(Dated: March 25, 2022)

We introduce and study a model of active Brownian motion with multiplicative noise describing fluctuations in the self-propulsion or activity. We find that the standard picture of density accumulation in slow regions is qualitatively modified by active fluctuations, as stationary density profiles are generally not determined only by the mean self-propulsion speed landscape. As a result, activity gradients generically correlate the particle self-propulsion speed and orientation, leading to emergent polarization at interfaces pointing either towards dense or dilute regions depending on the amount of noise in the system. We discuss how these features affect the onset of motility induced phase separation. Our work provides a foundation for systematic studies of active matter self-organization in the presence of activity landscapes and active fluctuations.

Active matter refers to a broad class of systems driven out of thermal equilibrium at the level of their microscopic constituents. Although detailed balance can be broken locally in various ways, including generation of local stresses [1, 2], local production and consumption of chemicals [3], non-reciprocity in the interactions [4–9], or growth [10–12], systems composed of self-propelled particles play a central role in active matter studies [13–17]. An interesting feature of the latter case is that activity trivially couples to the particles motion, so that it can be used as a way to control the spatial dynamics of active systems with promising practical applications [18, 19]. Spatial segregation of active particles can be achieved at the individual particle level, e.g. by imposing spatially varying self-propulsion speed [20–23], or at the collective level by engineering quorum-sensing-type interactions triggering motility inhibition [24–26].

The physical principles leading to such controls apply to a wide class of systems and can thus be understood from minimal models, which most often deal with Active Brownian Particles (ABPs) [13]. ABPs are generally studied in the overdamped regime under the assumption that their self-propulsion speed relaxes on infinitesimal timescales, so that its overall stochastic dynamics reduces to rotational Brownian motion. Actual active particles, on the other hand, self propel as a result of intricate processes involving nontrivial timescales [27, 28], and usually evolve inside complex and noisy environments [29]. Moreover, individual measurements of active self propulsion velocity often shows it to be dynamical fluctuating quantity [30–39], which is not a surprise, given what we expect from mechanistic descriptions of self-propulsion (see e.g. Refs. [40, 41]).

Such fluctuations, which hereafter we refer to as active, must by symmetry carry independent contributions along and transversally to the particles self-propulsion direction. Unlike thermal noise, active noise is therefore multiplicative by design. Despite a few studies characterising statistical properties of active fluctuations [13, 42–44], little is known about how the latter can in turn affect the spatial organization of the particles [45].

Here, we propose a formulation of fluctuating active Brownian motion in which the particles self propulsion evolution is governed by a deterministic active force and multiplicative noise. Considering the Fokker-Planck equation describing this fluctuating active dynamics, our analysis reveals that the long-time and large-scale description of the system depends tightly on the details of the self propulsion mechanism. Focusing on the case where the self-propulsion force derives from a quadratic potential, we moreover characterize the steady state properties of the model in presence of spatially varying activity. Namely, we find that density profiles created by activity gradients are not only set by the mean particle self propulsion speed but also by its higher order moments. We find that activity gradients generically correlate the particles self propulsion speed and orientation, and lead to an emergent polarization whose direction can point up or down activity gradients depending on the model parameters. Our results are moreover backed up by direct Langevin simulations of an underlying microscopic model. Our work demonstrates that active fluctuations can be used as a way to control the spatial organization of active matter, and leads to conclusions in sharp contrast with existing results obtained in the limit of constant speed ABPs. We finally discuss the consequences of the above features on the emergence of motility induced phase separation.

ABPs with active fluctuations.— We consider a model of overdamped ABPs in $d \geq 2$ dimensions whose coarse-grained description is given by the Fokker-Planck equation $\frac{\partial}{\partial t} \mathcal{P}(\mathbf{r}, \mathbf{v}, t) = -\nabla \cdot \mathbf{J}_r - \nabla v \cdot \mathbf{J}_v$, obeyed by $\mathcal{P}(\mathbf{r}, \mathbf{v}, t)$ the probability density for particles to be at position $\mathbf{r}$ with self-propulsion $\mathbf{v}$ at time $t$. The associated currents $\mathbf{J}_r$ and $\mathbf{J}_v$ read

$$\mathbf{J}_r = v \mathcal{P} - D_r(r) \nabla \mathcal{P}, \quad (1a)$$

$$\mathbf{J}_v = -n \partial_v W(\mathbf{r}, \mathbf{v}) \mathcal{P} - \Sigma(r, \mathbf{v}) \cdot \nabla_v \mathcal{P}, \quad (1b)$$

where in the first equation $D_r(r)$ stands for the translational particle diffusivity. The self propulsion current
in Eq. (1b) gathers two contributions. The first one corresponds to a deterministic active force pointing along \( \mathbf{n} \equiv v/v \), with \( v \equiv |v| \), and deriving from an effective potential \( W \). The second contribution to \( J_r \) results from active fluctuations which are parametrized by the rank-2 tensor \( \Sigma(r, v) \). Note that we allow all model parameters to depend on the particle position \( r \).

Contrary to thermal noise, the symmetries of active noise are dictated by those of \( v \) so that \( \Sigma \) must carry independent contributions along and transverse to \( \mathbf{n} \), corresponding respectively to speed and rotational noises. As discussed in [46], a general expression of diffusion matrix follows

\[
\Sigma(r, v) = D_v(r)\hat{\mathbf{n}}\mathbf{n} + v^2 D_r(r)P^\perp(\hat{\mathbf{n}}),
\]

where \( D_v(r) \) and \( D_r(r) \) are respectively the speed and rotational diffusivities, while \( P^\perp_j(\hat{\mathbf{n}}) \equiv \delta_{ij} - \hat{\mathbf{n}}_i\hat{\mathbf{n}}_j \) is the projector orthogonal to \( \hat{\mathbf{n}} \). Separating speed and orientational degrees of freedom, the Fokker-Planck equation is effectively recast as

\[
\partial_t P = -\nabla \cdot J_r + v^{1-d}\partial_v (v^{d-1}J_v) + D_r \nabla^2 P
\]

where \( \nabla^2 = P^\perp_j(\hat{\mathbf{n}})\partial^2_{\hat{\mathbf{n}}_i\hat{\mathbf{n}}_j} - (d-1)\hat{\mathbf{n}}_i\partial_v \) denotes the spherical Laplacian (summation over repeated indices is assumed), and the dependencies of all parameters on \( r \) and \( v \) are now implicit. The speed current is given by \( J_v \equiv -\partial_v W_{eff} - D_v\partial_v P \) where the effective potential governing the self-propulsion speed dynamics reads \( W_{eff} = W + (d-1)D_v \ln v \).

In the limit where \( D_t, W \) and \( \Sigma \) are independent of \( r \), steady state solutions of Eq. (3) can be factorized and the speed distribution takes the Boltzmann-like form [43]

\[
P_H(v) = Z^{-1}e^{-W_{eff}(v)/D_v} = Z^{-1}e^{-v^{1-d}e^{-W(v)/D_v}},
\]

with \( Z \equiv \int_0^\infty dv e^{-W(v)/D_v} \) ensuring normalization.

**Moment expansion.**—When the coefficients of Eq. (3) vary in space, the active current in Eq. (1a) coupling self-propulsion speed and orientation prevents any factorization of \( P \). However, the large-scale and long-time dynamics of the system is generally well captured by means of an expansion of Eq. (3) in the moments of the self-propulsion velocity \( v \). Given the symmetries of the problem we shall not directly consider moments associated with \( v \), but rather those related to the corresponding speed \( v \) and orientation \( \hat{\mathbf{n}} \). For the following discussion, we thus define the average: \( \rho(\cdot) \equiv \int d^dv(\cdot)P(r,v,t) \), where \( \rho(r,t) \equiv \rho(1) \) is the local particle density normalized to unity. With this definition and after some algebra, we obtain from Eq. (3) and \( k \geq 0 \) the following equations for speed and polarization moments:

\[
\partial_t \rho(v^k) = -\nabla \cdot \left[ \rho(\hat{\mathbf{n}}v^{k+1}) - D_v \nabla \rho(v^k) \right] + \rho(S_k + b_k),
\]

\[
\partial_t \rho(\hat{\mathbf{n}}v^k) = -\nabla \cdot \left[ \rho(qv^{k+1}) + \frac{f}{d}\rho(v^{k+1}) - D_t \nabla \rho(\hat{\mathbf{n}}v^k) \right] - (d-1)D_r \rho(\hat{\mathbf{n}}v^k) + \rho(\hat{\mathbf{n}}S_k) + \nabla \phi_k,
\]

where \( q \equiv \hat{\mathbf{n}}v - I/d \) measures nematic order, and \( S_k \equiv k[(k-1)v^{k-2}D_v - v^{k-1}\partial_v W] \). The boundary terms \( b_k \) and \( \nabla \phi_k \) on the rhs of Eqs. (5) are obtained after integrating by parts the speed current in Eq. (3), their presence results from the singular behavior of \( P \) at \( v = 0 \) (see Eq. (4)). Their expression depends on the behavior of the full distribution \( P(r, v, t) \) as \( v \to 0 \), which is in general unknown. However, we show in [46] that at leading order in gradients one can derive

\[
b_k = D_v\rho\gamma \delta_{k,1}, \quad \nabla \phi_k = \frac{D_v\delta_{k,0}}{d(d-1)D_r} \nabla (\rho\gamma),
\]

where \( \gamma(r) \equiv e^{-W(r,0)/D_v(r)}Z^{-1}(r) \).

The functions \( S_k \) depend explicitly on the potential \( W \); hence, the nature and number of terms present in Eqs. (5) depend closely on the specific form of \( W \). In order to keep the presentation simple while retaining relevant features associated with active fluctuations, we consider the quadratic form \( W(r, v) = \frac{v^2}{2\mu} [v - v_0(r)]^2 \), where \( \mu \) and \( v_0 \) are function of space and assumed positive. Here \( \mu^{-1} \) sets the timescale of speed relaxation, so that the limit ABPs self-propelling at constant speed \( v_0 \) is recovered for large \( \mu \).

As \( S_k = 0 \) for \( k = 0 \) only, the unique slow mode of the dynamics is the particle density \( \rho \). Therefore, in the long-time and large-scale limit the dynamics of all higher order (in speed and orientations) moments can be neglected, and they can all be enslaved to \( \rho \). As the contribution from the nematic order parameter in Eq. (5b) contributes to \( O(\nabla^2) \) [46], we find that

\[
\rho(\hat{\mathbf{n}}) = -\frac{\tau_r}{d} \nabla \rho(v) + \frac{D_v\tau_r^2}{d} \nabla (\rho\gamma) + O(\nabla^2),
\]

\[
\rho(v^2) = -\frac{\tau_r}{d(1 + \alpha)} \nabla (\rho(v^2)) + \frac{\alpha v_0}{1 + \alpha} \rho(\hat{\mathbf{n}}) + O(\nabla^2),
\]

where \( \tau_r \equiv (d-1)D_r^{-1} \) sets the typical timescale of rotational diffusion, while \( \alpha \equiv \mu\tau_r \). At this order in gradients the self-propulsion speed moments moreover solve \( \langle S_k \rangle + b_k = 0 \), such that they are given by the homogeneous distribution (4). Hence, up to \( O(\nabla^2) \) terms,

\[
\langle v \rangle = v_0 + \frac{D_v}{\mu} \gamma, \quad \langle v^2 \rangle = \frac{D_v}{\mu} + v_0(\gamma),
\]

where \( \gamma = \sqrt{2\mu/(D_v\pi)}f(\mu v_0^2/D_v) \) and \( f(x) \equiv e^{-x^2/[1 + \text{Erf}(\sqrt{2}/x)]} \). Combining Eqs. (5a) and (7), we thus find that the density obeys a continuity equation \( \partial_t \rho = -\nabla \cdot J \), with the following effective current

\[
J = -D_t \nabla \rho - \frac{\tau_r}{d(1 + \alpha)} \nabla (\rho(v^2)) + \alpha v_0 \nabla (\rho(v)/v),
\]

and where the boundary term \( \sim \tau_r^2 D_vv_0 \nabla (\rho\gamma) \) coming from (7a) has been discarded as its contribution is generally subleading. For a quadratic potential \( W \), the density
This feature allows for counter intuitive behavior, as we speed, as gradients of $\rho$ depend on the mean particle speed with an ex-

Contrary, when active noise dominates Fig. 1(b) shows that the effect of rotational noise disappears as $D_v/\mu$.
Set $D_v = 0$, the rotational diffusivity $D_v$ appears in the expression of $\rho_s$ only through the parameter $\alpha$. Spatial variations of $D_v$ alone are therefore unable to generate density gradients, in agreement with usual considerations [15] and recent experimental results [48]. However, the value of $\alpha$ sets the scaling of the steady state density with the speed moments. For fast speed dynamics ($\alpha \gg 1$) Eq. (10) leads to the standard relation $\rho_s \sim \langle v \rangle^{-1}$ [47], while in the opposite case of fast rotational diffusion ($\alpha \ll 1$) we instead get $\rho_s \sim \langle v^2 \rangle^{-1}$. Assuming $\alpha$ uniform we moreover obtain from Eq. (10) in the active force, or noise dominated, regimes

$$\rho_s \sim v_0^{-2(\alpha+1)/(1+\alpha)} \quad (D_v \ll \mu v_0^2), \quad (11a)$$

$$\rho_s \sim \langle v \rangle^{-2} \sim (D_v/\mu)^{-1} \quad (D_v \gg \mu v_0^2). \quad (11b)$$

For low noises, the steady state density therefore scales algebraically with the mean particle speed with an exponent set by the ratio between rotational diffusion and speed relaxation timescales as shown in Fig. 1(a). On the contrary, when active noise dominates Fig. 1(b) shows that the effect of rotational noise disappears as $\rho_s$ always scales as the inverse of $D_v/\mu$.

From Eq. (10), for $D_v$ and $\mu v_0^2$ of similar order the stationary density is no more enslaved to the mean particle speed, as gradients of $\langle v^2 \rangle$ can compete with that of $\langle v \rangle$. This feature allows for counter intuitive behavior, as we show by considering the following configuration: we partition the space into two distinct sub-regions 1 and 2 in which active particles experience different uniform values of $v_0 = v_{1,2}$ and $D_v = D_{v_1,2}$ (see Fig. 1(e)). We denote $\tilde{v} = v_1 - v_2$ and $\tilde{D}_v = D_{v_1} - D_{v_2}$, and consider the case $\tilde{v} \tilde{D}_v < 0$. $\tilde{v}$ is kept fixed, and we vary $\tilde{D}_v$. For $|\tilde{D}_v|$ small enough, $\rho_s$ is maximal in the region with the smallest $v_0$, as generally the case for constant speed ABPs [15, 47] (see blue lines in Figs. 1(c,d)). Increasing $|\tilde{D}_v|$ progressively leads to a density profile having a different shape, such that for large $|\tilde{D}_v|$ particles instead accumulate on average in the region where $v_0$ is largest (green lines in Figs. 1(c,d)). The density inversion partly follows the behavior of the mean speed $\langle v \rangle$, also affected by $|\tilde{D}_v|$ (see Eq. (8) and Fig. 1(e)). While $\rho_s$ globally remains largest in small $\langle v \rangle$ regions, a direct inspection of the $\rho_s(\langle v \rangle)$ curves reveals

**FIG. 1.** Steady state density with spatially varying activity. (a) Mean stationary density as function of $v_0$ for $\mu v_0^2 \gg D_v$; the colors respectively correspond to $(\mu, D_v) = (1, 1)$ (green), $(1,10)$ (red), $(10,1)$ (blue) and (10,10) (yellow). (b) Mean stationary density as function of $D_v/\mu$ for $\mu v_0^2 \ll D_v$, the color code is same as (a). In (a,b) the data have been shifted vertically for clarity. (c) Imposed one dimensional $v_0$ (black dash-dotted line) and $D_v$ (colored dashed lines) profiles splitting the space in two nearly homogeneous regions with different activities. (d,e) The mean density(d) and particle speed(e) profiles corresponding to (c). (f) The relation $\rho(\langle v \rangle)$ corresponding to (d,e). In (d-f) $\mu = D_v = 1$, the $v_0(x)$ profile is unchanged and the color codes the maximal value of $D_v$ in each case. In all panels except (c) open circles show results obtained from Langevin simulations while dashed lines indicate the corresponding theoretical predictions.
that when $\nabla v_0$ and $\nabla D_v$ are both nonzero, $\rho_s$ can locally increase with $\langle v \rangle$ (Fig. 1(f)), something impossible in absence of active fluctuations.

**Orientation-speed correlations and emergent polarization.**— As stated above, the phase space distribution solving Eq. (3) with spatially varying coefficients cannot be factorized in general due to the coupling between particle motion and activity (see Fig. 2(b)). We now discuss the consequences of such feature on the particles orientational dynamics in presence of spatially varying activity. For the sake of clarity, we focus on the case $\mu v_0^2 \gg D_v$ where Eq. (8) implies $\langle v \rangle \approx \sqrt{\langle v^2 \rangle} \approx v_0$, but the results presented below hold in a more general context.

Correlations between the active particles speed and orientation are quantified considering the connected moment $C(v, \hat{n}) \equiv \langle v \hat{n} \rangle - \langle v \rangle \langle \hat{n} \rangle$. Using Eqs. (7) and (8), we obtain the following expression

$$C(v, \hat{n}) = -\frac{\tau_r v_0 \nabla v_0}{d(1 + \alpha)} (\mu v_0^2 \gg D_v),$$

showing that $C$ is nonzero in regions of non vanishing activity gradients, as shown in Fig. 2(a). Naturally, speed-orientation correlations are moreover suppressed in the cases of fast rotational and speed relaxation (resp. $\tau_r \to 0$ and $\alpha \to \infty$).

As the relation $\rho_s \propto \langle v \rangle^{-1}$ does generally not hold in presence of active fluctuations or for $\alpha$ finite, Eq. (7a) implies that spatially varying activity spontaneously generates local orientational order. Namely, using the zero flux solution (10) we derive for the average stationary state polarization

$$\langle \hat{n} \rangle_s = \frac{\tau_r \left[ v_0^2 - dD_t(1 + \alpha)\tau_r^{-1} \right] \nabla v_0}{d(1 + \alpha)(dD_t \tau_r^{-1} + v_0^2)} (\mu v_0^2 \gg D_v).$$

Equation (13) highlights two mechanisms at the origin of polar order in regions of nonzero activity gradients. For fast speed relaxation ($\alpha \to \infty$), the steady state active flux $v_0(\hat{n})_s$ must compensate the diffusive flux $-D_t \nabla \rho_s$, so that $\langle \hat{n} \rangle_s$ points towards slow (or dense) regions (see Fig. 2(d)) [23, 49, 50]. This gradient aligning mechanism is consistent with the polarization generally observed at interfaces of repelling ABPs in the phase separated regime [51–53], where in this case the mean-field spatial diffusion results from particle collisions [54]. On the other hand, for self-propulsion speeds $v_0$ such that $v_0^2 > dD_t(1 + \alpha)\tau_r^{-1}$ Eq. (13) predicts a reversal of the mean polarization direction towards fast (or dilute) regions (see Fig. 2(c)). Indeed, neglecting the effect of positional diffusion particles crossing an interface separating two regions with different activities will be on average slower—and thus stay longer at the interface— if they come from the slower (or denser) region. Consequently, the local polarization will in this case be oriented towards the most dilute region.

**Onset of Motility Induced Phase Separation (MIPS).**—

The origin of MIPS can be understood at the mean field level from an effective density dependence of activity [15, 54, 55]. Namely, if active particles slow down fast enough when reaching dense regions, a positive feedback loop leads to a linear instability of homogeneous systems which marks the onset of phase separation. As the above derivation considers general spatial dependencies of the model parameters, it allows us to study how active fluctuations can influence the onset of MIPS. Imposing that the spatial dependency of the speed moments are due to their variation with the local particle density, Eq. (9) reduces to $\mathbf{J} = -D_{\text{eff}}(\rho) \nabla \rho$, where the effective mean field diffusivity reads

$$D_{\text{eff}}(\rho) = D_t + \frac{\tau_r \left[ \langle v^2 \rangle 1 + \frac{\rho \langle v^2 \rangle}{\langle v^2 \rangle} \right] + \alpha v_0 \langle v \rangle (1 + \frac{\rho \langle v \rangle}{\langle v \rangle})}{d(1 + \alpha)},$$

and where primes denote derivatives with respect to $\rho$. A homogeneous system at density $\bar{\rho}$ is thus linearly unstable to small wavenumber perturbations whenever $D_{\text{eff}}(\bar{\rho}) < 0$, which for large $\alpha$ and small $D_t$ imposes $\bar{\rho} \langle v \rangle^2 < -\langle v \rangle$ [15, 55]. However, in the presence of active fluctuations this condition is in general not necessary, as the sign of $D_{\text{eff}}(\bar{\rho})$ depends on the second speed moment. We moreover note that, in contrast with constant speed ABPs, the rotational diffusivity $D_r$ may influence the emergence of MIPS through the coefficient $\alpha$. 

![FIG. 2. Speed-order correlations and local polarization. (a) The steady state correlation function $C_s(v, \hat{n}_s)$ in presence of spatially varying activity $v_0(x)$ (grey dashed lines) as well as uniform $D_t = 0.1$ and $\mu = D_r = 1$ with $D_t = 0.1$ (blue) and 1 (red). (b) The joint speed-orientation distribution associated with (a) for $D_t = 0.1$, at the center of the domain ($x = 50$) and at the interface between the two regions with different activities ($x = 25$). (c,d) The local averaged polarization profiles corresponding to (a) with the same color code, while the dashed grey line shows the corresponding stationary density profiles. In (a,c,d) open circles show the simulations data, while continuous lines indicate theoretical predictions.](image-url)
We have introduced a general model of active noise and studied its consequences on the free motion of ABPs. Our analysis reveals a number of striking differences with respect to the widely used constant speed ABPs model, such as the breakdown of the $\rho_s \sim \langle \psi \rangle^{-1}$ law for comparable self-propulsion speed and orientational relaxation timescales, leading under these conditions to possibly counter-intuitive stationary density profiles. Moreover, our results illustrate how the interplay of active noise and activity gradients leads to correlations between particles speeds and orientation, as well as emergent polar order in absence of explicit aligning interactions. Finally, we have found that active noise qualitatively modifies the shape MIPS spinodals. Considering more complex expressions of the potential $W$ or studying interacting systems [56, 57], it thus appears clear that further consequences of active noise on the dynamics of active matter are expected.
