),
\]

where \( \xi_n := \xi(x_n, \omega_n) \).

We assume that the noise has the following properties.

**Assumption 2.2.** The noise satisfies that

(i) \( \mathbb{E} [\xi(x, \omega) | x] = 0 \) for any \( x \in \mathbb{R}^d \),

(ii) There exists some \( \sigma_K > 0 \) for any compact set \( K \) such that

\[
\sup_{x \in K} \mathbb{E} \left[ \| \xi(x, \omega) \|^2 | x \right] \leq \sigma_K.
\]

The first part of the assumption is standard, allowing an unbiased stochastic gradient at any \( x \). The second part means that the variance of the noise in a compact set is uniformly bounded. Our assumption is equivalent to the one in [11]). But it is weaker than those assumptions made in ([4, 35]).

Next, we make the standard assumption on the learning rates ([4, 36]), as follows.

**Assumption 2.3.** The learning rates satisfy that

\[
a_n > 0, \quad \sum_{n=1}^{\infty} a_n = \infty, \quad \sum_{n=1}^{\infty} a_n^2 < \infty.
\]

Now, we consider landscapes possibly seen in the non-convex optimization. fig. [2] we present three examples. The left figure shows the case of isolated local minima, while a loss function with a connected set of local minima is depicted in the middle and the right panels. Other than these figures, there is an interesting example, where a function has a local minimum, but it is not locally convex at the point.

**Example 2.1.** Let \( f : [-1, 1] \to \mathbb{R} \) be a function with \( f(0) = 0 \), whose derivative defined as a piecewise linear continuous function as follows

\[
f'(x) = \begin{cases} 
x - \frac{x}{2m+1}, & x \in \left[ \frac{1}{2m+1}, \frac{1}{2m+1} + \frac{2}{2m} \right], \\
x + \frac{x}{2m+1}, & x \in \left[ \frac{1}{2m+1} + \frac{2}{2m}, \frac{1}{2m+1} \right],
\end{cases} \quad \text{for } m \geq 0
\]

\[
f'(-x) := -f'(x).
\]
Pictorially, the graph of $f'$ has the saw teeth on the line $y = 0.5x$ in $[0,1]$. By this construction, one can see that the derivative $f'$ is Lipschitz continuous and the original function $f$ has the local minimum at $x = 0$, without being locally convex. There is a sequence of points convergent to $x = 0$ where the function is locally concave. This is due to the construction that $f'$ increases in some intervals and decreases in others.

In fact, the examples that are introduced so far are motivated by [18]. The paper revealed interesting features of the quasar convexity which is firstly defined by [17]. Since we focus on the local convergence, we weaken their global assumption as follows.

**Assumption 2.4.** Let $\zeta \in [0,1]$ and $x^*$ be a local minimum of $f$. We say that $f$ is locally $\zeta$-quasar-convex with respect to $x^*$ if there exists a closed ball $B_\epsilon(x^*)$ such that for all $x \in B_\epsilon(x^*)$,

$$
(\nabla f(x), x - x^*) \geq \zeta(f(x) - f(x^*)) \quad (10)
$$

We remark that this condition is certainly weaker than the local convexity. Specifically, the function in Example 2.1 satisfies Assumption 2.4. The reason is as follows: The function $f$ has a strict local minimum as $x = 0$ and its derivative is certainly continuous. Thus, the function satisfies Assumption 2.4 by [18], Observation 1.

The parameter $\zeta$ describes the tendency of non-convexity at $x^*$. As illustrated in [18], this condition is weaker than the star-convexity ($\zeta = 1$, [33]), the usual convexity, and obviously, the strong convexity.

One can observe that if a loss function is locally quasar-convex with respect to $x^*$, any critical point in $B_\epsilon(x^*)$ must be a local minimum where the loss function equals $f(x^*)$. As illustrated in fig. 2, Assumption 2.4 can include the case of a connected local minima (the middle figure). However, this assumption may not work for some cases like the right figure in fig. 2. Let us discuss on the example, more precisely.

**Example 2.2.** In fact, the right figure in fig. 2 is the graph of the function

$$
f(x, y) = \frac{1}{1 + \exp(-0.07\sin(y) - x^2)}.
$$

Clearly, when a point $(x, y)$ lies in the curve $\sin(y) = x$, this function achieves the global minimum value. However, we claim that this function is not locally quasar-convex. For instance, at the origin $(0,0)$ as a global minimum, one can follow any line $y = mx$. We consider the graph at the cross section of the surface and the plane $y = mx$. An immediate observation is that as the slope $m$ increases to $+\infty$, the graph becomes more oscillatory at the origin, and the set of local maxima near the origin are more and more clustered. In light of this, $f$ is not locally quasar-convex. (Otherwise, $f$ has to have a critical point being not a local minimum near the origin, which contradicts to the condition in[2.4].) For similar reasons, this function cannot be locally quasar-convex at any point on $\sin(y) = x$.

To include this example and more classes of non-convex loss functions, we generalize the assumption 2.4. Toward this end, we introduce the notion of a projection onto a set.

**Definition 2.3.** For a compact set $\mathcal{X}$, the set-valued mapping $\Pi_\mathcal{X} : \mathbb{R}^d \to 2^\mathcal{X}$ is defined by

$$
\Pi_\mathcal{X}(x) = \{ z \in \mathcal{X} : \| x - z \| = \text{dist}(x, \mathcal{X}) \}.
$$

This is known as the metric projection. Again, we consider the projection with respect to the usual Euclidean topology.

Let us consider $\mathcal{X}$ as a compact subset of local minima. Let $\mathcal{N}(\mathcal{X})$ denote a $r$-neighborhood of $\mathcal{X}$. We also use $\bar{\mathcal{N}}(\mathcal{X})$ to represent the closure of the neighborhood.

**Assumption 2.5.** There exists a non-negative function $h : \bar{\mathcal{N}}(\mathcal{X}) \to \mathbb{R}$ such that

$$
(\nabla f(x), x - x_p) \geq h(x) \quad (11)
$$

for any $x \in \bar{\mathcal{N}}(\mathcal{X})$ and any projection $x_p \in \Pi_\mathcal{X}(x)$.

Intuitively, the non-negative function $h$ can interpreted as the slope in the direction towards $\mathcal{X}$. This can be understood by a simple one-dimensional example: If $f : \mathbb{R} \to \mathbb{R}$ satisfies that $f'(x)(x - x^*) \geq 0$ for any $x$ near $x^*$, $x^*$ is a local minimum. In this case, $h(x) = 0$. Another example is $f'(x)(x - x^*) \geq c(x - x^*)^2$, which is the case of the strong convexity near $x^*$.

**Remark 2.1.** Assumption 2.5 is a generalization of Assumption 2.4. For instance, if $\mathcal{X} = \{ x^* \}$ and $h(x) = \zeta(f(x) - f^*)$, Assumption 2.4 immediately follows. Also, in the right figure in fig. 2 if one takes a valley properly as a neighborhood of the set of the local minima, then Assumption 2.5 is fulfilled.
Local Analysis for SGD in non-convex optimization with non-isolated local minima

2.4 Assumptions for SAG

Assumption 2.6. The gradient of $f_i$ is locally Lipschitz-continuous for any convex and compact set $K$ with some constant $L_K > 0$:

$$\|\nabla f_i(x) - \nabla f_i(y)\| \leq L_K \|x - y\| \text{ for any } x, y \in K \text{ and any } i \in \{1, 2, ..., M\}.$$

3 Main Results and Technical Theorems

This section is organized as follows. In section 3.1, we summarize our results with iteration complexity of both SGD and SAG together with the best possible failure probability. In section 3.2, we present a probability bound for the stability of a SGD near local minima and its complexity in each of the non-convex landscapes 2.4 and 2.5. Similar analysis for the SAG method is shown in section 3.3.

3.1 Main Results

To state our results in the simplest possible form with little or no loss of their implications, we removed some terms in the following estimations and first state the theorems only informally. More technical details can be found in the following sections.

Theorem A for SGD For a non-convex loss $f(x)$ and mini-batch size $I \in \{M\}$, starting from an initial guess $x_1$ near a subset of local minima, $\mathcal{X}$, iterations from SGD converge to global minima with probability at least $S_\infty$ where

$$S_N := 1 - \frac{\exp(L_r \sum_{n=1}^{N-1} a_n^2)}{r^2} \left(\text{dist}(x_1, \mathcal{X})^2 + \frac{\sigma_r}{T} \sum_{n=1}^{N-1} a_n^2\right).$$

(12)

Here, $L_r$ and $\sigma_r$ are the constants associated with the $r$-neighborhood of $\mathcal{X}$, $N_r(\mathcal{X})$, as defined in Assumptions 2.1 and 2.2 respectively.

This theorem is applicable to any non-convex landscape satisfying the assumption 2.3. As demonstrated in this argument, Assumption 2.3 is required to ensure a positive probability of stability for a very large number of steps ($N \gg 1$).

Based upon Theorem A, we deduce that the probability of stability, $S_N$, is essentially the best possible failure probability as in the following theorem.

Theorem B for SGD In the same setting as in Theorem A, suppose the learning rate is given by $a_n = \frac{\alpha}{n^\beta}$ with $\beta \in (\frac{1}{2}, 1)$ and sufficiently small $\alpha > 0$. Then, for tolerance $\epsilon > 0$ and failure probability $\gamma \in (S_N, 1)$, SGD finds $f(x) \leq f^* + \epsilon$ in the number of iterations

$$N = \Theta \left(\frac{\text{dist}(x_1, \mathcal{X})^2 + \frac{\sigma_r}{T}}{\epsilon(\gamma - S_N)}\right)^{-1/\gamma}.$$

Furthermore, finding an approximate first-order stationary point, namely, $\|\nabla f(x)\| \leq \epsilon$ requires a similar number of iterations

$$N = \Theta \left(\frac{f(x_1) - f^* + \sigma_r}{\epsilon(\gamma - S_N)}\right)^{-1/\gamma},$$

where $L_{r+\delta}$ is the Lipschitz constant associated with the $r + \delta$-neighborhood of $\mathcal{X}$, $N_{r+\delta}(\mathcal{X})$. Besides, $f^*$ is the minimum in the closure of the neighborhood, $N_{r+\delta}(\mathcal{X})$.

Theorem C for SAG For a locally strongly-convex loss $f(x)$ about a local minimum $x^*$ and tolerance $\epsilon > 0$, starting from an initial guess $x_1$ near $x^*$, with probability at least

$$1 - \mathcal{O} \left(\frac{\|x_1 - x^*\|^2 + \frac{\sigma}{L_x}}{r^2}\right),$$

SAG finds $\|x - x^*\| \leq \epsilon$ in the number of iterations

$$N = \Theta \left(\log \frac{1}{\epsilon}\right).$$
The estimate above involves the sample variance \( \sigma := \frac{1}{M} \sum_{i=1}^{M} \|y_i^1 - \nabla f_i(x^*)\|^2 \) with auxiliary gradients \( \{y_i^1\}_{i=1}^{M} \) initially chosen. The complexity did not include the cost associated with the initialization of \( \{y_i^1\} \).

Similar to the discussion in [3, 37], we organize the computational complexity for SGD and SAG as follows.

<table>

\[ \text{Remark 3.1. As we will show in Theorem 3.4, the results on SGD can be extended under a condition weaker than the LQC, such as the Assumption 2.5, but the number of iterations \( N \) in the complexity estimate may be different in this case.} \]

### 3.2 Stability and Complexity of SGD

We state technical results for the SGD iterations (2a). The first two results are probabilistic estimates for the stability of SGD for the non-convex conditions 2.4 and 2.5 respectively. In the last two results, we show the lower bound complexity corresponding to these results on stability. Note that Theorem 3.2 (resp. theorem 3.4) is stronger than Theorem 3.1 (resp. theorem 3.3) due to the relationship between Assumptions 2.4 and 2.5.

We state our main theorem on the stability and convergence of the SGD iterations (2a) when \( f \) is locally \( \zeta \)-quasar convex with respect to \( x^* \).

**Theorem 3.1.** Under Assumptions 2.1 to 2.4, the iterations from SGD (2a) satisfy the following properties

(i) For \( \zeta \in [0, 1] \), there exists a ball \( B_r(x^*) \), such that for any \( x_1 \in B_r(x^*) \),

\[
\mathbb{P}\{x_n \in B_r(x^*) \text{ for all } n \in |N| | x_1 \} \geq 1 - C_{\zeta,N} \text{ for each } N \geq 2,
\]

where \( L_r \) is the Lipschitz constant associated with \( B_r(x^*) \), and

\[
C_{\zeta,N} := \frac{b_N}{r^2} \left( \|x_1 - x^*\|^2 - \frac{2\zeta a_1}{b_2} (f(x_1) - f^*) + \sigma_r \sum_{n=1}^{N-1} \frac{a_n^2}{b_{n+1}} \right),
\]

\[
b_n := \prod_{j=1}^{n-1} \left( 1 + L_r a_j^2 \right), \quad b_1 := 1.
\]

This can be extended to the limiting case \( N = \infty \) as follows.

\[
\mathbb{P}\{x_n \in B_r(x^*) \text{ for all } n \geq 1 | x_1 \} \geq 1 - C_{\zeta,\infty}.
\]

(ii) In the case when \( \zeta \in (0, 1] \), almost surely each stable path (Cf. Def. 2.1) converges to some interior critical point in \( K \) where the function value equals \( f^* \). Namely,

\[
\mathbb{P}\left\{ \lim_{n \to \infty} x_n = x, f(x) = f^* | \{x_n\}_{n=1}^{\infty} \subseteq B_r(x^*) \right\} = 1.
\]

Consequently, these statements imply that

\[
\mathbb{P}\left\{ \lim_{n \to \infty} x_n = x, f(x) = f^* | x_1 \right\} \geq 1 - C_{\zeta,\infty}.
\]

We refer the reader to the proof in appendix B.1.

The first statement implies that with sufficiently small learning rates and \( x_1 \) being sufficiently close to \( x^* \), SGD is stable with high probability (at least \( C_{\zeta,\infty} \)). Secondly, \( f(x_n) \) converge to \( f^* \) with probability one if they are stable paths.

The following is a generalization of the preceding theorem.
Theorem 3.2. Suppose there exists a \( r \)-neighborhood of \( \mathcal{X} \) such that \( N_r(\mathcal{X}) \) satisfies Assumption 2.5. Under Assumptions 2.7 to 2.3, the following statements hold for the SGD iterations (2a).

(i) For any initial \( x_1 \in N_r(\mathcal{X}) \),
\[
P \left\{ x_n \in N_r(\mathcal{X}) \text{ for all } n \in [N] \mid x_1 \right\} \geq 1 - C_N, \tag{14}
\]
where \( L_r \) is the Lipschitz constant for \( N_r(\mathcal{X}) \), and
\[
C_N := \frac{b_N}{r^2} \left( \text{dist}(x_1, \mathcal{X})^2 - \frac{2a_1}{b_2} (\nabla f(x_1), x_1 - (x_1)_p) + \sigma_r \sum_{n=1}^{N-1} \frac{a_n^2}{b_{n+1}} \right), \tag{15}
\]
\[
b_n := \prod_{j=1}^{n-1} (1 + L_r a_j^2), \quad b_1 := 1.
\]

(ii) If \( h(x) > 0 \) in Assumption 2.5, then
\[
P \left\{ \lim_{n \to \infty} x_n = x, \ f(x) = f^* \mid \{x_n\}_{n=1}^\infty \subset N_r(\mathcal{X}) \right\} = 1.
\]

Consequently, these statements imply that
\[
P \left\{ \lim_{n \to \infty} x_n = x, \ f(x) = f^* \mid x_1 \right\} \geq 1 - C_{\infty}.
\]
The proof is in appendix \([3.2]\).

According to Theorems 3.1 and 3.2, one can summarize that the condition of stability can be fulfilled if \( C_{\zeta, \infty} \) or \( C_{\infty} \) is less than one. For the learning rate \( a_n = \frac{\alpha_n}{n^\beta} \) with \( \beta \in (\frac{1}{2}, 1] \), we show a upper bound for the damping parameter \( \alpha \), which ensures that the probability of stability is positive at least.

Corollary 3.1. For the choice of the learning rate \( a_n = \frac{\alpha_n}{n^\beta} \) with \( \beta \in (\frac{1}{2}, 1] \), the condition of stability in Theorems 3.1 and 3.2 is satisfied for any sufficiently small parameter \( \alpha > 0 \) such that
\[
e^{\frac{2\beta L_r}{2\beta - 1} n^2} \left( \text{dist}(x_1, \mathcal{X})^2 + \frac{2\beta \sigma_r}{2\beta - 1} a^2 \right) < r^2.
\]
The proof is in appendix \([3.3]\).

Next, we identify a bound for the complexity associated with SGD (2a) based upon the stability results from the proceeding results. Toward this end, we establish concentration inequalities for the error criteria, \( f(x) - f^* \) and \( \|\nabla f(x)\|^2 \). The following theorems are related to Theorems 3.1 and 3.2, respectively. The proofs are presented in appendix \([3.4]\).

Theorem 3.3. Denote by \( E_N := \{x_n \in B_r(x^*) : \forall n \in [N]\} \) the event that iterations are stable up to the \( N \)-th step. Under the same assumptions as in theorem 3.1, SGD (2a) with initial guess \( x_1 \in B_r(x^*) \) satisfies that \( P_{x_1} \{E_N\} \geq 1 - C_{\zeta,N} \), and additionally,

(i) For \( 0 < \zeta \leq 1 \),
\[
\min_{1 \leq n \leq N} E[(f(x_n) - f^*)\|E_N \mid x_1] \leq \frac{\parallel x_1 - x^* \parallel^2 + \sigma_r \sum_{n=1}^{N} \frac{a_n^2}{b_{n+1}}}{2\zeta \sum_{n=1}^{N} \frac{a_n^2}{b_{n+1}}}.
\]
where \( b_n \) is defined according to (13) and \( \sigma_r \) is the constant associated with the closed ball \( B_r(x^*) \) by Assumption 2.2.

(ii) For \( 0 \leq \zeta \leq 1 \) and any \( \delta > 0 \),
\[
\min_{1 \leq n \leq N} E [\|\nabla f(x_n)\|^2 \|E_N \mid x_1] \leq \frac{f(x_1) - f^* + \sigma_{r+\delta} C \sum_{n=1}^{N} a_n^2}{\sum_{n=1}^{N} a_n (1 - C a_n)}.
\]
where \( f^* := \inf_{x \in B_{r+\delta}(x^*)} f(x) \). The constant \( \sigma_{r+\delta} \) is associated with the closed ball \( B_{r+\delta}(x^*) \) by Assumption 2.2.
With the learning rate $a_n = \frac{a}{n^\beta}$ with $\beta \in (\frac{1}{2}, 1)$ and a sufficiently small parameter $a$ from Corollary 3.1 for tolerance $\epsilon > 0$ and failure probability $\gamma \in (C_{\zeta,N}, 1)$, SGD (2a) produces iterates such that
\[
P\{F_N \leq \epsilon | x_1 \} \geq 1 - \gamma,
\]
where the inequality holds for $F_N$ defined by either of the following error estimates,
\[
F_N := \begin{cases}
\min_{1 \leq n \leq N} f(x_n) - f^*, & N = \Theta \left( \frac{\|x_1 - x^*\|^2 + \frac{\epsilon r}{\epsilon(\gamma - C_N)} \right)^{\frac{1}{1-\beta}} ) \right) \zeta \in (0, 1], \\
\min_{1 \leq n \leq N} \|\nabla f(x_n)\|^2, & N = \Theta \left( \frac{f(x_1) - f^* + \frac{\epsilon r}{\epsilon(\gamma - C_N)} \right)^{\frac{1}{1-\beta}} ) \right) \zeta \in [0, 1].
\end{cases}
\]

We did not consider the case of the learning rate with $\beta = 1$, since it leads to exponential iteration cost in terms of $\epsilon$. We show a similar result related to Theorem 3.2 as follows.

**Theorem 3.4.** Denote by $E_N := \{ x_n \in \hat{N}_r(X), \forall n \in [N]\}$ the event that iterations are stable up to the $N$-th step. Under the same assumptions in Theorem 3.2, SGD (2a) with initial guess $x_1 \in \hat{N}_r(X)$ satisfies that $P_{x_1}\{E_N\} \geq 1 - C_{\zeta,N}$ and additionally,

(i) With $E_N$ defined in the previous theorem, one has,
\[
\min_{1 \leq n \leq N} \mathbb{E}[h(x_n) \mathbb{I}_{E_N}|x_1] \leq \frac{\text{dist}(x_1, X)^2 + \sigma_r \sum_{n=1}^{N} \frac{\epsilon^2}{\sigma_{n+1}}}{2 \sum_{n=1}^{N} \frac{\epsilon n}{b_{n+1}}}. \tag{19}
\]

Here $b_n$ is defined in (15). The constant $\sigma_r$ is associated with the closed neighborhood $\hat{N}_r(X)$ by Assumption 2.2.

(ii) For any $\delta > 0$,
\[
\min_{1 \leq n \leq N} \mathbb{E}[\|\nabla f(x_n)\|^2 \mathbb{I}_{E_N}|x_1] \leq f(x_1) - f^* + \sigma_r C \sum_{n=1}^{N} \frac{\epsilon^2}{\sigma_{n+1}}, \tag{20}
\]

where $f^*_k := \inf_{x \in \hat{N}_{r+k}(X)} f(x)$. The constant $\sigma_r$ is associated with the closed neighborhood $\hat{N}_{r+\delta}(X)$ by Assumption 2.2.

With the learning rate $a_n = \frac{a}{n^\beta}$ with $\beta \in (\frac{1}{2}, 1)$ and a sufficiently small parameter $a$ from Corollary 3.1 for tolerance $\epsilon > 0$ and failure probability $\gamma \in (C_{\zeta,N}, 1)$, SGD (2a) produces iterates such that
\[
P\{F_N \leq \epsilon | x_1 \} \geq 1 - \gamma,
\]
where the inequality holds when $F_N$ is defined by either of the following expressions,
\[
F_N := \begin{cases}
\min_{1 \leq n \leq N} h(x_n), & N = \Theta \left( \frac{\text{dist}(x_1, X)^2 + \frac{\epsilon r}{\epsilon(\gamma - C_N)} \right)^{\frac{1}{1-\beta}} \right) \\
\min_{1 \leq n \leq N} \|\nabla f(x_n)\|^2, & N = \Theta \left( \frac{f(x_1) - f^* + \frac{\epsilon r}{\epsilon(\gamma - C_N)} \right)^{\frac{1}{1-\beta}} \right).
\end{cases}
\]

In particular, if $X$ consists of local minima where the loss function $f$ equals $f^*$ and $h(x_n) = \zeta(f(x_n) - f^*)$ with $\zeta > 0$, we obtain a similar complexity for the error $f(x_n) - f^*$ as in the result (18).

**Remark 3.2.** In both Theorems 3.3 and 3.4 we observe that as $\beta$ is chosen sufficiently close to $\frac{1}{2}$, the iteration complexity for the norm of the gradient becomes closer to $O(\epsilon^{-4})$. This is consistent with the standard complexity result on vanilla SGD (10 and 22). In those previous works, the best choice $\beta = \frac{1}{2}$ is allowed thanks to the assumption that the gradient of the loss function is controlled by the global Lipschitz condition (14). In contrast, under only the local assumptions 2.1, 2.2, 2.4 and 2.5, the failure probability $\gamma$ can not be set lower than $C_{\zeta,N}$ (resp. $C_N$), as it is a bound for the probability of instability.
### 3.3 Stability and Complexity of SAG

We now turn to the SAG method (2b). Aimed at problems with finite training set, the SAG method employs an averaging step that reduces the variance of the noise [37]. Our analysis begins with the assumption that the functions $f_i$’s in (1) are locally Lipschitz continuous.

We denote the $\ell_2$-regularized function by $f_\mu(x) := f(x) + \frac{\mu}{2}\|x\|^2$. Let $x^*$ be a local minimum of $f_\mu(x)$ in $K$. The Lyapunov function $V(\theta)$ is defined by the quadratic form [38] of a variable $\theta$ that involves the stochastic gradients and the gradients $\nabla f_i(x)$. Due to the non-trivial derivation by [37], we include the specific form of $V(\theta)$ in appendix C.

**Theorem 3.5.** Assume that a local minimum $x^*$ of $f_\mu(x)$ is isolated and each loss function $f_i$ in Assumption 2.6 is convex in a neighborhood of $x^*$. Then, the following statements hold for the iterations from SAG (2b).

(i) There exists $r > 0$ such that for the constant step size $a = \frac{1}{2MLr}$ and any $x \in B_r(x^*)$,

$$\mathbb{E}[V(\theta_{n+1})|x_n = x] \leq c_{\mu,r}V(\theta_n), \text{ for any } n \geq 1,$$

where $L_{2r}$ is the Lipschitz constant associated with the region $B_{2r}(x^*)$ and

$$c_{\mu,r} = 1 - \frac{\mu}{8ML_{2r}}.$$

Note that the constant rate $c_{\mu,r}$ depends on the Lipschitz constant associated with the region $B_{2r}(x^*)$ not $B_r(x^*)$.

(ii) For any initial guess $x_1 \in B_r(x^*)$,

$$\mathbb{P}\left\{\|x_n - x^*\| \leq r \left(\sqrt{c_{\mu,r}}\right)^{n-1} \text{ for all } n \geq 1|x_1\right\} \geq 1 - \frac{3V(\theta_1)}{r^2}.$$

Particularly, for the zero initialization $\theta_1 = (0, 0, \ldots, x_1)$,

$$V(\theta_1) := \|x_1 - x^*\|^2 + C_r,$$

with $C_r = \frac{3}{4L_{2r}^2}\sum_{i=1}^M \|\nabla f_i(x^*)\|^2$. The factor $\sum_{i=1}^M \|\nabla f_i(x^*)\|^2$ can be interpreted as the variance of the randomly selected gradient at $x^*$.

Consequently, for any tolerance $\epsilon > 0$, the solution $\|x_n - x^*\| \leq \epsilon$ can be found in the number of iterations

$$N = \left\{\begin{array}{ll} \Theta \left(\log \frac{1}{\epsilon}\right), & \text{zero initialization} \\ \Theta \left(\log \frac{1}{\epsilon}\right) + M, & \theta_1 = (y_1, \ldots, y_M, x_1) \text{ with } y_i^1 = \nabla f_i(x_1) - \nabla f(x_1). \end{array}\right.$$

Both initializations are suggested in [38]. After the $N$ iterations, a candidate for the solution is the last iterate $x_N$.

We refer the reader to the proof in appendix C.

**Remark 3.3.** Comparing the results, we see that SAG has two advantages over SGD. As expected from the analysis in [37], SAG converges linearly even under the local conditions. Moreover, the failure probability $\gamma$ can be set as low as the probability of instability without increasing the number of iterations in the lower complexity bound, whereas in SGD, such a choice leads to additional computational overhead. Nevertheless, this analysis for SAG is limited to the case of isolated local minima. This technical challenge is due to the fact that the positivity of the Lyapunov function in [37] requires the loss to be locally convex.

### 4 Summary and Discussions

Many interesting issues have emerged from optimizations with non-convex landscape, primarily driven by the rapidly development of machine learning applications. In this paper, we have focused on local convergence in the context of non-convex optimization, with the stochastic gradient descent (SGD) and the stochastic averaged descent (SAG) methods as specific examples. In additional to the probabilistic convergence of the stochastic methods to isolated and non-isolated minima, we have proved the corresponding concentration inequalities in terms of several error indicators. The technical results rely on the martingale theorems for discrete stochastic processes and geometric characterizations of non-isolated minima.
Our analysis only requires the local information regarding the loss function, such as the local Lipschitz continuity of the gradient and the locally bounded variance of noise. For the stochastic gradient descent methods (SGD and SAG), no assumption has been made for the Hessian of the loss function. An extension of our analysis to other variants of stochastic gradient method is likely, and it is expected to provide sufficient conditions on the learning rates and the local Lipschitz constant to guarantee the convergence with high probability.

There are several interesting remaining questions. First, whether SGD avoids saddle points has drawn much recent attention ([13, 20, 23, 31, 35]). Studying this question under very mild assumptions would be interesting. Secondly, our analysis relies on the smoothness of the gradient of the loss function. For non-smooth loss functions that come up in applications such as deep neural networks with ReLU activation functions, e.g., in [1], local convergence would be another interesting direction. Finally, by applying the post optimization scheme in [14], we can leverage the concentration inequalities developed in this paper to determine a stopping criterion.

A Preliminary Notation and Some Lemmas

A.1 Properties near degenerate minimizers

Proposition A.1. For a compact set \( \mathcal{X} \subset \mathbb{R}^d \) and any \( x \in \mathbb{R}^d \), let \( x_p \in \Pi_{\mathcal{X}}(x) \). If \( x \neq x_p \), then for any \( y \in \{ z : z = (1 - t)x_p + tx, \ t \in (0, 1) \} \),

\[
\Pi_{\mathcal{X}}(y) = \{ x_p \}.
\]

That is, the projection of any \( y \) between \( x \) and \( x_p \) onto \( \mathcal{X} \) is uniquely equal to \( x_p \).

Proof. To start, we show that \( \Pi_{\mathcal{X}}(y) \) contains \( x_p \). Note that for any \( z \in \mathcal{X} \), \( \| x - x_p \| \leq \| x - z \| \) by the definition of the projection. From this, the colinear relation between \( x, y \) and \( x_p \) implies that

\[
\| y - x_p \| + \| x - y \| = \| x - x_p \| \leq \| x - z \|.
\]

Furthermore, by the triangle inequality,

\[
\| y - x_p \| \leq \| x - z \| - \| x - y \| \leq \| y - z \|.
\]

That is, \( \Pi_{\mathcal{X}}(y) \) at least contains \( x_p \).

Now, we prove that this set is indeed a singleton. Suppose on the contrary that there is \( y_p \in \Pi_{\mathcal{X}}(y) \) and \( y_p \neq x_p \). We show that \( y_p \) does not lie on the line through \( x_p \) and \( x \). First of all, \( y_p \) cannot lie on \( (x_p, x) \). Otherwise, \( x_p \) is not projection of \( x \). The other possibility is that \( y_p = x_p + t(x - x_p) \) for some \( t > 1 \). However, we can see that

\[
\| y - x_p \| < \| x - x_p \| \leq \| x - y_p \| < \| x - y_p \| + \| x - y \| = \| y - y_p \|.
\]

In the second inequality, we recall the fact that \( x_p \) is a projection of \( x \) onto \( \mathcal{X} \). This inequality is not true as opposes to the hypothesis that both sides must be equal as dist\((y, \mathcal{X})\).

As a result, we can assume that \( y_p \) is not on the line passing through \( x \), \( y \) and \( x_p \). However, this results in the strict triangle inequality.

\[
\| x - y_p \| < \| x - y \| + \| y - y_p \|.
\]

This inequality, together with \( \| y - y_p \| = \| y - x_p \| = \text{dist}(y, \mathcal{X}) \), leads to a contradiction to \( x_p \in \Pi_{\mathcal{X}}(x) \), i.e.,

\[
\| x - y_p \| < \| x - x_p \|.
\]

This completes the proof.

This proposition can be used to establish the following proposition, where the landscape of \( f \) in the neighborhood \( N_r(\mathcal{X}) \) can be visualized as a wide valley.

Proposition A.2. The loss function \( f(x) \) under Assumption 3.5 satisfies that

(i) For any \( x \in N_r(\mathcal{X}) \), \( f(x) \geq f(x_p) \).
A careful inspection of the derivation of the conditions (2.1.7) and (2.1.8) from the condition (2.1.6) in [32, Theorem 2.1.9] with the stopping time $\tau$.

Also, by Assumption 2.5, it follows that

$$f(x) - f(x_p) \geq 0.$$ 

As stated in [32, Theorem 2.1.9], it is easy to examine the property of a strongly-convex function as follows.

**Lemma 1.** Suppose that $f(x)$ is convex and its gradient is $L$-Lipschitz continuous in $K$. If $x, y \in K$ and $y - \frac{1}{L} (\nabla f(x) - \nabla f(y)) \in K$, then the following inequalities hold

\begin{align}
\tag{28a}
f(x) + (\nabla f(x), y - x) + \frac{1}{2L} ||\nabla f(x) - \nabla f(y)||^2 &\leq f(y), \\
\tag{28b}
\frac{1}{L} ||\nabla f(x) - \nabla f(y)||^2 &\leq (\nabla f(x) - \nabla f(y), x - y).
\end{align}

**Proof.** The second result follows by summing two copies of the first inequality with $x$ and $y$ switched. It suffices to check the first result only. The key step [32] is the inequality

$$\phi(x) \leq \phi(y) - \frac{1}{L} \nabla \phi(y)) \leq \phi(y) - \frac{1}{2L} ||\nabla \phi(y)||^2,$$

where $\phi(y) = f(y) - (\nabla f(x), y)$. Note that

$$y - \frac{1}{L} (\nabla f(y) - \nabla f(x)) = y - \frac{1}{L} \nabla \phi(y).$$

By the assumption that

$$y - \frac{1}{L} \nabla \phi(y) \in K,$$

the first inequality holds, since $\phi(y)$ takes the local minimum at $x$. The second inequality holds by the assumptions that

$$y - \frac{1}{L} (\nabla f(y) - \nabla f(x)) \in K$$

and $K$ is convex. Specifically, the convexity of $K$ ensures the segment between $y$ and $y - \frac{1}{L} \nabla \phi(y)$ to be in $K$. Therefore, by applying the condition (2.1.6) in [32], Lemma 1 holds true.

As stated in [32, Theorem 2.1.9], it is easy to examine the property of a strongly-convex function as follows.

**Lemma 2.** Let $f(x)$ is $\mu$-strongly convex. If $x, y \in K$, then the following inequality holds

$$\mu ||x - y||^2 \leq (x - y, \nabla f(x) - \nabla f(y)).$$
Proof. By the definition of strong convexity, we prove the statement by summing the following inequalities
\[ f(y) \geq f(x) + \langle \nabla f(x), y - x \rangle + \frac{\mu}{2} \| y - x \|^2 \]
\[ f(x) \geq f(y) + \langle \nabla f(y), x - y \rangle + \frac{\mu}{2} \| y - x \|^2. \]

\[ \square \]

For Theorems 3.1 and 3.2, we restate the results in [35, Appendix C] as in the following two lemmas. Let \( K \) denote a compact and convex set in \( \mathbb{R}^d \).

**Lemma 3.** Under Assumptions 2.1 to 2.3, for any \( \bar{r} \) a compact and convex set in \( \mathbb{R}^d \),

\[ \text{Lemma 4.} \quad \text{Under Assumptions 2.1 to 2.3, for any } \delta > 0, \text{ SGD (2a) has the property that there exists } C > 0 \text{ such that for any } n \geq 1 \text{ and any } x \in K, \]

\[ E \left[ (f(x_{n+1}) - f^\star)^2 \mathbf{1}_{\{x_{n+1} \in \tilde{N}_\delta(K)\}} \right]_{x_n = x} \leq f(x_n) - f^\star - a_n(1 - Ca_n)\| \nabla f(x_n) \|^2 + \sigma_{K,\delta}Ca_n^2, \]

where \( f^\star := \inf_{x \in \tilde{N}_\delta(K)} f(x) \). Here, the constant is given by,

\[ C = \frac{L_{N_\delta(K)}}{2} + \sup_{x \in K} \| \nabla f(x) \|_\delta. \]

\[ \sigma_{K,\delta} \] is the constant associated with \( \tilde{N}_\delta(K) \) by Assumption 2.2.

**B Proofs related to SGD**

**B.1 The Proof of Theorem 3.1**

Proof. By Assumption 2.4, we take a closed ball \( \tilde{B}_r(x^\star) \) where \( f \) is \( \zeta \)-quasar-convex. Next, we estimate the distance between \( x_n \) from SGD (2a) and \( x^\star \) as follows,

\[ E \left[ \| x_{n+1} - x^\star \|^2 | x_n \right] \leq \| x_n - x^\star \|^2 - 2a_n(x_n - x^\star, \nabla f(x_n)) + a_n^2 \| \nabla f(x_n) \|^2 + a_n^2 \sigma_r^2 \]

\[ \leq \left( 1 + L_r a_n^2 \right) \| x_n - x^\star \|^2 - 2\zeta a_n(f(x_n) - f^\star) + \sigma_r a_n^2, \]

for any \( x_n \in \tilde{B}_r(x^\star) \). Here, \( L_r \) is the Lipschitz constant from Assumption 2.1 and \( \sigma_r \) can be found by Assumption 2.2. The first inequality is a direct calculation using (2a) and Assumption 2.2. We remark that the cross term with the full gradient \( \nabla f(x_n) \) and the noise \( \xi_n \) vanishes by Assumption 2.2. In the second inequality, we use Assumption 2.1 by noting that \( \nabla f(x^\star) = 0 \).

Let us define the following

\[ b_n := \prod_{j=1}^{n-1}(1 + L_ra_n^2), \quad b_1 := 1 \]

\[ V_n(x_n) := \frac{\| x_n - x^\star \|^2}{b_n} + \sigma_K \sum_{j=n}^{N-1} a_j^2 \]

\[ k_n(x_n) := \frac{a_n}{b_{n+1}} k(x_n), \quad k(x_n) := 2\zeta (f(x_n) - f^\star). \]

Based on the idea in [25, Theorem 5.1], by setting the stopping time \( \tau = \inf \{ n \geq 2 : x_n \notin \tilde{B}_r(x^\star) \} \) with \( K = \tilde{B}_r(x^\star) \) in the inequality (27), we can modify the inequality (31) as follows

\[ E[\tilde{V}_{n+1}(\tilde{x}_{n+1})| F_n] \leq \tilde{V}_n(\tilde{x}_n) - \tilde{k}_n(\tilde{x}_n), \]

(33)
where \( \{ \tilde{V}_n(\tilde{x}_n) \} \) is a non-negative supermartingale. Furthermore, by applying the Markov’s inequality to this supermartingale, we arrive at,
\[
\mathbb{P} \left\{ \sup_{N \geq n \geq 2} \tilde{V}_n(\tilde{x}_n) > \frac{r^2}{b_N^2} | x_1 \right\} \leq \frac{b_N}{r^2} (V_1(x_1) - k_1(x_1)) \text{ for } x_1 \in \tilde{B}(x^*) .
\]

On the other hand, we observe that
\[
\mathbb{P} \left\{ \sup_{N \geq n \geq 2} \| x_n - x^* \| > r | x_1 \right\} \leq \mathbb{P} \left\{ \sup_{N \geq n \geq 2} \| \tilde{x}_n - x^* \| > r | x_1 \right\} \leq \mathbb{P} \left\{ \sup_{N \geq n \geq 2} \tilde{V}_n(\tilde{x}_n) > \frac{r^2}{b_N} | x_1 \right\} .
\]

The first inequality follows by the stopping time \( \tau \) as defined above. The second inequality can be deduced from the definition (32). Therefore, the first statement follows by combining these two inequalities. Moreover, Assumption 2.3 guarantees the case \( N = \infty \).

For the second statement, we telescope the inequality (33) and recall \( k_n(x_n) \) in the definition (32):
\[
\sum_{n=1}^{\infty} \zeta_n a_n \mathbb{E}[k(\tilde{x}|x_1)] \leq V_1(x_1) < \infty . \tag{34}
\]

Note that conditioned on \( x_1 \in \tilde{B}_r(x^*) \), the event that \( \{ x_n \}_{n=1}^{\infty} \subset \tilde{B}_r(x^*) \) occurs with some positive probability thanks to the first statement. In this event, \( \{ x_n \}_{n=1}^{\infty} \subset \tilde{B}_r(x^*) \) with probability one by Lemma 3. This guarantees \( f(x_n) \) converges to some value \( f^* \) by the continuity of \( f \), which is no less than the local minimum \( f^* \). In fact, we show that \( f(x_n) \) converges to \( f^* \) almost surely in this event.

Suppose on the contrary that \( k(x_n) \) in the definition (32) converges to a positive random variable with some positive probability. By the continuity of a measure, there exists a \( \delta > 0 \) such that
\[
\mathbb{P} \left\{ \lim_{n \to \infty} k(x_n) > \delta \big\| \{ x_n \}_{n=2}^{\infty} \subset \tilde{B}_r(x^*), x_1 \right\} > 0 .
\]

[24], Theorem 4.11 and Lemma E.1] established that there exists a \( N \in \mathbb{N} \) satisfying
\[
\mathbb{P} \left\{ k(x_n) > \frac{\delta}{2} \text{ for all } n \geq N \big| \lim_{n \to \infty} k(x_n) > \delta, \{ x_n \}_{n=2}^{\infty} \subset \tilde{B}_r(x^*), x_1 \right\} > 0 .
\]

These two inequalities imply that with some positive probability the event \( k(x_n) > \frac{\delta}{2} \) for all \( n \geq N \) occurs when \( \{ x_n \}_{n=2}^{\infty} \subset \tilde{B}_r(x^*) \) given \( x_1 \in \tilde{B}_r(x^*) \). Again, \( \delta > 0 \) and \( N \in \mathbb{N} \) are universal constants. However, by the definition of the conditional probability, we have
\[
\mathbb{P} \left\{ k(x_n) > \frac{\delta}{2} \text{ for all } n \geq N, \{ x_n \}_{n=2}^{\infty} \subset \tilde{B}_r(x^*) | x_1 \right\} = \mathbb{P} \left\{ k(x_n) > \frac{\delta}{2} \text{ for all } n \geq N \big| \{ x_n \}_{n=2}^{\infty} \subset \tilde{B}_r(x^*), x_1 \right\} \mathbb{P} \left\{ \{ x_n \}_{n=2}^{\infty} \subset \tilde{B}_r(x^*) | x_1 \right\} > 0 , \text{ by the previous result of stability} .
\]

Furthermore, together with the inequality (34), Assumption 2.2 the condition \( \zeta > 0 \) and the Markov’s inequality, one has,
\[
\sum_{n=1}^{\infty} \zeta_n a_n \delta \mathbb{P} \left\{ k(x_n) > \frac{\delta}{2} \text{ for all } n \geq N, \{ x_n \}_{n=2}^{\infty} \subset \tilde{B}_r(x^*) | x_1 \right\} \leq V_1(x_1) < \infty ,
\]
which is a contradiction. Therefore, in the case \( \zeta > 0 \), \( \lim_{n \to \infty} k(x_n) = 0 \) or \( \lim_{n \to \infty} f(x_n) = f^* \) with probability one conditioned on the event that \( \{ x_n \}_{n=2}^{\infty} \subset \tilde{B}_r(x^*) \).
Local Analysis for SGD in non-convex optimization with non-isolated local minima

B.2 The Proof of Theorem 3.2

Proof. The proof is very similar to the preceding proof.

First of all, we obtain a recursive inequality similar to the inequality (31) as follows,

\[ E[\text{dist}(x_{n+1}, \mathcal{X})^2 | x_n] \leq E[\| x_{n+1} - (x_n)_p \|^2 | x_n] \]

\[ \leq \text{dist}(x_n, \mathcal{X})^2 - 2a_n(\nabla f(x_n), x_n - (x_n)_p) + a_n^2\|\nabla f(x_n)\|^2 + \sigma_r a_n^2 \]

\[ \leq (1 + L_r a_n^2)\text{dist}(x_n, \mathcal{X})^2 - 2a_n(\nabla f(x_n), x_n - (x_n)_p) + \sigma_r a_n^2 \]

(35)

for any \( x_n \in \bar{N}_r(\mathcal{X}) \). By setting the stopping time \( \tau := \{ n \geq 2 : x_n \notin \bar{N}_r(\mathcal{X}) \} \), we obtain the first result in Theorem 3.2 by making an argument similar to the previous proof.

Let us denote \( k_n(x_n) = a_n k(x_n) \) with \( k(x) = 2(\nabla f(x), x - x_p) \). Similar to the previous proof, by the assumption that \( \nabla f(x), x - x_p \geq 0 \) for all \( x \in N(\mathcal{X}) \), we can deduce that \( \nabla f(x), x - x_p = 0, x = \lim_n x_n \) almost surely conditioned on the event that \( x_n \in \bar{N}_r(\mathcal{X}) \) for all \( n \geq 2 \).

Furthermore, if \( x \in \bar{N}_r(\mathcal{X}) - \mathcal{X} \), then Assumption 2.5 implies that \( \nabla f(x), x - x_p \geq h(x) > 0 \), which is a contradiction. Therefore, the limit \( x \) must lie in \( \mathcal{X} \) and \( f(x) = f^* \).

B.3 The Proof of Corollary 3.1

Proof. By the integral test, we have

\[ \sum_{n=1}^{\infty} \frac{1}{n^{2\beta}} \leq 1 + \int_1^{\infty} \frac{dx}{x^{2\beta}} = \frac{2\beta}{2\beta - 1}. \]

With this, we use the inequality (31) and trace back to the condition of stability

\[ r^2 > e^{\sum_n c_n a_n^2} \left( \text{dist}(x_1, \mathcal{X})^2 + \frac{2\beta\sigma_r}{2\beta - 1} a_1^2 \right) \geq e^{L_r \sum_n a_n^2} \left( \text{dist}(x_1, \mathcal{X})^2 + \sigma_r \sum_{n=1}^{\infty} a_n^2 \right) \]

\[ \geq b_\infty \left( \text{dist}(x_1, \mathcal{X})^2 + \sigma_r \sum_{n=1}^{\infty} a_n^2 \right) \implies 1 - C_\infty > 0, \]

where \( C_\infty \) is defined in Theorem 3.2. In the third inequality, we used the well-known inequality that \( \prod_n (1 + c_n) \leq e^{\sum_n c_n} \) for any real-valued sequence \( \{c_n\} \) with \( c_n > -1 \).

B.4 The Proofs of Theorem 3.3 and 3.4

Proof. We check the first statement. From the inequality (31) and the counterpart (33) with the stopped process, a telescoping trick can be used:

\[ \sum_{n=1}^{N} \mathbb{E}[k_n(x_n) \mathbb{I}_{E_n} | x_1] \leq \sum_{n=1}^{N} \mathbb{E}[\hat{k}_n(\bar{x}_n) | x_1] \leq V_1(x_1). \]

(36)

By taking the minimum of the expectations, we obtain the first result.

Pick \( \delta > 0 \). For the second statement, we use Lemma 4. By setting \( K = \hat{B}_r(x^*) \) in Lemma 4 and using the notation in the lemma, we define

\[ V_n(x_n) := (f(x_n) - f^*_n) \mathbb{I}_{\{x_n \in \hat{B}_{r+\delta}(x^*) \}} + \sigma_r \delta C' \sum_{i=1}^{N} a_i^2 \]

(37a)

\[ k_n(x_n) := a_n (1 - Ca_n) k(x_n), \quad k(x_n) := \| \nabla f(x_n) \|^2. \]

(37b)

With the stopping time \( \tau = \{ n \geq 2 : x_n \notin \hat{B}_r(x^*) \} \), a telescoping trick similar to the inequality (43) yields

\[ \sum_{n=1}^{N} a_n (1 - Ca_n) \mathbb{E}[\hat{k}(\bar{x}_n) | x_1] \leq f(x_1) - f^* + \sigma_r \delta C \sum_{n=1}^{N} a_n^2, \]

which implies the second statement.
Local Analysis for SGD in non-convex optimization with non-isolated local minima

For the rest of results in the theorem, we use the stability result in Theorem 3.1 as well as the Markov’s inequality. For simplicity, we keep using the above notations. By applying the Markov’s inequality to the inequality (36), we have

\[ P \left\{ \min_{1 \leq n \leq N} k(x_n) > \epsilon \text{ and } E_N \text{ occurs} | x_1 \right\} \leq \frac{V_1(x_1)}{\epsilon \sum_{n=1}^{N} \frac{a_n}{b_n+1}}, \]

or equivalently,

\[ P \left\{ \min_{1 \leq n \leq N} k(x_n) \leq \epsilon \text{ or } E_N \text{ does not occur} | x_1 \right\} \geq 1 - \frac{V_1(x_1)}{\epsilon \sum_{n=1}^{N} \frac{a_n}{b_n+1}}. \]

However, according to the result in Theorem 3.1, we see that

\[ P \{ E_N \text{ does not occur} | x_1 } \leq C_{\zeta,N}, \]

which leads to

\[ P \left\{ \min_{1 \leq n \leq N} k(x_n) \leq \epsilon | x_1 \right\} \geq 1 - \frac{V_1(x_1)}{\epsilon \sum_{n=1}^{N} \frac{a_n}{b_n+1}} - C_{\zeta,N}. \]

By the integral test, we have

\[ \frac{V_1(x_1)}{\sum_{n=1}^{N} \frac{a_n}{b_n+1}} = O \left( \frac{1}{N^{1-\beta}} \right). \]

By letting \( \gamma = \frac{V_1(x_1)}{\epsilon \sum_{n=1}^{N} \frac{a_n}{b_n+1}} + C_{\zeta,N} \), we can deduce the result (18). Similarly, the result for the squared norm of the gradient can be drawn.

Similar to the above proof, Theorem 3.4 can be proven with the result in Theorem 3.2. One difference is that the more general assumption 2.5 is used in place of the quasar convexity 2.4, but the analysis on the squared norm of the gradient is almost the same, i.e., by an application of Lemma 4.

\[ \square \]

C The Proof of Theorems 3.5

Under the weaker assumptions in Theorem 3.5, we extend the analysis in [37], Appendix A.5, where a Lyapunov function was defined as follows,

\[ V(\theta_n) = (\theta_n - \theta^*)^{T} \begin{bmatrix} A & B \\ B^{T} & I \end{bmatrix} (\theta_n - \theta^*), \]

where

\[ a = \frac{1}{2ML}, \]

\[ E = \begin{bmatrix} I \\ \vdots \\ I \end{bmatrix} \in \mathbb{R}^{Md \times d}, \]

\[ A = 3Ma^{2}I + \frac{a^{2}}{M} (1 - 2)EE^{T}, \]

\[ B = -a(1 - \frac{1}{M})E. \]

Here \( a \) is the constant step size for \( a_n \) in the iteration of SAG (2b). \( E \) is the block matrix with the identity matrices. We recall that \( M \) is the number of data points and \( d \) is the dimension of input \( x \). The matrices \( A \) and \( B \) form the Lyapunov function \( V(\theta_n) \). Lastly, \( \theta_n \) and \( \theta^* \) denote the following column vectors

\[ \theta_n = \begin{bmatrix} y_n^{1} \\ \vdots \\ y_n^{M} \\ x_n \end{bmatrix} \in \mathbb{R}^{(M+1)d}, \quad \theta^* = \begin{bmatrix} \nabla f_1(x^*) \\ \vdots \\ \nabla f_M(x^*) \end{bmatrix} \in \mathbb{R}^{(M+1)d}, \]

where the random vector \( y_n^i \) is defined in (2b).
Proof. By the assumption that $x^*$ is an interior point of $K$, there exists a closed ball $B_{2r}(x^*)$ inside $K$ for some $r > 0$ with Lipschitz constant $L_{2r}$ associated with Assumption[2][4]. Let us consider the smaller ball $B_r(x^*)$. We prove the first statement by examining the sufficient conditions assumed in [37]. Essentially, we need to check whether the following two conditions hold for any $x_n, x, y \in B_r(x^*)$.

\[ \|\nabla f_i(x_n) - \nabla f_i(x^*)\|^2 \leq L_{2r}(\nabla f_i(x_n) - \nabla f_i(x^*))^T(x_n - x^*), \]
\[ \mu \|x - y\|^2 \leq (x - y, \nabla f(x) - \nabla f(y)). \]

(41a)

(41b)

For the first condition, we use the triangle inequality

\[ \|x_n - x^*\| + \frac{1}{L_{2r}} \|\nabla f_i(x_n) - \nabla f_i(x^*)\| \leq 2r, \]

which means that the first term on the left hand side lies in $B_{2r}(x^*)$. In addition, note that $x_n \in B_r(x^*) \subset B_{2r}(x^*)$. Then, according to Lemma[1] the first condition is fulfilled. The second condition follows from the fact that $f_{\mu}(x)$ is strongly convex in $K$ and Lemma[2]. This proves the first statement.

To prove the second statement, we rewrite the inequality in the first statement:

\[ \mathbb{E}[v_{n+1}|x_n = x] \leq y_n, \]

for any $x \in B_r(x^*)$ and any $n \geq 1$

(42)

where $v_n = \frac{V(\theta_n)}{c_{\mu,r}^n}$. Define the stopping time

\[ \tau = \inf \{ n \geq 2 : \|x_n - x^*\|^2 > c_{\mu,r}^{n-1}r^2 \}. \]

Accordingly, we define the stopped process such that $\tilde{v}_n = v_n$ for $n \leq \tau$ and $\tilde{v}_n = v_\tau$ for $n > \tau$. Noticing that $\{\tilde{y}_n\}$ is a non-negative supermartingale, one sees that for any $\epsilon > 0$,

\[ \mathbb{P}\left( \sup_{n \geq 2} \tilde{y}_n > \epsilon|x_1 \right) \leq \frac{v_1}{\epsilon} = \frac{V(\theta_1)}{\epsilon}. \]

By recalling the stopping time $\tau$ and the stopped process $\{\tilde{y}_n\}$, and substituting $\epsilon$ with $\frac{\epsilon^2}{r}$, we proceed to show that,

\[ \mathbb{P}\left( \|x_n - x^*\|^2 > c_{\mu,r}^{n-1}r^2 \text{ for some } n \geq 2|x_1 \right) \]
\[ = \mathbb{P}\left( \|\tilde{x}_n - x^*\|^2 > c_{\mu,r}^{n-1}r^2 \text{ for some } n \geq 2|x_1 \right) \]
\[ \leq \mathbb{P}\left( \sup_{n \geq 2} \tilde{y}_n > \frac{2}{3}|x_1 \right) \]
\[ \leq \frac{3V(\theta_1)}{r^2}. \]

The first inequality holds by the dominance relation $V(\theta_n) \geq \frac{1}{2}\|x_n - x^*\|^2$ in [37], p22, which is independent of the Lipschitz constant. This verifies the first part of the second statement. For the second part, we use the result in [37], Appendix A.6] that if $\theta_1 = (0, 0, \ldots, x_1)$, then

\[ V(\theta_1) = \frac{3\sigma^2}{4L_{2r}} + \|x_1 - x^*\|^2, \]

where $\sigma^2 := \frac{1}{M} \sum_{i=1}^{M} \|\nabla f_i(x^*)\|^2$.

\[ \square \]
