ABSTRACT

In the paper "Andrew D.P. Smith, Peter T. Haugen, Boyd F. Edwards: Hysteretic transition between states of a filled hexagonal magnetic dipole cluster, Journal of Magnetism and Magnetic Materials 549 (2022): 168991" a hysteretic transition between two stable arrangements of a cluster of seven dipoles is presented. The relative strength of the center dipole in a hexagonal arrangement serves as the bifurcation parameter. The authors clearly demonstrate the existence of two instabilities accompanied by discontinuous jumps of the dipole arrangement, but leave the question about the nature of these instabilities unanswered. This comment clarifies the nature of the two instabilities: the first one is a symmetry-breaking sub-critical bifurcation with parabolic scaling of the magnetic potential energy difference between the two branches, and the second one is a fold with its characteristic scaling in the form of a semi-cubic parabola.

1. Introduction

The natural arrangements of a relatively small number of spherical magnets are a great source of inspiration for experimental classroom demonstrations of magnetostatic problems in general, and bifurcations between static equilibrium states in particular. Smith et al. discuss a filled hexagonal arrangement based on seven spherical permanent magnets [1]. Their experimental investigation is compared with a mathematical model based on dipole-dipole interactions, which nicely explains the physics of this magnetostatic problem. Within a certain range of their control parameter \( \alpha \) — the strength of the central dipole relative to the perimeter dipoles of the hexagonal arrangement — they find bistability. This bistable range is bounded by two instabilities leading to discontinuous jumps of the dipole arrangement. This comment clarifies the nature of these instabilities.

2. Unveiling the nature of the instabilities

In Fig. 1, we use the nomenclature and color code for the stable branches as introduced in [1]. It shows the bistable range of the control parameter \( \alpha \) between the two bifurcations at \( \alpha_1 \approx 1.1545 \) and \( \alpha_2 \approx 2.4724 \). The dipolar and the circular state are stable within \( \alpha_1 < \alpha < \alpha_2 \). They were calculated here with a relaxation code that was developed for studying a similar magnetic cluster problem [2], and is described in detail in another comment [3]. Due to the symmetries of these stable states, only three angles, e.g., \( \phi_{3,4,5} \), are necessary to characterize the circular state, and even one angle is sufficient to describe the dipolar state unambiguously.

In Figs. 1(a)–(c), \( \phi_{3,4,5} \) is shown as a function of \( \alpha \). In addition to the two stable branches, we also show two unstable branches necessary and sufficient to understand the bifurcations. The first unstable branch is the continuation of the circular state. It has been traced using the function 'root' from SciPy [4]. We name it "unstable circular state" and plot the corresponding \( \phi(\alpha) \) as a dashed light blue line. The second unstable state bifurcates at \( \alpha_1 \) from the dipolar state, breaking its symmetry and destabilizing the highly symmetric dipolar state for \( \alpha < \alpha_1 \). We name this branch "subcritical branch", because it emerges as a subcritical bifurcation from the dipolar state. The arrangement of all seven dipoles for the four modes of interest within this comment is shown for the middle of the bistable range, namely at \( (\alpha_1 + \alpha_2)/2 \), and is presented in the form of insets. Both unstable branches have the symmetries of the circular state.

By visual inspection of the \( \phi(\alpha) \)-curves, the two bifurcations of interest can most clearly be seen in the plot of \( \phi_{3}(\alpha) \). The circular state extends to \( \alpha_2 \). Of course, it does not simply end here: It folds over into its unstable branch shown as a dashed line in this comment.

The instability of the ensuing dipolar state with \( \phi_4 = 0 \) and its higher symmetry (\( \phi_5 = 360° - \phi_3 \)) is also visible here: At \( \alpha_1 \), a symmetry breaking solution branches off from the dipolar state. It bends over into the stable range of the dipolar solution, i.e., it is a subcritical pitchfork bifurcation. Being unstable itself, it destabilizes the dipolar state for \( \alpha < \alpha_1 \).

A natural order parameter for transitions between the dipolar and the circular state is the toroidal magnetic moment

\[
m_{tor} = \sum_i p_i \times m_i
\]

as described, e. g., in Ref. [5]. The z-component of this vector is shown in Fig. 1(d). For clarity, the symmetric counterparts with negative toroidal moments are omitted, as they are simply obtained by reversing the perimeter dipoles. It must start from the value 6 for \( \alpha = 0 \), because the six dipole orientations \( \phi_{1...6} \) are perpendicular to their corresponding location \( p_{1...6} \) here. The fold can nicely be seen with this order parameter. Fig. 1(d) also demonstrates that the unstable circular state — destabilizing the dipolar state at \( \alpha_1 \) — does not have the higher symmetry of the dipolar state. The latter
Hysteretic transition in a dipole cluster

The magnetic potential energy $U$ of the four states is shown in Fig. 1(e). The energies of the dipolar and the subcritical branch meet at $\alpha_1$, and those of the two branches of the circular state coincide at $\alpha_2$. The fundamentally different nature of the two bifurcations leads to distinctive energy difference scalings when approaching the corresponding critical point. For the subcritical bifurcation one expects

$$\Delta U \propto (\alpha - \alpha_1)^2$$

by analysis of the corresponding normal form of this bifurcation [6]. The scaling is best demonstrated visually when plotting the square of the energy difference in Fig. 1(e), which leads to a finite slope of the line starting from zero at $\alpha_1$.

For the fold we expect

$$\Delta U \propto (\alpha - \alpha_2)^{3/2},$$

a semi-cubic parabola, reminiscent of the scaling near a cusp catastrophe [7]. This scaling is best demonstrated visually when plotting the energy difference raised to the power of $2/3$, which leads to the corresponding straight line in Fig. 1(f).

3. Conclusion

This experiment is great for classroom demonstrations, because it shows with its spontaneous symmetry breaking, the bi-stability, and the two different bifurcations leading to discontinuous jumps almost all of the elementary features of static nonlinear systems. An interactive Python program demonstrating the relaxation of the cluster is available [8].
