Vibrational and elastic properties of the $R Fe_4 Sb_{12}$ skutterudites are investigated by, respectively, temperature ($T$) dependent extended X-ray absorption fine structure (EXAFS) and pressure ($P$) dependent x-ray diffraction (XRD) experiments. The Fe K-edge EXAFS experiments of the $R$ = K, Ca and Ba materials were performed in the $T$-interval $06 < T < 300$ K and XRD experiments of the $R$ = Na, K, Ca, Sr and Ba materials were performed in the $P$-interval $1$ atm $< P <$ 16 GPa. From EXAFS, we obtained the correlated Debye-Waller parameters that were thus analyzed to extract effective spring constants connected with the Fe-Y (where Y = either R, Fe or Sb) scattering paths. Our findings suggest that in the case of the light cations, $R$ = K or Ca, the $R$ atoms are relatively weakly coupled to the cage, in a scenario reminiscent to the Einstein oscillators. From the XRD experiments, we obtained the bulk modulus $B_0$ for all $R$ = Na, K, Ca, Sr and Ba materials, with values ranging from 77 GPa ($R$ = K) to $R$ = 99 GPa ($R$ = Ba) as well as the compressibility $\beta$ as a function of $P$. The trend in $\beta$ as a function of the $R$ filler is discussed and is shown that it does not correlate with simple geometrical considerations, and is likely related to bonding specific properties.

I. INTRODUCTION

Filled skutterudites are materials with chemical formula $RT_4 X_{12}$ where the $T_4 X_{12}$ elements form a relatively rigid cage framework inside which the $R$ elements are allocated [1]. In the simplest chemical bonding scenario, the cage is structured by strong $T-X$ covalent bondings and the $R$ fillers generically display a cationic character, donating electrons that further stabilize the $T_4 X_{12}$ cage. While it is well known that the description of bonding in filled skutterudites is more involved [2], this simple picture can be applied as a guide to discover new filled skutterudites [3] as well as to justify their unusual vibrational dynamics [4].

Concerning the latter topic, research on the filled skutterudites is indeed triggered mostly by the presence of an unusual vibrational dynamics that makes the filled skutterudites good candidates for thermoelectric applications [5–7]. In this regard, earlier contributions proposed that the $R$ fillers behave as independent, non dispersive and low energy oscillators (or rattlers), that scatter the cage derived phonons, giving rise to a phonon glass. This phonon glass impedes the thermal conduction and effectively raises the material thermoelectric figure of merit $ZT$ [8].

On one account, the phonon glass scenario provided a first approach to understand the skutterudites’ vibrational dynamics. For instance, filling the cages with distinct fillers may cause the smaller $R$ cations to display an unusual rattling behavior in the oversized cage, as observed [9–10]. This scenario, however, was soon challenged [11] and it is now well understood that the separation between rattler and cage vibrational dynamics do not offer an adequate description of the filled skutterudite vibrational properties [12–13]. All this understanding is particularly true in the case of the $R Fe_4 Sb_{12}$ ($R$ = Na, K, Ca, Sr, Ba) skutterudites [14–20] and provides support for the design of more efficient antimony based skutterudite materials [21–23].

On top of the good potential for thermoelectric applications, filled skutterudites are very flexible platforms, displaying a broad range of electronic, magnetic and thermal properties [24]. The $R Fe_4 Sb_{12}$ ($R$ = Na, K, Ca, Sr, Ba and La) materials, in particular, are itinerant magnets [15–25] whose magnetic properties are dominated by a high density of states due to the mixing between the Fe derived 3d states and Sb derived 5p states forming heavy bands in the vicinity of the Fermi level [30–31].

In this work, we focus on the vibrational and structural properties of the $R Fe_4 Sb_{12}$ ($R$ = Na, K, Ca, Sr and Ba) filled skutterudites as investigated, respectively, by temperature ($T$) dependent extended x-ray absorption fine structure (EXAFS) and pressure ($P$) dependent x-ray diffraction (XRD) experiments. EXAFS was soon recognized by Cao et al [32] as a suitable probe to the site-specific vibrational dynamics in skutterudites. Later contributions [33–35] developed the application of the technique to the correlated nature of the filler-cage vibrational dynamics. Here, we focus on the Fe K-edge EXAFS of the $R$ = K, Ca and Ba samples. In our investigation, we find that the cage vibrational dynamics clearly depend on the filler type, corroborating the correlated nature of the filler-cage dynamics. Moreover, the $R$ = Ca sample data is best described by the inclusion of an anharmonic contribution to the EXAFS analysis.

Our XRD experiments were carried out for pressures typically up to $\approx$ 16 GPa for all samples, except in the case of the BaFe$_4$Sb$_{12}$, which was investigated up to 24 GPa. Overall, the $P$-dependence of all samples is well described by the Birch-Bridgman model [36]. More-
over, starting at pressures about \( \approx 12 \) GPa, the XRD results display broad reflections. This finding suggests that the\( \text{RFe}_2\text{Sb}_{12} \) materials undergo a process of increasing lattice disorder triggered by pressure, which is reminiscent of the pressure induced partial amorphization observed for other cage systems \[37\].

II. METHODS

High quality polycrystalline samples of \( \text{RFe}_2\text{Sb}_{12} \) (\( \text{R} = \text{Na}, \text{K}, \text{Ca}, \text{Sr}, \text{Ba} \)) skutterudites were synthesized by a solid state sintering method \[27\]. \( \text{Fe} K\)-edge EXAFS experiments of the \( \text{R} = \text{K}, \text{Ca}, \text{and Ba} \) samples were performed at the XAFS2 \[38\] beamline of the Brazilian Synchrotron Light Source (CNPEM-LNLS). The spectra of the \( \text{K} \) and \( \text{Ca} \) filled materials were measured by both fluorescence and transmission modes, whereas the \( \text{Ba} \) filled material was measured only in the fluorescence mode. A complete temperature scan in the interval \( \text{T} = 6 \text{K} \) was obtained for the three samples. A \( \text{Fe} \) foil, kept at room temperature, was measured in the transmission mode as a reference throughout the experiments. A conventional \( \text{He} \)-flow cryostat was employed to achieve temperatures down to \( \text{T} = 6 \text{K} \).

The EXAFS data were analyzed by multiple scattering theory implemented by the FEFF code \[39\]. The graphical Demeter platform \[40\] was adopted to perform the fittings of a structural model including single and multiple scattering paths up to 5 Å from the \( \text{Fe} \) absorber. To decrease the number of parameters in the fitting, the \( S_0^2 \) parameter of the EXAFS parameter was obtained from \textit{Ab initio} calculations implemented by the FEFF8.4 code. The \textit{Ab initio} calculations were performed for clusters of 226 atoms, adopting the Hedin-Lundqvist pseudopotential to account for the exchange interaction \[41\].

The powder XRD experiments were performed at the XDS beamline of the CNPEN-LNLS at room temperature. A diamond anvil cell (DAC) was employed during experiments to achieve pressures up to 24 GPa (\( \text{R} = \text{Ba} \)), but typically up to 16 GPa (\( \text{R} = \text{Na}, \text{K}, \text{Ca}, \text{and Sr} \)). A mixture of methanol and ethanol (in a 4 : 1 proportion) was adopted as a pressure media. The pressure was measured by monitoring the Raman fluorescence from a ruby filling element. The second and third \( \text{Sb} \) nearest neighbors, denoted \( \text{Sb}_{2} \) and \( \text{Sb}_{3} \), are too close to each other, and thus we adopt a single correlated Debye-Waller parameter \( \sigma_{\text{Fe}-\text{Sb}_{2,3}} \), to describe both paths. In total, four \( \sigma_{\text{Fe}-\text{Y}} \) are considered: \( \sigma_{\text{Fe}-\text{Sb}_{1}} \), \( \sigma_{\text{Fe}-\text{R}_{1}} \), \( \sigma_{\text{Fe}-\text{Sb}_{2,3}} \), and \( \sigma_{\text{Fe}-\text{Fe}} \).

Single scattering paths dominate the EXAFS signal, but multiple scattering paths were included to improve the data refinement. The disorder parameters of the latter were modeled in terms of the single scattering path \( \sigma_{\text{Fe}-\text{Y}} \) parameters. In its turn, the \( T \)-dependence of the three \( \sigma_{\text{Fe}-\text{Y}} \) parameters were modeled on the basis of the Einstein model (see eq. 1).

In Ref. \[41\], a preliminary EXAFS data analysis pointed out that the \( \text{CaFe}_4\text{Sb}_{12} \) disorder parameters stood out in comparison to other light fillers based materials. By direct comparison between the Fourier transformed data, one can see that, indeed, the \( \text{CaFe}_4\text{Sb}_{12} \) EXAFS is distinct from the one for \( \text{KFe}_4\text{Sb}_{12} \). The features are in general broader and much more oscillations are resolved in the \( \text{KFe}_4\text{Sb}_{12} \) case (compare, for instance, features in the \( 3 - 4 \) Å range in figures \[3 d \) and \( 3 e \)). We thus resorted to the use of higher order cumulants in the \( \text{CaFe}_4\text{Sb}_{12} \) EXAFS analysis. The need for higher order cumulants suggests the presence of anharmonic vibrations, as recently demonstrated in the case of the partially filled \( \text{Yb}_4\text{CoS}_{13} \) skutterudites \[43\]. The cumulants were modeled as a \( T \)-dependent parameter, and we tested linear and activated (exponential) models. The best fittings were obtained for the linear model adopting only third order cumulants. The third order cumulant temperature dependence is shown in the inset of figure \[2 b \). Anharmonic vibrations in the \( \text{CaFe}_4\text{Sb}_{12} \) case were not evidenced in previous studies \[17\]. It is likely that the probed anharmonic components do not carry enough weight to be relevant to either thermodynamic or vibrational properties of this skutterudite and were here detected only because of the sensitivity of the EXAFS technique. Representative fittings and residuals (for low and

high $T$ data) for the $R = K, Ca$ and Ba cases are displayed in figures (g) – (i), showing that the structural model adopted in this paper offers a fair description of the data in all $T$-interval.

To perform a quantitative analysis, we now turn to the parameters obtained by the EXAFS experiments. The model contains two parameters, namely the static disorder $\sigma_0^2$ (the low-temperature values of $\sigma^2$) and $\theta_E$. The expression for each $\sigma_{Fe,Y}^2$, for each $R$ filled sample, reads:

$$\sigma_{Fe,Y}^2(T) = \sigma_0^2 \delta_{Fe,Y} + \frac{K^2}{2\mu k_B \theta_E} \coth\left(\frac{\theta_{E,Fe,Y}}{2T}\right)$$  \hspace{1cm} (1)$$

where $\mu$ is the Fe-Y pair reduced mass. From now on, we denote by $\theta_{E,Fe-Y}$ the Einstein temperature obtained for the Fe-Y path of the $R$ filled sample. Similarly, we denote by $K_{eff,Fe-Y}$ the effective spring constant for the Fe-Y path of the $R$ filled sample. All results are compiled in table I.

Translated to $K_{eff,Fe-Y}$, the vibrational properties of Fe-Sb bondings for the $R = K, Ca$ and Ba filled materials are similar, with the difference being less than 15% between the parameters $K_{eff,Fe-Sb_1}$. It is also very similar to the vibrational properties of the Co-Sb bondings [44]. There is, however, a clear trend towards the softening of the Fe-Sb vibrations in going to the CaFe$_3$Sb$_{12}$ case, which is clearly observed in the case of the $K_{eff,Fe-Sb_2,3}$ parameters. Inspection of the $K_{eff,Fe-R}$ parameters, on the other hand, reveals a much larger variation. Indeed, $K_{eff,Fe-Ba}/K_{eff,Fe-Ca} \approx 5$, stressing a clear distinction between the cases of heavy and light fillers. It suggests

The Fe - Fe vibrations, as described by the $K_{\text{eff}}^{R,\text{Fe-Fe}}$ parameters, are comparable in the cases of the K and Ca filled samples and are more than 30% reduced when compared to the $R = \text{Ba}$ case. In the latter case, however, there is a caveat that undermines a reliable $K_{\text{eff}}$ determination. Indeed, the Sb$_2$ and Sb$_3$ atoms are only $0.01 \, \text{Å}$ apart and therefore FEFF takes all the atoms as a single scattering path with high multiplicity. In the K and Ca filled samples, these paths are distinct and they interfere destructively in some regions leaving room for the determination of $K_{\text{eff}}^{\text{K,Fe-Fe}}$ and $K_{\text{eff}}^{\text{Ca,Fe-Fe}}$ with good statistics. Therefore, the fact that the obtained $K_{\text{eff}}^{\text{Ba,Fe-Fe}}$ parameter is larger must be taken with care.

The effective spring constants can be applied to the discussion of an effective 1D model, introduced by Keiber et al. [33, 34], for the qualitative description of the correlated filler-cage motion in filled skutterudites. The model considers the three distinct elements illustrated in figure 1(c): the R filler (or rattler), the Sb square ring and the Fe metal cage, which denotes solely the Fe cubic lattice. The coupled character of vibrational dynamics is given by connecting the elements by four distinct spring constants: a rattler-square ring ($k_{rc}^{R}$), a rattler-metal cage ($k_{rc}^{R}$), a metal cage-metal cage ($k_{cs}^{R}$) and a metal cage-square ring ($k_{cs}^{R}$) spring constants for each $R$ filled skutterudite. The system dynamics is treated at a classical level and the corresponding dynamic matrix is diagonalized to find four phonon dispersion modes $\omega_j(q)$, where $q$ is the phonon wave-vector [33]. We shall discuss two aspects of the coupled vibrations that can be connected to our experimental results: i) the filler-cage mass relation; ii) the dependence of the $k_{rc}^{R}$ constants on whether $R$ is a light or heavy element (as suggested by the experimentally obtained $K_{\text{eff}}^{R,\text{Fe-R}}$ parameters). Moreover, we shall fix the $k_{cs}^{R}$ constants between samples and adopt a larger $k_{cc}^{R}$ in the BaFe$_4$Sb$_{12}$, as suggested by the experimentally obtained $K_{\text{eff}}^{R,\text{Fe-Sb}}$ and $K_{\text{eff}}^{R,\text{Fe-Fe}}$ parameters. Our experi-
One should keep in mind that there is no one-to-one correspondence between the $K_{eff}^{R,Fe-Y}$ and spring constants of the 1D effective model. Rather, the $K_{eff}^{R,Fe-Y}$ constants are adopted to get reasonable estimates to the spring constants, in particular to their relative values. Formally, one can say that the spring constants are a functional of the $K_{eff}^{R,Fe-Y}$ and that there is a strong functional dependence between, for instance, $K_{eff}^{R,Fe-Fe}$ and $k_{cc}$ or $K_{eff}^{R,Fe-R}$ and $k_{cc}^{R}$. Results of the phonon dispersions are displayed in figures 3(a) – (o). The exact parameters adopted are indicated in the figures or in the figure caption.

In figures 3(a)-(f), the mass-relation between the Rations and the cage elements is that of the KFe$_4$Sb$_{12}$ case (which, in view of the qualitative nature of the calculated dispersions, also describe the CaFe$_4$Sb$_{12}$ case) and is one of the key properties determining the phonon dispersion. The other relevant parameter is indeed the relatively small rattler-cage spring constant. These two parameters determine, respectively, the wide separation between the acoustic and optical modes and the conspicuous flattening of the second optical mode (thick orange line). The latter implies a wide range of $k$-values for which the phonon group velocity is very close to zero, describing a rather localized phonon mode, reminiscent of the Einstein oscillators scenario. In view of the ratio $K_{eff}^{Ca,Fe-Ca}/K_{eff}^{K,Fe-K} \approx 2/3$ (see table I) we propose that the CaFe$_4$Sb$_{12}$ and KFe$_4$Sb$_{12}$ vibrational dynamics are, respectively, described by figures 3(a)-(c) and 3(b)-(i). The range of values in the $k_{cc}^{R}$ does not bring any substantial change to the discussed features.

The mass relation of the BaFe$_4$Sb$_{12}$ case is represented in figures 3(j)-(o). We now observe a smaller frequency gap between the acoustic and optical modes (due to the filler-cage mass relation) and a much smaller region wherein the second optical mode is flat, due to the large rattler-cage coupling. Here, the parameter range is very similar to the one adopted in the CeRu$_4$As$_{12}$ cases and LaPt$_3$Ge$_{12}$ cases, which allows us to pinpoint that the filler-cage mass relation is also responsible for a larger flattening of the optical mode, contributing to the phonon localization as recently proposed. Furthermore, adopting a harder $k_{cc}^{R}$ constant essentially increases the frequency of the higher energy (third) optical mode. As consequence, the avoided crossing between the second and third optical modes is barely observed.

**B. X-ray diffraction and elastic properties**

We now turn to the $P$ dependent XRD experiments. In figures 4(a) – (e) representative data of the XRD experiments, after removing the background, are presented for all samples. The main diffraction peaks of the skutterudite structure are marked in red as a reference. The powder profile was compared to the skutterudite crystal structure (the thick red lines in figures 4(a) – (e) ) and the $P$ dependence of the lattice parameters was extracted from the peak positions.

Our analysis of the XRD experiments are in figures 5(a) – (d). In figure 5(a), the unit cell volumes ($V$) as a function of $P$ of all samples are presented. It is tempting to associate the skutterudite elastic properties to the relation between the cage volume and the filler cationic size. We then compile in figure 5(b) a phenomenological...
Parameter: the cage empty volume fraction $f_E$, that we define as $f_E = 1 - V_R/V_C$, where $V_R$ is the $R$ cationic volume and $V_C$ is the Sb cage volume, as a function of $P$. The cage is represented in the inset of figure 5(b) as a reference.

The volume pressure dependence is investigated by fitting $V \times P$ data to the Birch-Bridgman model [36]:

$$P(V) = \frac{3}{2} B_0 [\left(\frac{V}{V_0}\right)^{-3/2} - \left(\frac{V}{V_0}\right)^{-3}] [1 + \frac{3}{4} B'_0 - 4] [\left(\frac{V}{V_0}\right)^{-3} - 1]$$

(2)

where $V$ is the sample unit cell volume, $V_0$ is the sample volume at room conditions, $B_0$ is the bulk modulus and $B'_0$ is the bulk modulus derivative. In cubic systems, we expect $B'_0 \approx 4$ GPa, as recently adopted to describe other skutterudites [47, 48]. Values obtained for $V_0$ and $B_0$ are compiled in table II. The $V_0$ values obtained from the fitting deviate only about 1% from the experimentally determined from x-ray diffraction at room conditions suggesting the adequacy of our analysis. The $V \times P$ data and their respective fitting are in figure 5(c).

Table II. Parameters of the Birch-Bridgman model for all RFe$_4$Sb$_{12}$ samples.

</tbody>
</table>

The $B_0$ values thus obtained range from 77 GPa ($R = K$) to 99 GPa ($R = Ba$). The values compare well with a recent analysis of other skutterudites [45], including the EuFe$_4$Sb$_{12}$ case [47]. The latter further suggests that $B_0$ reflects the rigidity of the Fe$_4$Sb$_{12}$ framework which, however, is not independent of the choice of $R$. The experimentally obtained $B_0$ parameters are in the range of the values previously obtained by calculations of $R$ = Ca, Sr and Ba cases [17]. It is noteworthy, however, that the calculated values are nearly $R$ independent and about 80 GPa, while the observed variation is significant and there is a clear dependence as a function of $R$.

In possession of the $B_0$ values, we then obtain the materials’ compressibility $\beta$ as a function of $P$. The results are displayed in figure 5(d). The compressibility data express well how the elastic properties depend on $R$: it is shown that the Ba and Na filled materials have larger $\beta$ while the K and Ca filled materials have smaller $\beta$. In reference to our phenomenological parameter $f_E$, one can safely conclude that the observed trend in $\beta$ does not correlate with $f_E$ and therefore this simple geometric relation does not distinguish the skutterudite elastic properties. Rather, the trend in elastic properties should be connected to the filler-cage bonding specific properties, that not only distinguish the filler size, but also either we have $R+1$ or $R+2$ filled materials.

Lastly, we comment on the significant broadening of the diffraction peaks for high pressures that is observed. Starting at about 12 GPa in the $R = Na$ and $K$ cases and at higher $P$ in the case of the alkaline earth filled skutterudites, the peaks’ broadening amount to a partial structural amorphization, or at least to increasing structural disorder, induced by $P$. The alkaline earth filled materials are suggested to be relatively less susceptible to the disorder increase by $P$. Indeed, the diffraction peaks can still be observed for $P$ up to 24 GPa in the

IV. SUMMARY AND CONCLUSIONS

The site specific vibrational properties of the $R = K, Ca$ and Ba filled skutterudites $RFe_4Sb_{12}$ were investigated by EXAFS experiments. As concluded from the effective spring constants obtained from experiments, materials filled with light-weight cations display weak rattler-cage couplings, reminiscent of the independent rattler scenario and of the previously determined large ADPs in these two cases. Our analysis, in terms of an effective 1D model to the skutterudite phonon dispersion, proposes that the $R = K$ and Ca filled skutterudites should display a conspicuous optical flat mode in accordance with the Einstein oscillator scenario. Moreover, our findings suggest that the CaFe$_4$Sb$_{12}$ vibrational dynamics should include an anharmonic component.

We thus introduced our pressured dependent experiments. The $V \times P$ curves were determined and fitted to the Birch-Bridgman model to extract the bulk modulus $B_0$ and then the compressibility $\beta$. The obtained $B_0$ values are similar to previous experiments and it is in the range of previously calculated results of the $RFe_4Sb_{12}$ skutterudites. The obtained parameters, while suggestive of the stiffness of the Fe$_3Sb_{12}$ cage, is not independent of the choice of $R$. An attempt was made to associate the trend in $\beta$ as a function of $R$ to the geometrical parameter $f_E$, but the behavior is too complex to be captured by a single geometrical parameter. The $R$ dependence of the elastic properties is likely dependent on the bonding specific properties of each $R$.

ACKNOWLEDGMENTS

As observed, there is no systematic distinction between the $R^{+1}$ and $R^{+2}$ filled materials. We thus conclude that the larger structural stability of alkaline earth filled materials is likely due to the bonding stabilization of the extra charge offered by the $R^{2+}$ cations. This picture agrees with the current understanding of the chemical bonding in skutterudites [2, 3]. This effect, however, is difficult to quantify. For instance, no sizable shift is observed in the absorption edges of either the Fe or Sb atoms [31].
