Abstract

A variety of complex magnetic structures in a high-symmetry lattice can arise from a superposition of well-defined magnetic wave vectors. These “multi-q” structures have garnered much attention because their non-collinear magnetic moment patterns can generate interesting real-space spin textures such as skyrmions. However, the role multi-q structures play in the topology of electronic bands in momentum space has remained rather elusive. In this work, we show that 2q and 3q antiferromagnetic structures in a cubic lattice with band inversion, such as NdBi, can induce unconventional surface state pairs in the band-folding bulk gap. Our density functional theory calculations match well with the recent experimental observation of unconventional surface state hole Fermi arcs and electron pockets below the magnetic transition temperature, which can not be explained with its previously reported single-q structure. We further show that these multi-q structures have also 3D Dirac and Weyl nodal features. Our work reveals the special role that multi-q structures can play in the development of new quantum states and suggests that NdBi is a multi-q antiferromagnet.
I. Introduction

Rare-earth monopnictides (RPn) in the rock-salt crystal structure have been studied as promising materials for spintronics\(^1\). These compounds have attracted renewed interests because of emerging topological properties. The non-magnetic LaPn were first predicted as topologically non-trivial due to the band inversion between La \(d\) and Pn \(p\) orbitals\(^2\). The crossover and trend of such \(d-p\) band inversion in the RPn series have been studied by experiments\(^3-8\) and calculations\(^9,10\), which have largely focused on the paramagnetic state. The gradual filling of the \(4f\) orbitals and change of spin-orbit coupling (SOC) strength across the RPn series can potentially bring high tunability in the multitude of topological states when coupled with magnetic properties\(^11-15\). Although some RPn compounds, such as CeSb\(^16\), GdB\(^17\), and CeBi\(^18\), have been proposed to host magnetic Weyl points (WPs) in the ferromagnetic (FM) state when fully magnetized, most RPn prefer antiferromagnetic (AFM) configurations. Angle-resolved photo-electron spectroscopy (ARPES) study of the RPn in the AFM state remains rare except for CeBi\(^19\).

Very recently ARPES\(^20\) has discovered unconventional surface states (SS) in NdBi below the Neel temperature (\(T_N=24\) K) that display a combination of hole Fermi arcs and SS electron pockets, as well as a peculiar temperature-dependent splitting. Unlike the Fermi arcs in cuprates\(^21\) induced by a pseudo-gap opening and those in Weyl semimetals\(^22\) by the opposite chirality of WPs, the origin of the newly discovered hole Fermi arcs in AFM NdBi is unclear. Figures 1(a) and 1(b) show the ARPES data on NdBi(001) above and below \(T_N\), respectively. Above \(T_N\) and similar to other paramagnetic RBi, a large star-shaped bulk hole pocket and another small one at the \(\bar{F}\) point overlap with the electron pocket projected from the \(X\) point in Fig.1(a). These results match reasonably well with the 2D surface Fermi surface (SFS) calculated with density functional theory\(^23,24\) (DFT) for the non-magnetic (NM) NdBi in Fig.1(c). Surprisingly, when cooling below \(T_N\) for NdBi (Fig.1(b)), ARPES observed unconventional hole Fermi arcs and SS electron pockets emerging out of the bulk band projections. The hole Fermi arcs connect to the bulk hole pockets and the elliptical SS electron pockets have a sharp cusp. However, the DFT-calculated SFS of NdBi (001) in Fig.1(e) with the reported layer-stacking AFM structure\(^25\) (referred as 1q) in Fig.1(d) lacks any of these unconventional SS features. NdBi has a high-
symmetry crystal structure without Nd-4f-level hybridization (e.g. Kondo effect), which makes the ARPES discovery more intriguing.

Multi-q magnetic structures have garnered much attention because of their interesting real-space spin textures such as skyrmions\textsuperscript{26-31}. Generally, multi-q structures are difficult to distinguish from the simple 1q using standard neutron diffraction techniques, and have been only reported before for monopnictide compounds with actinides (5f), such as UP, UAs, USb\textsuperscript{32} and NpBi\textsuperscript{33}. Here, we explore the effects of multi-q magnetic structures on the band structure and topology of NdBi using DFT calculation. We find that NdBi AFM multi-q structures with two (2q) and three (3q) wave vectors give rise to unconventional surface state pairs (SSP) on (001) surface that match well with the ARPES data below \(T_N\) as shown in Fig.1 (f)-(g) for 2q and Fig.1(h)-(i) for 3q, respectively. In addition to revealing the multi-q origin of the unconventional SSP, we find that NdBi 2q is a Dirac semimetal and 3q is a Weyl semimetal. Our result shows that a Fermi-arc-like signature on a surface does not always imply the presence of Weyl fermions in the bulk, as in the case of 2q, making an unambiguous discovery of magnetic Weyl semimetals more elusive. Our work is also a rare example of ARPES data combined with band structure analysis in predicting specific magnetic ordering.

II. Hybridization gap opening in multi-q bulk band structures

The three different multi-q magnetic structures of NdBi are shown in Fig.1 (d), (f) and (h) with the corresponding bulk band structures presented in Fig.2 (a), (c) and (d), respectively. The NM NdBi is known to have a band inversion between the Bi \(p\) and Nd \(d\) orbitals with anti-crossing along the \(\Gamma\)-\(X\) direction to host a strong topological insulator (TI) state\textsuperscript{2} (see SM Fig.S1(a)). The 1q band structure along the \(\Gamma\)-\(M'\) direction (Fig.2(a)) retains the same band inversion in NM (neck-narrowing region). The hybridization gap opening from the band-folding of the band-inversion region is best seen in 2q (Fig.2(c)). The band-folding in 2q happens at the \(X\) point (half-way along the \(\Gamma\)-\(M'\) direction highlighted by the green arrows), where a bulk band gap of about 0.2 eV opens near \(E_F\) due to the hybridization between the folded bands of the same Bi \(p\) orbitals. The original band inversion now becomes the upper valence bands and is pushed to higher energy. Interestingly, with the magnetic moments changing from [001] in 1q to in-plane directions
in 2q, the hybridization gap along the $\Gamma$-Z direction is reduced and two new band crossings emerge to form two pairs of DPs. Comparing the band structure of 3q in Fig. 2(d) to 2q in Fig. 2(c), the $\Gamma$-X and $\Gamma$-Z directions become equivalent and so are the hybridization gaps. With lifting of the band double degeneracy along the other directions in 3q, new band crossings emerge around the $\Gamma$ point, giving WPs along the $\Gamma$-R direction, which will be discussed later together with the DPs in 2q.

The detailed magnetic space group (MSG) description of the multi-q bulk band structures can be found in SM. With the inversion symmetry intact for all three magnetic structures, parity eigenvalues at time-reversal invariant momentum (TRIM) can be used to calculate $Z_4 = \left(\frac{1}{2}\right) \sum_{k \in \text{TRIM}} (n_k^+ - n_k^-) \mod 4$, where $n_k^+$ and $n_k^-$ are the number of filled states with even and odd parity, respectively. Interestingly, $Z_4=2$ for all the three gapless phases in the different multi-q structures, because the sum of the difference in the number of opposite parity eigenvalues over TRIM does not change. NdBi 1q and 2q are Dirac semimetals, while 3q is a Weyl semimetal.

III. Unconventional surface state pairs

Next, we discuss the surface states generated by the different multi-q structures. For 1q, the (001) surface spectral function has gapped surface Dirac cones at $\bar{M}$ point, but not around $\bar{\Gamma}$ (see SM Fig.S2). The 1q (010) has only one surface state in the hybridization gap in a disagreement with ARPES data. In contrast, both the cubic 3q and tetragonal 2q give the unconventional SSP around the $\bar{\Gamma}$ point that matches well with the ARPES data\(^\text{20}\) below $T_N$. The surface spectral function of 3q (001) is presented in Fig. 3 (a), and 2q (001) in (b) and (010) in (c), respectively. For all the three surfaces in Fig.3, a pair of surface states emerge inside the bulk hybridization gap with similar dispersion along the $\bar{\Gamma}$-$\bar{X}$ direction. The SSP starts from the overlapped bulk band projection near the $\bar{\Gamma}$ point and the splitting increases toward the $\bar{X}$ point. Then along the $\bar{\Gamma}$-$\bar{M}$ direction, the upper (lower) SS quickly merges with the bulk electron (hole) pocket. Thus, the upper SS is of electron character, while the lower SS is of hole character, respectively.

The SFS are plotted at $E_F=0.100$ eV for 3q (001) (Fig.3(g)) and $E_F=0.050$ eV for 2q (001) (Fig.3(h)). The hole SS merges with the bulk hole pocket when going off the $\bar{\Gamma}$-$\bar{X}$
direction, showing a Fermi-arc-like feature. The electron SS forms an elliptical pocket by itself with a cusp toward the $\bar{X}$ point. Both of these SSP features are in a good agreement with ARPES\textsuperscript{20} near the $\bar{\Gamma}$ point. The electron SS pocket comes from the upward dispersion of the upper SS near the $\bar{X}$ point (Fig.3 (a)-(c)). At $E_F$, the SFS in Fig.3 (d)-(f) clearly show the upper SS envelops the bulk electron pocket when going off the $\bar{\Gamma}$-$\bar{X}$ direction. For $2q$ bulk band structure, the hybridization gap only appears along the $\Gamma$-$X$ not the $\Gamma$-$Z$ direction as seen in Fig.2(b). As the result, in the SFS on $2q$ (001) (Fig.3(f) and (i)), the SSP hole Fermi arc and electron pocket also only appear along the $\bar{\Gamma}$-$\bar{X}$ direction, while along the $\bar{\Gamma}$-$\bar{Z}$ direction is mainly bulk state projections, giving a clearly 2-fold symmetry. Note (001) surface for both $3q$ and AFM$2q$ is also 2-fold but with the slightly distorted 4-fold SSP.

The slightly distorted 4-fold SSP on (001) of both $3q$ and $2q$ after some shift of $E_F$ match well with the ARPES data\textsuperscript{20} for NdBi below $T_N$. Because the $E_F$ shift of 0.01 eV needed for $2q$ (001) is smaller than the 0.04 eV shift for $3q$ (001), the detailed comparison to ARPES data will next be made with $2q$ (001) in Fig.4. Figure 4 (a) and (b) plot the surface spectral functions of $2q$ and NM on (001) along the high symmetry $\bar{\Gamma}$-$\bar{X}$ direction to highlight the band-folding effects on the surface spectral functions (similar comparison of $3q$ (001) can be found in SM Fig.S3). Although the paramagnetic phase observed in ARPES above $T_N$ is different from the calculated NM state regarding the location of the band inversion, and the temperature dependence of the SSP is more complicated, the calculated NM can still be used as a reference for the effects of the band-folding in $2q$. As shown in Fig.4(b), for NM with band inversion near the $\bar{X}$ point in a strong TI, the topological SS emerge from the band inversion region and disperse away from the $\bar{\Gamma}$ point to form two gapped surface DPs at the $\overline{M'}$ point (see Fig.S1). Upon the band-folding along the dashed line at the $\bar{X}$ point in Fig.4(b), the topological SS associated with the strong TI is folded to the $\bar{\Gamma}$ point and overlapped with the bulk band projection in Fig.4(a). But more importantly for $2q$, a hybridization bulk band gap is opened up along the $\bar{\Gamma}$-$\bar{X}$ direction and the unconventional SSP emerges inside the hybridization gap.

To compare with ARPES data\textsuperscript{20} and analyze the SSP away from the high symmetry directions, two sets of cuts with black and white dashed lines shown on top of the SFS at $E_F$–0.050 eV in Fig.4(c) are made to the calculated spectral function. As moving away from $k_z$=0 along the $\bar{\Gamma}$-$\bar{X}$ direction in the black vertical dashed cuts, the spectral function in
Fig. 4(d) shows that the upper SS connects and forms an envelope to the bulk electron pocket, while the lower TSS starts to merge with the bulk hole pocket \((k_z=0.08)\) until it disappears into the bulk bands \((k_z=0.16)\) below \(E_F\). These behaviors of the SSP agree very well with the ARPES data (see Fig. 3 of Ref.\(^{20}\)) and confirm the upper and lower SS are of electron and hole character, respectively. For the cuts with the white dashed lines rotated 45 degree and moving away from the \(\bar{I}-\bar{M}\) direction in Fig. 4(e), the gradual emergence and shift of the asymmetric splitting between the upper and lower SS also agree well with the ARPES data. The enveloping of the lower SS to bulk hole pockets and that of upper SS to bulk electron pockets are also evident in Fig. 4(e). Furthermore, the spin texture of the SSP hole arc and electron pockets are plotted in Fig. 4(f). The orange arrows show the in-plane components of the expectation value of electron spin weighted by the SFS at the specific \(k\)-point and energy (see Eqn. (32) in Ref.\(^{34}\)). The opposite spin texture between the SSP hole arc and electron pocket is in a very good agreement with the spin-polarized ARPES data\(^{20}\).

**IV. Nodal features in multi-q structures**

As mentioned above, in addition to the unconventional SSP, 3q and 2q also have nodal features. We will show that the unconventional SSP does not arise from the WPs in 3q or the DPs in 2q. For 3q with the all-in-all-out magnetic configuration (first predicted Weyl semimetal in iridates\(^{35}\)), we found 16 WPs in two sets along the \(\bar{I}-\bar{R}\) direction (see Fig. 5(a)) with the momentum-energy of \((\pm0.0875, \pm0.0875, \pm0.0875\ 1/\text{Å}, E_F+12.6 \text{ meV})\) and \((\pm0.1133, \pm0.1133, \pm0.1133\ 1/\text{Å}, E_F+14.9 \text{ meV})\), respectively. In contrast to the axion insulator in \(\text{NpBi}\) with the same 3q structure as analyzed in the Xu et al.\(^{12}\), the even number of WPs in half of the BZ is also compatible with \(Z_f=2\) for \(\text{NdBi}\) 3q here. The Berry curvatures near a pair of these WPs are plotted in the vertical and horizontal planes in Fig. 5(b) and (c) to confirm the opposite chirality of \(\pm1\). When projected on (001) surface, the WPs of opposite chirality overlap and usually Fermi arcs are not expected. But as shown by the SFS around the WP binding energy of \(E_F+0.014 \text{ eV}\) in Fig. 5(d) and (e), there are small protrusions along the \(\bar{I}-\bar{M}\) direction connecting the hole SS on both the top and bottom surfaces. After zooming in Fig. 5(f) and (g) with the surface-only contribution, it turns out that the hole SS connects the projections of outer WPs (green circles), but not the inner WPs (black squares). The usual explanation for the disappearance of open Fermi arcs
when two WPs of the opposite chirality overlap has the assumption that the open Fermi arcs connect in the direction of the shortest path between the WP projections. When the WP projections of opposite chirality move closer and overlap, such as the black squares, Fermi arcs disappear. However, as shown in the earlier study\textsuperscript{36}, the open Fermi arc connectivity of the WP projections are not restricted to only one direction and can actually change to the opposite direction depending on the surrounding SS. In such a scenario, the overlap of WP projections of opposite chirality can give a full circle for the Fermi arcs, which is seen here for the case of the outer set of WPs in NdBi 3q.

For the DPs in 2q, the bulk band structure is plotted in Fig.6(a) along the $\Gamma$-Z direction, where the top valence and bottom conduction bands cross twice with different orbital content. The two pairs of DPs have the momentum-energy of \((0, 0, \pm 0.1501 \text{ 1/Å, } E_F + 73.0 \text{ meV})\) and \((0, 0, \pm 0.4330 \text{ 1/Å, } E_F - 177.5 \text{ meV})\), respectively. The upper DP has a switch of orbital content between Bi $p_z$ and $p_x$, while the lower DP has the switch between Nd $d_{xy}$ and Bi $p_x$ orbitals. These DPs are protected by the 4-fold screw axis. To search for any topological SS signature of the DPs, the (010) surface spectral function is presented in Fig.6(b). But the SS around the binding energy of the upper DP at $E_F + 0.073$ eV does not originate from the DP projection. For the lower DP at $E_F - 0.178$ eV, two SS follow the narrow band gap from $E_F$ to $E_F - 0.1$ eV moving toward the DP, but they merge into the bulk band projection before reaching the DP. The lack of the closed Fermi arcs connecting two DP projections in 2q are also seen in the SFS in Fig.6(c) and (d) at the binding energies of these DPs. Although the closed Fermi arcs connecting two DP projections often found in some other Dirac semimetals, they are not guaranteed with topological protection and are fragile as discussed before in a theoretical model\textsuperscript{37} and for PtBi\textsubscript{2}\textsuperscript{38}. Our results for NdBi 2q provide such an example showing the fragility of the Fermi arcs for DPs.

Lastly, from the perspective of using symmetry-based indicators and topological invariants to diagnose topological states for magnetic space groups, a previous theory work\textsuperscript{12} has noticed that the parity-based index $Z_f \equiv 2$ can correspond to different topological states including both gapped and gapless phases. Although NpBi with 3q has been predicted\textsuperscript{12} as an axion insulator with gapped surface Dirac cones and chiral hinge states, our current study on multi-q NdBi realizes several other compatible scenarios with $Z_f \equiv 2$, including a Weyl semimetal with an even number of WPs in half of the bulk BZ for 3q and
a Dirac semimetal for 2q. Remarkably, the unconventional SSP spanning the hybridization gap remains very robust for all these changes in 3q (Weyl) and 2q (Dirac) to give the key features of unconventional surface hole Fermi arcs and elliptical electron pocket as observed in ARPES. Thus, besides explaining the magnetic multi-q origin of the unconventional SSP in NdBi below T_N, our study also expands the variety of topological phases and features that are compatible with the parity-based index Z_4=2.

V. Conclusions

We find that magnetic multi-q structures, 2q and 3q, can host unconventional surface state pairs (SSP) that are consistent with the ARPES data around the $\bar{\Gamma}$ point of NdBi below T_N. These unconventional SS appear in pairs and reside in the bulk hybridization gap region formed by the band-folding of the band inversion region along the $\Gamma$-X direction. The lower SS forms the Fermi-arc-like features connected with the bulk hole pocket and the upper SS forms an elliptical electron pocket with a cusp toward the $\bar{X}$ point, agreeing very well with the experiment. We also find NdBi 2q is a Dirac semimetal with two pairs of Dirac points (DPs) along the $\Gamma$-Z direction, but without the closed Fermi arcs connecting the DP projections. In contrast, NdBi 3q is a Weyl semimetal with two sets of 16 Weyl points (WPs) along the $\Gamma$-R direction. The projections of the outer set are connected by the hole SS arcs in a full circle, despite that the WP projections are overlapped with opposite chirality. Our results also expand a variety of topological nodal features that are compatible with the parity-based Z_4=2. From a more general point of view, we stress that the multi-q analysis presented here is the first step to gain a full understanding into the intriguing behavior of NdBi and related AFM materials. This work will contribute to formulating a new phenomenological framework to understand the peculiar temperature-dependent splitting of the unconventional SSP, which requires further theoretical modeling, such as dynamical mean field theory, to include electron correlation and temperature effect. Our work is also a rare example of combining ARPES data with band structure analysis to predict specific magnetic ordering and notably calls for the need of new experiments and analysis to verify the multi-q AFM structures in NdBi.
VI. Computational Methods

All density functional theory (DFT) calculations with spin-orbit coupling (SOC) were performed with the PBE exchange-correlation functional using a plane-wave basis set and projector augmented wave method, as implemented in the Vienna Ab-initio Simulation Package (VASP). Using maximally localized Wannier functions, tight-binding models were constructed to reproduce closely the band structure including SOC within $E_F \pm 1$ eV with Nd $s$-$d$-$f$ and Bi $p$ orbitals. The surface spectral function and 2D Fermi surface (FS) were calculated with the surface Green’s function methods as implemented in WannierTools. In the DFT calculations, we used a kinetic energy cutoff of 253 eV, $\Gamma$-centered Monkhorst-Pack ($8 \times 8 \times 8$) $k$-point mesh, and a Gaussian smearing of 0.05 eV. For band structure calculations of NdBi, we have used the experimental structural parameter of 6.41 Å. To account for the strongly localized Nd 4$f$ orbitals, an onsite Hubbard-like $U=6.3$ eV and $J=0.7$ eV have been used. Our DFT+U+SOC calculation gives a spin moment of 2.7 $\mu_B$ and an orbital moment of 5.8 $\mu_B$ in the opposite direction, resulting in a total magnetic moment of 3.1 $\mu_B$ on Nd, agreeing very well with the experimental data of 3.1±0.2 $\mu_B$.
