Density Matrix Renormalization Group (DMRG) algorithm has been extremely successful for computing the ground states of one-dimensional quantum many-body systems. For problems concerned with mixed quantum states, however, it is less successful in that either such an algorithm does not exist yet or that it may return unphysical solutions. Here we propose a positive matrix product ansatz for mixed quantum states which preserves positivity by construction. More importantly, it allows to build a DMRG algorithm which, the same as the standard DMRG for ground states, iteratively reduces the global optimization problem to local ones of the same type, with the energy converging monotonically in principle. This algorithm is applied for computing both the equilibrium states and the non-equilibrium steady states, and its advantages are numerically demonstrated.

For many problems of interest, the underlying quantum states are not pure states. In this work we will primarily consider two such instances: 1) the finite temperature equilibrium states (ESs) and 2) the non-equilibrium steady states (NESSs) of Lindblad equations. Similar to the MPS representation for pure states, mixed quantum states can generally be written as MPDs. The MPO representation for a quantum state is efficient if only a small bond dimension is required for the MPO (the number of parameters for a generic matrix product ansatz usually grows quadratically with the bond dimension, and linearly with the system size). However a generic MPO does not guarantee positivity, which means that iterative algorithms built on variational MPO ansatz could easily result in unphysical solutions. The Matrix Product Density Operator (MPDO) representation for the many-body Hamiltonian [8–10]. DMRG-like algorithms have also been applied to solve machine learning problems [11–14].

However, even if certain many-body mixed states can be efficiently represented as MPDOs [16], there lacks a DMRG algorithm which directly works on a variational MPDO ansatz. For the NESS which is an eigenstate of a Lindblad operator $L$ with eigenvalue $0$, two approaches based on variational MPO ansatz have been used, which either substitute $L$ [17] or $L^+L$ [18] into standard DMRG. Since $L$ is not Hermitian in general, convergence (even to local minima) is not guaranteed in the first approach. In the second approach the nature of the original problem is completely ignored, the usage of $L^+L$ will also introduce longer range interactions and square the bond dimension in the MPO representation. Moreover for problems with vanishing spectrum gaps for $L$ [19], the convergence could be extremely slow.

The difficulty for building a DMRG algorithm directly on a variational MPDO ansatz is deeply related to the fact that the information about the mixedness (entropy) of a quantum state is global, for example one can not tell whether an unknown quantum state is mixed or not by only performing local measurements on it. MPDO breaks the global mixed state into product of local mixed states. However, the ES, as an example, is formulated as a minimization problem that directly relies on the entropy. The local problem, if it can be formulated from a variational MPDO (or generally MPO) ansatz, is likely to lose the physical content that it originates from a globally mixed state and the nature of the local problem could be completely different from the global one.

In this work we propose a variational positive matrix product ansatz (PMPA) for mixed states which overcomes the difficulty of MPDO. It can be seen as a very special form of MPDO with an orthogonal center at certain site $c$, similar to the mixed canonical representation of MPS. The orthogonal center is itself a proper mixed state on site $c$ and an effective environment. Most importantly, the orthogonal center is related to the global (mixed) quantum state by an isomorphism, thus it fully encodes the mixedness of the latter. We show that the standard DMRG algorithm can be straightforwardly generalized to work on the variational PMPA. The generalized DMRG algorithm is then applied for computing ESs and NESSs, and its advantages are numerically demonstrated against current state of the art algorithms.

**Variational positive matrix product ansatz.** The MPO representation of an $L$-site mixed quantum state is written as

$$
\rho_{s_1 \cdots s_L} = \sum_{b_1, \cdots b_{L-1}} W_{b_1, s_1}^* W_{b_1, b_2, s_2} \cdots W_{b_{L-1}, s_L}^*.
$$

with $s_l$ the physical index of size $d$, $b_l$ the auxiliary index and

with $\rho_{s_1 \cdots s_L}$ being the physical index of size $d$, $b_l$ the auxiliary index and...
FIG. 1. (a) Positive matrix product ansatz for mixed quantum states. (b) Procedures to move the current orthogonal center to a nearby site: clockwise for the left-to-right sweep and anti-clockwise for the right-to-left sweep. (c) Preparation of a generic mixed state into the positive matrix product form.

Now defining the isometry $V_{\tau_c}^{a_1,\ldots,a_L} = \delta_{\tau_c,a_c} \otimes \sum_{a_1,\ldots,a_{L-1}} A_{a_1}^{a_2} \cdots A_{a_{L-2}}^{a_{L-1}} \otimes \sum_{a_{c+1},\ldots,a_{L-1}} B_{a_c,a_{c+1}}^{a_{c+2}} \cdots B_{a_{L-1}}^{a_L}$, which simply reshuffles the indices of $W_c$, then the PMPA for $\rho$ can be written as

$$\rho = V \tilde{\rho} V^\dagger.$$  (4)

It follows that $\tilde{\rho}$ has exactly the same spectrum property as $\rho$, therefore the mixedness of $\rho$ is fully encoded in $\tilde{\rho}$ and $R$ is simply the Schmidt rank of $\rho$. As such PMPA is only efficient for mixed states which are fairly pure [20], that is, they can be written as the sum of a few pure states which can be efficiently represented as MPSs.

Given a (positive semidefinite) optimization problem on $\rho$, denoted as $f(\rho)$, a local problem $\tilde{f}(\tilde{\rho})$ naturally follows as $\tilde{f}(\tilde{\rho}) = f(V \tilde{\rho} V^\dagger)$, by keeping the isometry $T$ as constant. Importantly, due to the relation in Eq.(4), $\tilde{f}$ is often a same (positive semidefinite) optimization problem as $f$ as in the standard DMRG, which will be explicitly demonstrated in the applications. After solving the local problem, one needs to move the orthogonal center as required by the DMRG iteration (sweep) [8], for which one can first contract the current center $M_c$ with the nearby site tensor $A_{c-1}$ or $B_{c+1}$ depending on the direction of the sweep, and then split the resulting two-site tensor (using SVD) with $\tau_a$ attached to the next center. This procedure is shown in Fig. 1(b). If the error induced by SVD is negligible, the new center will still be a proper mixed state and can be used as an initial guess for solving the next local problem. Therefore the local optimization can only improve the ‘energy’ (value of $\tilde{f}(\tilde{\rho})$ since its solution should not be worse than the initial guess. With a well-defined local optimization problem and the center move technique, the standard DMRG algorithm for pure states can be straightforwardly generalized to mixed states. We will refer to this generalized DMRG algorithm as positive DMRG (p-DMRG) since it directly works on mixed states and preserves positivity. The initial PMPA for p-DMRG can be simply chosen as a randomly generated pure state in mixed canonical form (which can be seen as a PMPA with $R = 1$). More details of the p-DMRG algorithm can be found in Supplementary.

A generic mixed state $\rho$ can be systematically prepared into a PMPA with orthogonal center $c$, using the procedures shown in Fig. 1(c). That is, one first performs an eigenvalue decomposition on $\rho$ and get $\rho = U \Lambda U^\dagger$, then one performs a sequence of SVDs on $U$ to bring it into the desired matrix product form. In the next we explicitly demonstrate the p-DMRG algorithm for computing ESs and NESSs.

**Positive DMRG algorithm for equilibrium states.** The ES of temperature $T$ for a Hamiltonian $H$ is the minimum of the free energy

$$\min_{\rho} \left( \text{tr}(H\rho) - TS(\rho) \right)$$  (5)
With the local effective operator $\tilde{L}$ satisfying

$$\tilde{L}(\tilde{\rho}) = -i[\tilde{H}, \tilde{\rho}] + \sum_k (2\tilde{C}_k \tilde{\rho} \tilde{C}_k^\dagger - \{V^\dagger \tilde{C}_k^\dagger \tilde{C}_k V, \tilde{\rho}\}).$$

(11)

Therefore the cost of solving each local problem is similar to that of standard DMRG, and in the infinite temperature limit, $M_c$ becomes the ground state of $\tilde{H}$.

To this end we note that in practice there are two effects that can hinder the monotonic convergence of the p-DMRG algorithm. First, there is a boundary effect that is absent in standard DMRG. Assuming $c = 1$, then the size of $\tilde{H}_1$ is at most $d^2 \times d^2$ since $\dim(a_1) \leq d$. If $d^2 < R$, $\tilde{\rho}_1$ does not have enough degrees of freedom to accommodate $R$ nonzero Schmidt numbers. As a result optimization at the boundaries could be less accurate and the energy may fluctuate. This effect can be avoided by grouping sites at the boundaries into larger ones [22]. Here we simply put the final orthogonal center at the middle site to avoid this effect. Second, the SVD performed during the center move could also be a source of inaccuracy, similar to the SVD performed after a local optimization in the two-site DMRG algorithm. This effect could be leveraged by using a larger $D$.

To demonstrate the powerfulness of p-DMRG, we apply it to compute the low temperature ES for the transverse field Ising chain and compare its performance with the imaginary time-evolving MPS (t-MPS) algorithm [15, 23–25]. The Hamiltonian is

$$H_{\text{Ising}} = \sum_{i=1}^L \sigma_i^x + \sum_{i=1}^{L-1} \sigma_i^x \sigma_{i+1}^x,$$

with $\sigma^x$, $\sigma^y$, $\sigma^z$ the Pauli operators. The results are shown in Fig. 2, where we have computed the correlation $C_l = -(\text{tr}(\sigma_{i}^x \sigma_{i+1}^x \rho_T) + \text{H.c.})$ at different sites (the correlation is chosen instead of an on-site observable such as $\text{tr}(\sigma_i^z \rho_T)$ since it is in general much harder to converge). From Fig. 2(a,c) we can see that the p-DMRG results match very well with t-MPS results (difference of the order $10^{-3}$ at $L = 200$). Meanwhile, p-DMRG has a more than 3 and 21 times speed up at $\beta = 10$ and $\beta = 20$ respectively, compared to t-MPS.

Positive DMRG algorithm for non-equilibrium steady states. Computing the NESS $\rho_{\text{st}}$ of a Lindblad equation $\mathcal{L}(\rho) = -i[H, \rho] + \sum_k D_k(\rho)$ [26, 27], with $D_k(\rho) = 2C_k \rho C_k^\dagger - \{C_k^\dagger C_k, \rho\}$, is equivalent to the following minimization problem

$$\min_{\rho} \left| \frac{\text{tr}(\rho^\dagger \mathcal{L}\rho)}{\text{tr}(\rho^\dagger \rho)} \right|. \quad (9)$$

Substituting Eq.(4) into Eq.(9), we get the local problem

$$\min_{\tilde{\rho}} \left| \frac{\text{tr}(\tilde{\rho}^\dagger \tilde{\mathcal{L}}\tilde{\rho})}{\text{tr}(\tilde{\rho}^\dagger \tilde{\rho})} \right|, \quad (10)$$

with the local effective operator $\tilde{\mathcal{L}}$ satisfying

$$\tilde{\mathcal{L}}(\tilde{\rho}) = -i[\tilde{H}, \tilde{\rho}] + \sum_k (2\tilde{C}_k \tilde{\rho} \tilde{C}_k^\dagger - \{V^\dagger C_k^\dagger C_k V, \tilde{\rho}\}).$$

(11)
Here $\tilde{H}$ is the same to that for ESs, and $\tilde{C}_k = V^\dagger C_k V$. The second term in Eq. (11) is not in the standard Lindblad form (a standard Lindblad operator is the generator of some completely positive and trace preserving quantum map $\mathcal{E}$ [28, 29]). Nevertheless, it has been shown that an operator in the form of Eq. (11) is a generator of a completely positive quantum map [30–32]. The complexity of solving Eq. (10) generally scales as $O(d^2 D^6)$ [33], compared to the $O(dD^3)$ scaling in standard DMRG.

We demonstrate the p-DMRG algorithm in this case for a boundary driven XXZ chain [34, 35], with the Hamiltonian $H_{L,XXZ} = \sum_{l=1}^{L-1} (\hat{\sigma}_l^x \hat{\sigma}_{l+1}^x + \hat{\sigma}_l^y \hat{\sigma}_{l+1}^y + \Delta \hat{\sigma}_l^z \hat{\sigma}_{l+1}^z)$, and the boundary dissipations $D_1(\rho) = 2\sigma_1^x \rho \sigma_1^x - \{\sigma_1^x, \rho\}$ and $D_L(\rho) = 2\sigma_L^z \rho \sigma_L^z - \{\sigma_L^z, \rho\}$. Boundary driven open quantum systems provide important setups to study nonequilibrium transport problems [36, 37]. In case the bulk system is integrable, the spectrum gap of $L$ typically scales as $1/L^3 [19, 38]$, which makes it extremely difficult to compute the steady state even for small systems. Utilizing a special global U(1) symmetry of such systems [39], exact diagonalization (ED) up to 14 spins has been performed [40]. Here we note that DMRG based on $L$ almost cannot never converge in this case (in comparison for bulk dissipative systems it can often quickly converge for even hundreds of spins [41]), while DMRG based on $L^1 L$ converges extremely slowly and can easily be trapped [42].

In our numerical simulations we compute the steady state current defined as $J_l = i \text{tr}(\sigma_l^z \rho_{st}^\dagger \rho_{st}) - \text{H.c.}$ with ED, DMRG and p-DMRG (since $J_l$ is $l$-independent if $\rho_{st}$ is exact), where for DMRG $L^1 L$ is used. We focus on the strongly interacting scenario with $\Delta = 1.5$, where $\mathcal{J}$ decreases exponentially with $L$ (insulating) [35]. The results are shown in Fig. 3. From Fig. 3(a) we can see that p-DMRG results with $D = 20$, $R = 50$ and 2 sweeps agree fairly well with exact results up to $L = 12$ (still reasonable for $L = 15$), while DMRG results with $D = 15$ and 10000 sweeps fails to converge as early as $L = 9$. The major issue for DMRG is that the observables are very off even if the final energy is of the same order as p-DMRG (although the energies in these two cases have completely different meanings), and this situation does not seem to improve for larger $D$s or more sweeps. More details of the simulations done here can be found in Supplementary.

**Discussions.** We have proposed a positive matrix product ansatz (PMPA) for mixed quantum states, and demonstrated a generalized DMRG algorithm (p-DMRG) which directly works on the variational PMPA and preserves positivity. The advantages of p-DMRG for both equilibrium states and non-equlibrium steady states are numerically demonstrated with comparisons to state of the art algorithms. The p-DMRG algorithm is likely to be useful for other one-dimensional optimization problems whose solutions are mixed states.

To this end we stress again that p-DMRG is only efficient for quantum states that are fairly pure. Therefore it is complementary, instead of a substitution, to existing algorithms. As a trivial example that p-DMRG will not work, PMPA fails to (efficiently) represent the maximally mixed state (for which it requires $R = d^L$), which however can be efficiently represented as an MPO with bond dimension 1. Therefore if the solution is close to the maximally mixed state, t-MPS algorithm which directly starts from the maximally mixed state is the method of choice [43]. Nevertheless, PMPA can efficiently represent many physically important quantum states, such as the low-temperature equilibrium states of one-dimensional systems.

PMPA could also be useful in other settings such as quantum information, as a convenient ansatz that allows to efficiently compute many important quantities. For example, given two quantum states $\rho$ and $\sigma$ that can be efficiently represented as PMPAs, the quantum fidelity, defined as $F(\rho, \sigma) = tr(\sqrt{\sqrt{\rho} \sigma \sqrt{\rho}})$, can be efficiently computed, which is not possible even if both $\rho$ and $\sigma$ can be efficiently written as MPOs or MPDOs. Interestingly, an unknown quantum state, if assumed to be efficiently representable as PMPA, allows efficient quantum tomography [44, 45]. Generalization of PMPA to higher dimensions could be interesting but also more challenging.

The code for the p-DMRG algorithm together with the examples used in this work can be found at [46]. C. G. acknowledges support from National Natural Science Foundation of China under Grant No. 11805279.

Supplemental Material: Density Matrix Renormalization Group Algorithm For Mixed Quantum States
(Dated: March 31, 2022)

I. GENERAL PROCEDURES FOR THE POSITIVE DMRG ALGORITHM

For a global (positive semidefinite) optimization problem on \( \rho \), denoted as \( f(\rho) \), the positive DMRG (p-DMRG) algorithm used in this work exactly follows the procedures shown in Algorithm 1. Note that the main procedures of the p-DMRG algorithm is fully in parallel with the standard DMRG, except that in the end we have used an additional half sweep from the left boundary to the middle site to get rid of the boundary effect as explained in the main text. The p-DMRG algorithm optimizes a single site for each step, similar to the single-site DMRG algorithm. While after the single site optimization, p-DMRG generates a two-site tensor, and then perform SVD on it, which is similar to the case of two-site DMRG algorithm. Due to these features, p-DMRG can also be directly used in presence of global quantum symmetries [1–3], since even though the quantum numbers remain the same during the local optimization, they could be changed during the center move as the two-site DMRG.

Algorithm 1: Positive DMRG algorithm to find \( \rho \) in positive matrix product form to minimize \( f(\rho) \).

**Result:** Optimal \( \rho \) in positive matrix product form which minimizes \( f(\rho) \).

Initialize a random MPS with bond dimension \( D \), and prepare it into right-canonical form

while \( n < \text{maxiter} \) do

for \( c = 1 : L - 1 \) do

Construct the local problem \( \tilde{f}(\tilde{\rho}_c) = f(V \tilde{\rho}_c V^\dagger) \) and find the optimal solutions \( \tilde{\rho}_c \) and \( M_c \) (keeping only the \( R \) largest Schmidt numbers of \( \tilde{\rho}_c \))

Compute the two-site tensor \( \Psi^{s_e_\tau,s_e_{+1}}_{a_e-1,a_e+1} = \sum_{a_e} M^{s_e_\tau}_{a_e-1,a_e} B^{s_e_{+1}}_{a_e-1,a_e+1} \)

Perform SVD on \( \Psi \) (possibly with truncation): \( \text{SVD}(\Psi^{s_e_\tau,s_e_{+1}}_{a_e-1,a_e+1}) = \sum_{a_e} U^{s_e_\tau}_{a_e-1,a_e} \lambda_{a_e} V^{s_e_{+1}}_{a_e-1,a_e+1} \)

Update \( A^{s_e_\tau}_{a_e-1,a_e} \leftarrow U^{s_e_\tau}_{a_e-1,a_e} \)

Choose \( M^{s_e_\tau}_{a_e,a_e+1} = \sum_{a_e} \lambda_{a_e} V^{s_e_{+1}}_{a_e,a_e+1} \) as the new orthogonal center on site \( c + 1 \), which may be used as the initial guess for solving \( \tilde{f}(\tilde{\rho}_{c+1}) \)

end

for \( c = L : 2 \) do

Construct the local problem \( \tilde{f}(\tilde{\rho}_c) = f(V \tilde{\rho}_c V^\dagger) \) and find the optimal solutions \( \tilde{\rho}_c \) and \( M_c \) (keeping only the \( R \) largest Schmidt numbers of \( \tilde{\rho}_c \))

Compute the two-site tensor \( \Psi^{s_e_\tau,s_e_{-1}}_{a_e-2,a_e-1} = \sum_{a_e} A^{s_e_\tau}_{a_e-2,a_e-1} M^{s_e_\tau}_{a_e-1,a_e} \)

Perform SVD on \( \Psi \) (possibly with truncation): \( \text{SVD}(\Psi^{s_e_\tau,s_e_{-1}}_{a_e-2,a_e-1}) = \sum_{a_e} U^{s_e_\tau}_{a_e-2,a_e-1} \lambda_{a_e-1} V^{s_e_{-1}}_{a_e-2,a_e-1} \)

Update \( A^{s_e_\tau}_{a_e-1,a_e} \leftarrow U^{s_e_\tau}_{a_e-1,a_e} \)

Choose \( M^{s_e_\tau}_{a_e,a_e-1} = \sum_{a_e} U^{s_e_\tau}_{a_e-1,a_e-1} \lambda_{a_e-1} \) as the new orthogonal center on site \( c - 1 \), which may be used as the initial guess for solving \( \tilde{f}(\tilde{\rho}_{c-1}) \)

end

for \( c = 1 : L/2 - 1 \) do

Construct the local problem \( \tilde{f}(\tilde{\rho}_c) = f(V \tilde{\rho}_c V^\dagger) \) and find the optimal solutions \( \tilde{\rho}_c \) and \( M_c \) (keeping only the \( R \) largest Schmidt numbers of \( \tilde{\rho}_c \))

Compute the two-site tensor \( \Psi^{s_e_\tau,s_e_{+1}}_{a_e-1,a_e+1} = \sum_{a_e} M^{s_e_\tau}_{a_e-1,a_e} B^{s_e_{+1}}_{a_e-1,a_e+1} \)

Perform SVD on \( \Psi \) (possibly with truncation): \( \text{SVD}(\Psi^{s_e_\tau,s_e_{+1}}_{a_e-1,a_e+1}) = \sum_{a_e} U^{s_e_\tau}_{a_e-1,a_e} \lambda_{a_e} V^{s_e_{+1}}_{a_e-1,a_e+1} \)

Update \( A^{s_e_\tau}_{a_e-1,a_e} \leftarrow U^{s_e_\tau}_{a_e-1,a_e} \)

Choose \( M^{s_e_\tau}_{a_e,a_e+1} = \sum_{a_e} \lambda_{a_e} V^{s_e_{+1}}_{a_e,a_e+1} \) as the new orthogonal center on site \( c + 1 \), which may be used as the initial guess for solving \( \tilde{f}(\tilde{\rho}_{c+1}) \)

end

Construct the local problem \( \tilde{f}(\tilde{\rho}_{L/2}) = f(V \tilde{\rho}_{L/2} V^\dagger) \) and find the optimal solution \( \tilde{\rho}_{L/2} \) and \( M_{L/2} \)

Return the matrix product formed by tensors \( A_l \) with \( 1 \leq l < L/2, M_{L/2} \) and \( B_l \) with \( L/2 < l \leq L \)
II. EFFICIENT CONSTRUCTION OF THE LOCAL PROBLEM FOR COMPUTING THE EQUILIBRIUM STATES

As a standard practice in DMRG algorithm, the local problem \( \tilde{f}(\tilde{\rho}) \) can be efficiently constructed by reusing a large portion of the previous calculations [4]. In case of equilibrium states, it reduces to the construction of \( \tilde{H} \) as shown in the main text, which is exactly the same as the standard DMRG. We will sketch the procedures to build \( \tilde{H} \) here for completeness.

Assuming that the \( L \)-site many-body Hamiltonian \( H \) can be written as an MPO

\[
H_{s_1,s_2,...,s_L} = \sum_{b_1,b_2,...,b_{L-1}} O_{b_1}^{s_1,s_2} O_{b_1,b_2}^{s_2,s_3} \cdots O_{b_{L-1}}^{s_L,s_1},
\]

with \( s_l \) the physical index and \( b_l \) the auxiliary index. The largest size of the auxiliary index is referred to as the bond dimension of the MPO, denoted as \( D_w = \max_l (\dim(b_l)) \). Then \( \tilde{H} \) at the orthogonal center \( c \) can be computed as

\[
\tilde{H}_{s_c,a_{c-1},a_c} = \sum_{b_{c-1},b_c} L_{b_{c-1},a_{c-1}}^{a_c} O_{b_{c-1},b_c}^{s_c,a_{c-1},a_c} R_{b_c}^{a_c},
\]

where \( L \) and \( R \) are rank-3 tensors which represent the effective environments left and right to the orthogonal center \( c \). They can be computed iteratively

\[
L_{b_{c-1},a_{c-1}}^{a_c} = \sum_{b_{c-1},a_{c-1},a_{c-1},s_{c-1}} L_{b_{c-1},a_{c-1}}^{a_c} O_{b_{c-1},b_c}^{s_c,a_{c-1},a_c} (A_{a_{c-1}}^{s_{c-1}})^*;
\]

\[
R_{b_{c-1}}^{a_{c-1}} = \sum_{b_{c-1},a_{c-1},s_{c-1}} R_{b_{c-1}}^{a_{c-1}} O_{b_{c-1},b_c}^{s_c,a_{c-1},a_c} (B_{a_{c-1}}^{s_{c-1}})^*;
\]

with the starting tensors

\[
L_{b_1,a_1}^{a_2} = \sum_{s_1,s_1'} O_{b_1}^{s_1,s_1'} A_{a_1}^{s_1'},
\]

\[
R_{b_{L-1}}^{a_{L-1}} = \sum_{s_L,s_L'} O_{b_{L-1}}^{s_L,s_L'} B_{a_{L-1}}^{s_L},
\]

Here we note that computing \( L_{c-1} \) and \( R_c \) for center \( c \) requires to compute Eqs.(3, 4) throughout the chain. However, computations can be saved if we first compute all the \( H \) tensors before hand and store them in memory, then during the left to right sweep at site \( c \), one only have to evaluate Eq.(3) for \( l = c \) to update the storage. This can be done similarly during the right to left sweep. In this way one reduces the total number of evaluations of Eqs.(3, 4) from \( L^2 \) to \( 2L \). Additionally, instead of building \( \tilde{H} \) explicitly as in Eq.(2), one can simply implement its operation on an input rank-3 tensor \( X \) with an output rank-3 tensor \( Y \), that is \( Y = \tilde{H}(X) \), which is explicitly

\[
Y_{s_c,a_{c-1},a_c}^{s_c} = \sum_{b_{c-1},b_c,a_{c-1},a_c} L_{b_{c-1},a_{c-1}}^{a_c} O_{b_{c-1},b_c}^{s_c,a_{c-1},a_c} R_{b_c}^{a_c} X_{s_c,a_{c-1},a_c},
\]

The complexity of evaluating Eq.(7) is \( O(dD_wD^3) \). An iterative eigensolver is able to compute the lowest eigenpairs once the operation in Eq.(7) is given.

III. BUILDING THE LOCAL PROBLEM FOR COMPUTE THE NON-EQUILIBRIUM STEADY STATE OF A LINDBLAD OPERATOR

Assuming that the Lindblad operator \( \mathcal{L} \) can be written as

\[
\mathcal{L}(\rho) = -i[H,\rho] + \sum_k \left( 2C_k \rho C_k^\dagger - \{C_k^\dagger C_k, \rho \} \right),
\]

then using \( \rho = V \tilde{\rho} V^\dagger \) we have

\[
\text{tr}(\rho [H,\rho]) = \text{tr}(V \tilde{\rho} V^\dagger H V \tilde{\rho} V^\dagger) - \text{tr}(V \tilde{\rho} V^\dagger H \tilde{\rho}) - \text{tr}(\tilde{\rho} V^\dagger H \rho) = \text{tr}(\tilde{\rho} V^\dagger H V \tilde{\rho}) - \text{tr}(V \tilde{\rho} V^\dagger H \rho) = \text{tr}(\tilde{\rho} [H,\tilde{\rho}]);
\]

\[
\text{tr}(\rho C_k \rho C_k^\dagger) = \text{tr}(V \tilde{\rho} V^\dagger C_k V \tilde{\rho} V^\dagger C_k^\dagger) = \text{tr}(\tilde{\rho} C_k \tilde{\rho} C_k^\dagger);
\]

\[
\text{tr}(C_k^\dagger C_k \rho) = \text{tr}(C_k^\dagger C_k V \tilde{\rho} V^\dagger) = \text{tr}(V \tilde{\rho} V^\dagger C_k C_k^\dagger).
\]
Combining all these terms together, we get the local problem for computing the non-equilibrium steady state of $\mathcal{L}$ as

$$\hat{\mathcal{L}}(\hat{\rho}) = -i[\hat{H}, \hat{\rho}] + \sum_k \left( \hat{C}_k \hat{\rho} \hat{C}_k^\dagger - \{V^l C_k^l C_k V', \hat{\rho} \} \right).$$  \hspace{1cm} (12)

IV. EFFICIENT CONSTRUCTION OF THE LOCAL PROBLEM FOR COMPUTING THE NON-EQUILIBRIUM STEADY STATES

Now we assume that the Lindblad operator $\mathcal{L}$ can be written as an MPO

$$\mathcal{L}^s_{si_1, r_1; s'i_2, r_2; \ldots; s'i_L, r_L} = \sum_{b_1} O_{b_1}^{s_1, r_1; s_1', r_1'} O_{b_2}^{s_2, r_2; s_2', r_2'} \ldots O_{b_L}^{s_L, r_L; s_L', r_L'}.$$  \hspace{1cm} (13)

In the following we will use $x$, $y$ to denote the auxiliary indices of the positive matrix product ansatz. Then $\hat{\mathcal{L}}$ can be computed as

$$\tilde{\mathcal{L}}^x_{x_{e-1}, y_{e-1}; x'_c, y'_c} = \sum_{b_{e-1}, b_c} \tilde{L}^x_{b_{e-1}, x_{e-1}, y_{e-1}} O_{b_{e-1}, b_c}^{x_{e-1}, y_{e-1}} \tilde{R}^x_{b_c, x_{c-1}, y_c}.$$  \hspace{1cm} (14)

Here we have used the same symbol $L$ and $R$, but they are not directly related to Eq.(2). Similarly, the $L$ and $R$ tensors in this case can be iteratively computed as

$$L^x_{b_1, x_1, y_1} = \sum_{s_1, r_1, s_1', r_1'} O_{b_1}^{s_1, r_1; s_1', r_1'} A_{s_1}^{x_1, y_1} A_{s_1'}^{x_1, y_1'}.$$  \hspace{1cm} (15)

$$R^x_{b_L-1, y_{L-1}} = \sum_{s_L, r_L, s_L', r_L'} O_{b_L-1}^{s_L, r_L; s_L', r_L'} B_{x_{L-1}, y_{L-1}}^{x_{L-1}, y_{L-1}} B_{x_{L-1}, y_{L-1}}^{x_{L-1}, y_{L-1}'}.$$  \hspace{1cm} (16)

with the starting tensors

$$L^x_{b_1, x_1, y_1} = \sum_{s_1, r_1, s_1', r_1'} O_{b_1}^{s_1, r_1; s_1', r_1'} A_{s_1}^{x_1, y_1} A_{s_1'}^{x_1, y_1'}.$$  \hspace{1cm} (17)

$$R^x_{b_L-1, y_{L-1}} = \sum_{s_L, r_L, s_L', r_L'} O_{b_L-1}^{s_L, r_L; s_L', r_L'} B_{x_{L-1}, y_{L-1}}^{x_{L-1}, y_{L-1}} B_{x_{L-1}, y_{L-1}}^{x_{L-1}, y_{L-1}'}.$$  \hspace{1cm} (18)

Similar to the case of equilibrium states, one can first compute all the $R$ tensors and then update them one by one during each local optimization to reduce the total number of evaluations of Eqs.(15, 16). For the local optimization, one should in general also treat $\hat{\mathcal{L}}$ as a linear operation on an input rank-$6$ tensor $X$ with an output rank-$6$ tensor $Y$ ($Y = \hat{\mathcal{L}}(X)$), which is explicitly

$$Y_{x_{c-1}, y_{c-1}, x'_c, y'_c} = \sum_{b_{e-1}, b_c} \tilde{R}^x_{b_c, x_{c-1}, y_c} O_{b_{e-1}, b_c}^{x_{e-1}, y_{e-1}} \tilde{L}^x_{b_{e-1}, x_{e-1}, y_{e-1}}.$$  \hspace{1cm} (19)

V. MORE DETAILS OF THE NUMERICAL SIMULATIONS OF THE BOUNDARY DRIVEN XXZ CHAIN

The boundary driven XXZ chain, due to the rapid vanishing of the spectrum gap for $\mathcal{L}$ (typically $O(1/L^3)$), is extremely difficult to solve numerically. Nevertheless, this case can be analytically solved [5]. Therefore it is an ideal test ground for different numerical methods.

The additional details of our simulations for the boundary driven XXZ chain are shown in Fig. 1. In Fig. 1(a), we show the convergence of the DMRG and p-DMRG algorithm when increasing $D$ (and also increasing $R$ for p-DMRG). We can see that for both algorithms the relatively error $e$ compared to the exact values from ED does not improve significantly with $D$. For DMRG there is no clear improvement at $D = 25$ and $\mathcal{J}$ does not converge as well starting from $L = 8$ for $D = 25$, same to the case of $D = 15$. For p-DMRG we see tiny improvements starting from $L = 8$ (except for the case with $L = 11$ which may be due to a bad random initial state). In p-DMRG there is an additional source of error compared to the single-site DMRG, namely the SVD truncation used during center move (in single-site DMRG on truncation is done in the SVD used after local optimization). Since we are using a relatively small $D$ in both algorithms, we observe that the additional SVD truncation could easily induce an error of the order $10^{-5}$, which is the same order of $\mathcal{J}$ for large $L$. Thus a high-precision current can not be expected from
p-DMRG if one does not increase $D$ significantly, which would be extremely expensive. Nevertheless, we can see that for this problem p-DMRG can already reach a much higher precision compared to DMRG in almost all the cases we have considered. For p-DMRG we can still obtain relatively descent current at $L = 15$. In Fig. 1(b), we show the runtime scaling for DMRG and p-DMRG at different $D$s. First we see the exponential scaling of ED as expected. For p-DMRG the advantage compared to ED only appears from $L = 12$ (but the scaling of DMRG or p-DMRG is of course more favorable if the issue of convergence is not considered).

To better visualize the convergence for DMRG and p-DMRG, we further show the final energy $E_f$ as a function of $L$ in Fig. 1(c) and the energy $E$ as a function of the local minimization step for the particular case of $L = 12$ in Fig. 1(d). From Fig. 1(c) we can see that for all the 2 cases we have studied with p-DMRG, the final energy can only reach a value of the order $10^{-5}$, which is the reason that we could not expect to get a precise $\mathcal{J}$ for p-DMRG since one expects $\mathcal{J}$ to be the order $10^{-5}$ or less after $L = 12$. For DMRG $\mathcal{J}$ is completely wrong even for $L = 9,10$ where the final energies are of the order $10^{-7}$ (and for $L = 15$ where the final energy is less than $10^{-8}$). The most important reason for this discrepancy between the energy and $\mathcal{J}$ could be that the resulting state is unphysical (which can be directly seen by checking with a Hermitian observable such as $\sigma_z^l$, the imaginary part of which will be significantly different from 0). Another reason may be that the energy of $L^\dagger L$ loses the physical meaning of the spectrum of the original Lindblad operator $L$. From Fig. 1(d) we can see the extremely slow convergence of DMRG. Even the worse, although the energy could be significantly slower when we increase $D$ from 15 to 25 in DMRG, the predicted $\mathcal{J}$ is still completely wrong (even for the sign). For p-DMRG the results converge fairly well with only 2 sweeps, although monotonic convergence is lost due to the effects explained in the main text. Larger $D$ and $R$ are required to reach lower energies for p-DMRG. Nevertheless, $\mathcal{J}$ at $L = 15$ predicted with p-DMRG is still reasonable (although the error is not negligible).
In the end we note that due to the faster scaling of the complexity of p-DMRG compared to DMRG, the runtime for DMRG is not larger than p-DMRG even if the number of sweeps used for DMRG is much larger, which can be seen from Fig. 1(b). Actually the calculation becomes demanding when $L \geq 10$ for all the algorithms considered. The current issue with p-DMRG is that the local optimization is too expensive ($O(d^2 D^6)$), partially due to that the low-Schmidt-rank nature of $\tilde{\rho}$ is not made use of when solving the local problem, which we leave to future investigations.
