ABSTRACT

In this paper, we explore the use of GAN-based few-shot data augmentation as a method to improve few-shot classification performance. We perform an exploration into how a GAN can be fine-tuned for such a task (one of which is in a class-incremental manner), as well as a rigorous empirical investigation into how well these models can perform to improve few-shot classification. We identify issues related to the difficulty of training such generative models under a purely supervised regime with very few examples, as well as issues regarding the evaluation protocols of existing works. We also find that in this regime, classification accuracy is highly sensitive to how the classes of the dataset are randomly split. Therefore, we propose a semi-supervised fine-tuning approach as a more pragmatic way forward to address these problems.

1 INTRODUCTION

In the past decade, deep learning has demonstrated an immense level of success under many tasks and data modalities (Krizhevsky et al., 2012; LeCun et al., 2015; He et al., 2016). However, the issue of deep neural networks being highly data inefficient has been well established (Krizhevsky et al., 2012; Srivastava et al., 2014; Zhang et al., 2017; Tan et al., 2018), and this can be well accentuated by the fact that for some domains, obtaining a sufficient amount of labelled data can be laborious and expensive. Because this issue limits the real-world applicability of deep neural networks, an active area of research is in figuring out how to make these models transfer or learn better on underrepresented datasets. One of the very subfields that addresses this, few-shot learning, is centered around training models that are able to adapt to novel tasks which contain extremely few labelled examples.

Few-shot learning as a field is rather broad (Wang et al., 2020), and many techniques can be seen as incorporating prior knowledge into either the data, the model/architecture, or the algorithm in order to make the learning process more sample efficient. For example, this may be in the form of multitask learning (Caruana, 1997; Zhang & Yang, 2017) where the learning of a few-shot task can be augmented by learning other relevant tasks with more data, or in embedding learning (Bertinetto et al., 2016; Sung et al., 2018; Vinyals et al., 2016) where a low-dimensional metric space is learned to be able to easily facilitate comparisons between unseen classes. In terms of algorithmic few-shot learning, meta-learning (Finn et al., 2017; Ravi & Larochelle, 2016), i.e. learning how to learn, can be used to learn more sample efficient optimisers.

In this paper we specifically focus on the data aspect of few-shot learning, which at its core leverages some form of data augmentation to augment a small set of examples into a much larger set, one that is more amenable to the size of deep neural networks. In particular, we wish to explore this data augmentation in the form of generative models, where the goal is learning how to generate samples that are indistinguishable from ones from the few-shot task of interest. Specifically, in this paper we explore data augmentation-based few-shot learning with one of the more widely used generative models in the literature, the generative adversarial network (GAN) (Goodfellow et al., 2014), and detail our findings and challenges in using such a class of models. The very nature of these difficulties also means that many negative findings will be presented in this work. Concretely, our contributions are as follows:

\begin{itemize}
  \item We explore the entire few-shot data augmentation pipeline, where the goal is to pre-train a GAN on some set of source classes, fine-tune it on very few examples of target classes, and have it be able to generate new images from those classes to maximise generalisation performance of a pre-trained classifier that is also fine-tuned to predict those target classes. Unlike previous works (Antoniou et al., 2017; Hong et al., 2020a;b), we specifically fine-tune our GAN on novel classes rather than try to generate from them in ‘zero shot’ fashion.
  \item We perform a rigorous empirical evaluation (over different randomised splits of the dataset, or seeds) into how well few-shot data augmentation can perform. We highlight the difficulty of such a task, explain lim-
iterations with the empirical evaluation of existing work, and propose a more pragmatic strategy involving semi-supervised GAN fine-tuning.

- As a side contribution, we propose a simple GAN fine-tuning strategy which allows it to learn new classes in a class-incremental manner, without catastrophic forgetting of old ones. This may be of interest to those working in the intersection of generative modelling and generalised few-shot learning.

1.1 Few-shot data augmentation pipeline

![Diagram of the few-shot data augmentation pipeline](image)

Our few-shot data augmentation pipeline is illustrated in Figure 1. First, we divide our dataset into a training set $D_{\text{train}}$, validation set $D_{\text{valid}}$, and test set $D_{\text{test}}$, where $\mathcal{Y}_{\text{train}} \cap \mathcal{Y}_{\text{valid}} \cap \mathcal{Y}_{\text{test}} = \emptyset$. We can think of these sets as comprising our source, validation, and target classes, respectively, though for the sake of simplicity we can simply refer to the latter two as novel classes. Since the test set will only be used at the very end of evaluation, we can focus our immediate attention on just the training and validation sets. The few-shot setting arises when, in addition to our large training set of source classes, we are given a very small subset of the novel classes in the validation set, which are called the ‘supports’ $D_{\text{valid}}^{(k)}$. There are only $k$ of these supports per class. Essentially, we would like to train a generative model on $D_{\text{train}}$, fine-tune it on the very small set of examples defined in $D_{\text{valid}}^{(k)}$, and have it be able to generate examples that are hopefully indistinguishable from those in the validation set $D_{\text{valid}}$ which is used to evaluate the quality of the generative model. We would also like to fine-tune a classifier – one that was originally trained on the source classes – to the novel classes using the GAN as a data augmentation technique, and also evaluate its generalisation performance on the same validation set. We precisely describe each stage as follows:

1. Section 2.1: pre-train a classifier on $D_{\text{train}}$ which estimates $p(y \in \mathcal{Y}_{\text{train}}|x)$. This classifier will eventually be fine-tuned to adapt to the new classes in $D_{\text{valid}}$.

2. Sections 2.2 and 2.3: train a conditional GAN on $D_{\text{train}}$, where we learn a conditional generative model $p_G(x|y \in \mathcal{Y}_{\text{train}})$. When this is completed, fine-tune it on the support set $D_{\text{valid}}^{(k)}$, which will allow generation for the novel classes $p_G(x|y \in \mathcal{Y}_{\text{valid}})$.

3. Use the fine-tuned GAN to generate new examples for each class. These examples will be concatenated with the original support set $D_{\text{valid}}^{(k)}$ to produce an ‘augmented’ set which we denote $\tilde{D}_{\text{aug}}^{(k)}$.

4. Section 4: Lastly, we take the pre-trained classifier, replace its output probability distribution to be over the novel classes $p(y \in \mathcal{Y}_{\text{valid}}|x)$ and fine-tune it by using $\tilde{D}_{\text{aug}}^{(k)}$ as the training set and evaluate performance on $D_{\text{valid}}$.

Because the few-shot setting requires us to adapt our models to novel classes with very small amounts of data, the evaluation can be highly sensitive to how the dataset is split. Furthermore, it may also be sensitive to what classes comprise source classes (those in the training set) and what classes comprise novel classes (those in the validation or test set). Because of this, almost all quantitative results in this paper are averages over many randomised splits of
the dataset in order to produce reliable estimates of uncertainty. Concretely, if we denote the entire dataset as simply \( D \), we first use a fixed seed to split \( D \) into \( D_{\text{train+valid}} \) and \( D_{\text{test}} \), and then use an additional seed (the ‘dataset seed’) to split \( D_{\text{train+valid}} \) into \( D_{\text{train}} \) and \( D_{\text{valid}} \), and subsequently the \( D_{\text{valid}}^{(k)} \) which is derived from the latter. This is illustrated in Figure S10. Furthermore, evaluation on the test set follows the same process as described, which has its own support set \( D_{\text{test}}^{(k)} \).

2 PROPOSED METHOD

The following subsections describe our method to address the steps described in Section 1.1.

2.1 CLASSIFIER PRE-TRAINING

Before we train our generative model, we need to train a classifier which can easily be adapted to any new classes we encounter. To do this, we first need to train it on a large dataset where there exists many examples per class, so that the features learned are robust and reliable. In our case, this is the training set \( D_{\text{train}} \).

The classifier we train is a ResNet-50 (He et al., 2016) initialised from scratch, trained with ADAM (Kingma & Ba, 2014) using learning rate \( 1 \times 10^{-4} \) and moving average coefficients \( \beta = (0.9, 0.999) \). The training set is split into a 95%-5% split, with the latter forming an internal validation set for early stopping. We train this classifier with a moderate amount of data augmentation, which can comprise randomly-resized crops anywhere between 70% to 100% of the original image size, and random rotations anywhere between -10 and 10 degrees. We simply train the classifier using the small internal validation set as an early stopping criteria.

2.2 GENERATIVE ADVERSARIAL NETWORKS

The generative adversarial network (Goodfellow et al., 2014) we use here is based on the projection discriminator proposed by Miyato & Koyama (2018), with a slight modification to make it more similar to the recently proposed StyleGAN class of models (Karras et al., 2018).

In StyleGAN, rather than the latent code being fed directly as input to the generator network, the input is instead a learnable constant tensor \( h_0 \) whose progressively growing representation is modulated by the latent code, via adaptive instance normalisation. This decision was made to more easily facilitate fine-tuning to new classes, since their layers comprise a relatively small number of learnable parameters. However, it has also been shown in Karras et al. (2018) that this particular architecture is superior to traditional architectures in terms of image quality and disentanglement.

Figure 2: **Left:** overview of both the generator and discriminator. **Right:** The residual block used for the generator. The label \( y \)'s embedding is extracted and concatenated with the latent code to produce scale and shift coefficients for the second (last) batch normalisation layer. The addition symbol for the \( (z, y) \) part of the architecture indicates tensor concatenation.

---

The decision to build off of projection CGAN was simply due to time reasons. However, StyleGAN also has extra complexity due to a more sophisticated training algorithm (e.g. multi-resolution, mixing regularisation) and such complexity may not be necessary for a low-resolution toy dataset like EMNIST.
Because we are training a conditional GAN, we utilise embedding layers that map class indices to codes which are concatenated with the latent codes $z$, which in turn are used to modulate residual blocks in the generator. This is illustrated in Figure 2. The objective function we use is the non-saturating logistic loss originally proposed in Goodfellow et al. (2014):

$$\min_D \mathcal{L}_D = -\mathbb{E}_{x,y \sim p(x,y)} \log [D(x, y)] - \mathbb{E}_{z \sim p(z), y \sim p(y)} \log [1 - D(G(z, y), y)]$$ \hspace{1cm} (1)

$$\min_G \mathcal{L}_G = -\mathbb{E}_{z \sim p(z), y \sim p(y)} \log [D(G(z, y), y)] ,$$ \hspace{1cm} (2)

where $D = \text{sigm}(d(\cdot))$. In practice, we experienced an issue where the GAN would exhibit serious mode dropping. This appears to be because of our use of a learnable constant as input to the network, though it is currently unclear what architectural choices in StyleGAN mitigate this. For this fix, we utilise the InfoGAN (Chen et al., 2016) loss where the discriminator has to also predict the latent code $z$ from the generated image $G(z, y)$, which can be used to maximise mutual information between the generated image and $z$. This extra loss is $\|d(G(z, y))_z - z\|^2$ and is minimised wrt both networks and is weighted by coefficient $\gamma$, where $d(\cdot)_z$ is a prediction branch that stems off the main backbone of $d$. We suspect this loss may have a similar effect to the minibatch standard deviation layer in StyleGAN, which allows the discriminator to distinguish between real/fake based on minibatch statistics. We found that our InfoGAN loss does not have to be anywhere close to zero for it to have its intended effect of mitigating mode dropping. We train with ADAM (Kingma & Ba, 2014) parameters $\beta = (0.0, 0.9)$, $lr = 2 \times 10^{-4}$, InfoGAN coefficient $\gamma = 100$, with a G:D update ratio of 1:5. We periodically compute the FID (Heusel et al., 2017) between our generated samples and the training set as an early stopping criteria, using 50k samples from both.

2.3 Fine-tuning

![Figure 3: Left: comparing the finetuning strategy for D versus the InfoGAN coefficient $\gamma$, with FID on the validation set as the metric (lower FID is better). Results are shown for just one dataset seed. Right: for each $k$, we show the distribution of FID valid set scores (over each dataset seed), with hyperparameter tuning over dfm and $\gamma$.](image)

When GAN training has completed, we need to figure out how to best fine-tune it on our support set, which contains very few examples (only $k$) per class. Here, by ‘fine-tuning’, we mean optimising the same losses as we did earlier (i.e. playing the adversarial minimax game between $G$ and $D$), as opposed to only fine-tuning the generator with non-adversarial losses (such as in Li et al. (2019)). This is a difficult task because we may risk overfitting if we try and optimise too many parameters in both the generator and discriminator. For our fine-tuning strategy, we found that the best strategy is to optimise only the embedding layers in $G$ and, quite surprisingly, to optimise for all parameters in $D$, using the same adversarial losses and the same InfoGAN coefficient $\gamma$. In order to facilitate new classes, all that is required is for new indices (rows) to be added to each and every embedding layer’s matrix in both networks.

For the sake of comparison however, we also measure performance when considering different ways in which $D$ can also be finetuned, which we denote as dfm (‘D finetuning mode’). For a projection CGAN the discriminator logits can be written as $d(x, y) = y^T V \cdot \phi(h) + \psi(\phi(h))$, where $h = f_D(x)$ is the output of the discriminator’s backbone and $V$ is the embedding matrix that maps a (one-hot encoded) label to its embedding. From this equation, we can think of three ways in which $D$ could be finetuned: dfm=$\text{embed}$ corresponds to only updating $\{V, d(\cdot)_z\}$, dfm=$\text{linear}$ corresponds to updating $\{V, \phi, \psi, d(\cdot)_z\}$, and dfm=$\text{all}$ corresponds to updating the backbone $f_D$ as well. In Figure

---

2Implementation-wise, this is not necessary as we simply assume that we know the total number of classes beforehand (train+valid+test) and initialise the embedding matrix to have precisely this many rows.
3a we plot FID on the validation set (precisely, the FID between GAN-generated samples on the validation classes and the validation set) over different values of $\gamma$ and different dfms. We can see that dfm=embed performs the worst, and when $\gamma = 100$ there is not much difference between fine-tuning all of $D$ versus just its linear output layers. We find this to be an interesting result given it is the opposite of ‘Freeze-D’ (Mo et al., 2020), whose work found the best results in fine-tuning all of $G$ and just the later layers of $D$.

In Figure 4 we present some additional results comparing the fine-tuning mode of $G$, which we denote as $gfm$. We compare fine-tuning just the embeddings in $G$ ($gfm=embed$) versus also fine-tuning the MLPs that take part in adaptive batch normalisation ($gfm=linear$, see Figure 2b). Shaded regions (variance) is over all possible dfm’s (all, linear, or embed). Right: same as left but FID is computed between samples on the training classes and the training set. Here, we can see that fine-tuning only the embedding layers in $G$ does not result in catastrophic forgetting in how to generate samples for training classes.

One may wonder in what situations does it simply suffice to only finetune the embedding layers in $G$ and have it perform well for generation. We recognise that this is highly dependent on both the architecture and datasets used. Unlike the more ambitious task of domain transfer, here our source and target classes can be seen as coming from the same overall distribution $p(x)$, but with different sets of conditioning labels $y \in Y_{train}$ or $y \in Y_{valid}$ for the conditional distribution $p(x|y)$. If source classes in the training set share very similar factors of variation to target classes in the validation or test set, then we would expect the network to generalise to those new classes with minimal modification to the original weights of the network. A real world example of this would be finetuning from the source classes $\{cat, dog\}$ to $\{tiger, fox\}$, with many common factors of variation shared between the two (four legs, fur, tails, and so forth).

3 RELATED WORK

A very closely related work is DAGAN (Antoniou et al., 2017). The authors proposed training a GAN where the discriminator is trained to distinguish pairs of images, rather than images conditioned on labels.. This means that $D$ is trained to distinguish between a same-class tuples from the real distribution $(x_1, x_2)$ and a pair from the fake distribution, where one of the elements is generated $(x, \tilde{x})$, where $\tilde{x} = G(r(x), z)$. In this case, $r(x)$ is an encoder network and $G$ is the corresponding decoder. The authors motivate this by wanting a discriminator that can naturally generalise to new classes, since it is not explicitly conditioned on a label. For their generator network, $r(x)$ is meant to infer (without any explicit label supervision) the ‘content’ of the image, while $z$ serves as the ‘style’ which is simply noise injected from a prior. However, upon attempting to reproduce this model we found a major deficiency, in that the trained decoder $G$ ignores $r(x)$ completely, i.e $G(r, z) \approx G(0, z)$. This seems most likely attributable to the fact there is no supervision at all for $r(x)$, i.e. a reconstruction error or InfoGAN-style losses to ensure that both $z$ and $r(x)$ are used by the network. Such losses do not appear to be present the paper. Furthermore, from the results it is unclear if the method would outperform a discriminator that conditions on the class label for the training set. Despite this, a big difference between their works and ours is that they try to perform zero-shot generation with respect to the generative model, since it itself is not fine-tuned on the novel classes. In our own preliminary experiments however a model we trained similar to DAGAN, we found that when we tried to generate images from novel classes with $r(x)$, there was a strong bias towards it generating images that looked like classes from the training set.
Figure 5: Generated examples from the fine-tuned GAN for $k = 5$ (5a) and $k = 15$ (5b). In each subfigure, the left panel shows the supports $D^{(k)}_{\text{valid}}$ and the right panel shows the generated images (20 examples per class).

F2GAN (Hong et al., 2020b) proposes an adversarially-augmented autoencoder where $k$-way mixup (Zhang et al., 2017; Verma et al., 2019a) is performed between the latent features of $k$ images, coupled with an attention module to patch up discrepancies in the image (hence ‘fusing and filling’). Unlike DAGAN, a conditional discriminator is used which conditions on labels. In this work, a ‘mode seeking’ loss is proposed to ensure that, for the same pairs of images, different mixing coefficients correspond to sufficiently diverse images. While an ablation study was performed to justify each component/loss that was added, this was not done for any of the datasets for which few-shot classification was performed and therefore it is unclear which components of the model are most influential. Like DAGAN, there is no finetuning on the support set of novel classes, and the model is expected to perform zero-shot generation.

One crucial difference between what we propose and both of these works is that ours requires the generative model to be fine-tuned on novel classes. Wertheimer et al. (2020) argue that generative models such as GANs and VAEs have extreme difficulty generalising to novel classes in a ‘zero-shot’ manner (i.e. without fine-tuning) due to the fact that the training of either models enforces that all plausible regions in the space of the prior distribution decode into plausible samples from the training distribution. They argue that unlike their probabilistic variants, deterministic autoencoders are fit for few-shot generalisation because of this lack of rigidity, and propose a novel mixup scheme to ensure interpolations between images in novel classes do not produce images biased towards the training set. We argue that in the case of VAEs however, it depends on the trade-off between the two competing losses that comprise the evidence lower bound (ELBO), which is the likelihood + KL (between posterior and prior). The likelihood (reconstruction error) encourages a bijective mapping between $X$ and $Z$, which allows it to generalise to novel inputs. The KL loss acts as a regularisation to make the posterior $q(z|x)$ indistinguishable from the prior $p(z)$, and in the extreme case would bottleneck the capacity of the network and map many distinguishable inputs to the same mode, which is the opposite to the intended goal of the likelihood term (Esmaeili et al., 2019). An extensive literature surrounds the trade-off between these two terms (Burgess et al., 2018; Esmaeili et al., 2019; Mathieu et al., 2019). A similar analogy could be made for autoencoders with adversarial losses such as F2GAN, where we can imagine the KL loss being replaced with an ‘adversarial’ divergence between images created by the decoder and images from the training distribution (Berthelot et al., 2018; Sainburg et al., 2018; Beckham et al., 2019). Too much weighting on this term would produce a strong bias in the decoder to ensure all images are indistinguishable from those from the training distribution, potentially to the detriment of it being able to generate new samples from inputs coming from unseen classes. This seems to explain why F2GAN contains a multitude of losses to try and encourage sample diversity, though as we have stated, in our work we would prefer to simply fine-tune a GAN to novel classes directly.

One major issue in comparing these papers’ results is that there has not been a standardised way in which the data is split for training and evaluation. DAGAN is the most rigorous in its evaluation, utilising a ‘source’ domain (training
set), a ‘validation’ domain (validation set), and a ‘target’ domain (test set). For the validation and testing sets, \( k \) examples per class are held out in each, which can be thought of as the support sets for both the validation and testing sets, respectively. These support sets are leveraged by the generative model to create more examples for their respective classes. In DAGAN, the validation set is used to tune the number of synthetic examples that should be generated per class. Conversely, in F2GAN there appears to be no mention of a validation set, and the data is simply split between a training domain and a testing domain. Because of hyperparameter tuning, it is likely performance estimates are biased, and this will be discussed in further detail in Section 4.

There are many works which involve the fine-tuning of GANs. Robb et al. (2020) proposes a new method to fine-tune a pre-trained StyleGAN (Karras et al., 2018) in the few-shot regime by tuning only the singular values of both networks. Karras et al. (2020) propose a trick to mitigate discriminator overfitting to improve StyleGAN2 training, and present transfer learning results in the context of domain adaptation. Such tricks could be leveraged to potentially improve our results in Section 2.3. The aforementioned work of Wertheimer et al. (2020) also performs few-shot data augmentation but in the context of domain adaptation, where one is interested in mapping between datasets. Casanova et al. (2021) propose ‘instance conditioned’ GANs that condition on pre-trained self-supervised embeddings rather than class labels, and demonstrate impressive zero-shot transfer to other datasets, simply by computing embeddings over these other datasets. While these works undoubtedly present impressive results on larger and more ambitious datasets, none of them have examined a few-shot pipeline where the goal is to generate images to improve a downstream task directly, such as classification performance. These works instead primarily report image similarity metrics computed on their generated images.

Lastly, while we do not consider meta-learning here, our few-shot pipeline could be framed as an end-to-end approach under that paradigm. There are numerous works combining generation with few-shot classification (Zhang et al., 2018; Wang et al., 2018; Chen et al., 2019; Verma et al., 2019b).

## 4 Experiments and Results

Here, we present the results of our classifier fine-tuning experiments on both the validation and test sets, over five randomised dataset seeds (splits) on the balanced version of the EMNIST dataset (Cohen et al., 2017). Over these splits, the test set is the same (consisting of 10 classes), but the training and validation sets comprise different class splits corresponding to 28 and 9 classes, respectively. By fine-tuning, we refer to freezing the pre-trained classifier (Section 2.1) and replacing its output (logits) layer with a new layer which defines a probability distribution over either the validation classes \( Y_{\text{valid}} \) or the test classes \( Y_{\text{test}} \). Note that unlike with generalised few-shot learning, here we are not interested in maximising performance over both the old and new classes – we simply wish to maximise performance over the latter. Here, we use the same parameters for ADAM as described in Section 2.1 but lower the learning rate to \( 2 \times 10^{-5} \). We describe our experiments in the following paragraphs.

### Baselines

For the simplest baseline, we fine-tune the pre-trained classifier on \( \mathcal{P}_{\text{valid}}^{(k)} \). We run two experiments for this, one with and without traditional data augmentation applied. For the data augmentation experiment, we utilise random resized crops with a minimum resize area of 70% of the original image size. (Note that all remaining experiments we describe will also utilise this form of data augmentation.)

### Input mixup

We use mixup in input space (Zhang et al., 2017), where the mixing distribution Beta(\( \alpha, \alpha \)) is a hyperparameter, and \( \alpha \in \{0.1, 0.2, 0.5, 1.0\} \). This is done ‘on the fly’: for each minibatch seen during fine-tuning, input mixup is applied to both the images and their labels.

### Fine-tuned GAN

Using the fine-tuned GAN, we pre-generate \( n_s \) new samples per class and combine these with the original supports \( D_{\text{valid}}^{(k)} \) to create \( \hat{D}_{\text{aug}}^{(k)} \). Here, \( n_s \in \{2, 5, 10, 20\} \) is a hyperparameter that we explore.

We present our results in Table 1. We can see that all results are characterised by non-negligible variances, especially when \( k \) is small. This can be problematic because it can diminish the statistical significance of any claims in performance gains. If we just consider the mean accuracy however, for \( k = 5 \) the baseline performs the best. For \( k = 10 \), input mixup performs the best, and for \( k = 15 \) we perform slightly better than input mixup. Furthermore, it is unfortunately not the case that increasing the generated samples per class (\( n_s \)) leads to better accuracy on the validation set, which is illustrated in Figure 6a. In fact, for each value of \( k \), the mean optimal values of \( n_s \) were 4.20 \( \pm \) 3.12, 3.80 \( \pm \) 1.47, and 4.20 \( \pm \) 3.12, respectively. We conjecture that this is because there is a fundamental mismatch between the distribution of GAN-generated images and those from the validation set (whose accuracy we wish to maximise), and this is leading to overfitting on the former. To validate this, we generate a held-out validation set from the same GAN that we generated the images from, which we call our ‘fake’ validation set. We can see in Figure 6b
Table 1: Accuracy (%) of different methods on EMNIST in the low-data setting. The separating bar distinguishes between results we have lifted from the F2GAN (Hong et al., 2020b) paper and our own results. These two groups of results are not directly comparable due to a variety of confounding factors in the experimental setup. In our results, uncertainty estimates are computed over five different randomised dataset splits (seeds) on the validation set. For each of these seeds, hyperparameter tuning was used to obtain the best result.

</table>

The results reported by F2GAN (Hong et al., 2020b) in the upper panel of Table 1 are indeed notable compared to ours for k = 10 and k = 15, but unfortunately their description of how the dataset was split is confusing and there are concerns with how principled this evaluation is. In their work, they describe EMNIST as comprising of 47 classes but with 28 being selected as training classes and 10 as testing, leaving 9 classes unaccounted for. In their preceding work MatchingGAN (Hong et al., 2020a), the dataset is split into 20-10-10 (i.e. train-valid-test) for a total of 48 classes, with 10 classes being used as a validation set for GAN training. The test set (10 classes) is used for classifier evaluation, with a small support set of k examples per class used by the GAN to generate additional examples. However, excessive tuning of hyperparameters of the GAN (that is, the hyperparameters that directly control generation, e.g. the generation seed or number of generated samples per class n_s) and hyperparameters of the classifier can lead to biased estimates of performance on the test set, which is why we have also presented results on our test set in Table 2. In this table, we
find that for all values of $k$, the data augmentation baseline performs the best in terms of mean accuracy, though like we have mentioned earlier, these results have relatively inflated variances which diminish their significance.\(^3\)

Another confounder is that MatchingGAN report artificially reducing the size of all classes in EMNIST to be 100 examples per class to mimic DAGAN’s setup, but it is not clear whether F2GAN has also done this. For reference, the only two splits of EMNIST with 47 classes are ByMerge and Balanced, with Balanced containing 2,800 examples per class and ByMerge containing anywhere between 2,961-44,704 examples per class, so this is an enormous reduction in dataset size. Such a reduction would be detrimental to both classifier pre-training and GAN training. While DAGAN’s evaluation protocol differs slightly to our work and the other works, they report 76% test set accuracy on EMNIST with $k = 15$ with this artificial reduction in examples per class. Lastly, for both MatchingGAN and F2GAN, the number of samples generated per class with the GAN was set to $n_s = 512$, which is extraordinarily large, considering that we obtain worse results on our validation set with anything more than $n_s = 5$, on average. Our results appears to corroborate that of DAGAN, whose authors report only tuning $n_s \in \{1, \ldots, 10\}$. Because there are many subtle differences in the empirical evaluation between our work and the aforementioned ones, we simply defer the reader to Figures S10, S11, S12 for more information rather than enumerate all of these here.

Table 2: Results of selected experiments on the held-out test set. For each experiment and its dataset seed, the hyperparameters used for the test set evaluation correspond to the optimal hyperparameters found for the same corresponding experiment / seed on the validation set (e.g. number of epochs, $\alpha$ for input mixup, $n_s$ for the fine-tuned GAN).

5 FURTHER DISCUSSION

One major limitation of using conditional GANs for data augmentation is that there is no way to leverage unlabelled data, which tends to be more abundant than labelled data. Another issue with our setup is that downstream performance is likely to only give practical gains for a very specific range of values for $k$. For example, when $k$ is too small, there is a strong incentive for one to leverage GAN-based data augmentation since there are very few examples per class, but as we have demonstrated, fine-tuning a GAN is difficult precisely because of how few examples there are. Conversely, as $k$ becomes larger, even if we could finetune a better GAN we would also expect there to be diminishing returns when it comes to improving classification performance over the baseline, since there are an abundant number of labelled examples per class. Therefore, having the ability to leverage unlabelled data seems like a more pragmatic endeavour since we could still experiment with small $k$ but likely do a much better job at fine-tuning a better quality generative model over the new classes. Fortunately, it turns out that one can take the projection discriminator equation of Miyato & Koyama (2018) that we use and easily turn it into a semi-supervised variant. Recall from Section 2.3 that the output of the discriminator can be written as follows:

$$d(x, y) = y^T V \cdot \phi(h) + \psi(\phi(h)),$$

with $h = f_D(x)$, where $f_D$ is the backbone of $D$, and $D = \text{sigm}(d(\cdot))$. From Miyato & Koyama (2018), this equation is the result of modelling the likelihood ratio of both the data and generative distributions:

$$f(x, y) = \log \frac{q(x, y)}{p(x, y)} = \log \frac{q(y|x)q(x)}{p(y|x)p(x)} = \log \frac{q(y|x)}{p(y|x)} + \log \frac{q(x)}{p(x)},$$

where the last two terms here are modelled with their respective terms in Equation 3. From this, one can easily see that $d(x) = \psi(\phi(h))$ and that this is modelling the log ratio $q(x)/p(x)$, which is not a function of the label. From this, we can write the semi-supervised equations as:

$$\min \mathcal{L}_D = \mathcal{L}^{(sup)}_D - \mathbb{E}_{x \sim p_s(x)} \log [D(x)] - \mathbb{E}_{z \sim p(z), y \sim p(y)} \log [1 - D(G(z, y))]$$

$$\min \mathcal{L}_G = \mathcal{L}^{(sup)}_G - \mathbb{E}_{z \sim p(z), y \sim p(y)} \log [D(G(z, y))],$$

\(^3\)Admittedly, it is cumbersome to have to repeat GAN and classifier fine-tuning on the test classes in order to report an unbiased estimate of generalisation performance, and we may actually be ‘under-reporting’ it since the test set comprises of completely different classes. We will fix this by ensuring that the validation and test classes are the same (but with the latter containing held-out examples for unbiased evaluation).
where $L^{(sup)}_D$ and $L^{(sup)}_G$ are their respective terms in Equation 1, and $p_u$ denotes some unlabelled distribution (i.e. the validation set minus the labels). Here, the generator is not modified to perform unconditional generation – it simply has to fool both the conditional branch $d(x, y)$ and unconditional branch $d(x)$. We are not aware of any work which adapts the projection discriminator in this way, though Sricharan et al. (2017) proposed a semi-supervised CGAN variant which is conceptually similar to Equation 3. To train with this objective, we can simply consider fine-tuning using the entire validation set $D_{\text{valid}}$ for the unsupervised terms in Equation 5, in addition to the labelled support set $D^{(k)}_{\text{valid}}$ for the supervised terms. For reference, the validation set consists of 25k examples. We present FID barplots for these experiments in Figure 7. For $k = 5$ (Figure 7a) improvements were extremely marginal, and for $k = 15$ (Figure 7b) a large improvement in FID is achieved, especially if we unfreeze all parameters in $G$ and $D$. Unfortunately, we were unable to improve classification performance on the validation set even with $k = 15$, so we do not show those results here. A qualitative analysis of the generated images from these experiments indicate that too much weighting on the unlabelled loss results in images that do not always correspond to their intended class labels. In this case, it is probably more appropriate to compute an FID per class and average over those instead. A further exploration this is left to a future iteration of this work.

In general, we consider generative modelling in the few-shot regime to be a difficult task. All generative models present a trade-off (Xiao et al., 2021) between three criteria: sample quality, fast sampling, and mode coverage/diversity, with GANs tending to be problematic in the former. Variational autoencoders (VAEs) on the other hand suffer from reduced sample quality but at the benefit of mode coverage. Denoising diffusion probabilistic models (DDPMs) (Sohl-Dickstein et al., 2015; Song et al., 2020; Ho et al., 2020) appear to perform well in terms of both mode coverage and sample quality, and its main bottleneck – sample generation – is of the least concern since we have chosen to pre-generate examples rather than generate them on-the-fly. Given their heavy recent interest, they may be a viable alternative to GANs (Dhariwal & Nichol, 2021), though they may still suffer from the same limitations caused by few labelled examples.

6 CONCLUSION

In this paper, we explored the use of generative adversarial networks to perform few-shot data augmentation in order to improve classification performance on EMNIST. While we qualitatively demonstrated the ability to finetune a GAN to generate examples from novel classes in the few-shot regime, it is difficult to leverage a large number of generated examples from the GAN to fine-tune a classifier because it can easily overfit to those examples. Such a phenomena is due to the fact that there is an inherent mismatch between the actual vs generative distribution of examples conditioned on those novel classes, and this effect is further exacerbated by how few examples are used. Furthermore, we found that classification performance is highly dependent on how classes are partitioned and this can induce significant variance, which is something not accounted for or presented in previous works. In order to mitigate this, we experimented with more pragmatic training setup that allows for unlabelled examples to be used for GAN fine-tuning. While we achieved better FID scores with this approach, we were still unable to significantly improve classification performance with it, which suggests that the small $k$ regime we are operating in is too restrictive. Therefore, we conclude that considering larger $k$ under a semi-supervised setup may be a more fruitful endeavour.

S7.1 Generated Images

Figure S8: GAN-generated images from the training (source) classes. See Section 2.2 for more information.

Figure S9: Training class interpolations using the GAN. This is done by interpolating pairs of class embeddings for each embedding layer in the generator network (one per residual block). The top and bottom-most rows consist of randomly selected classes in the training set, and rows in between correspond to interpolations $\alpha \cdot \text{embed}_i(y_1) + (1 - \alpha) \cdot \text{embed}_o(y_2)$, where $i$ denotes the $i$th residual block of the generator. Text labels show in blue denote $\alpha$. 

**S7.2 Dataset Splits**

Figure S10: Illustration of how we split our dataset. The dataset seed is used to control what classes comprise training (source) classes and validation (target) classes. The GAN and classifier are trained on $D_{train}$. The GAN is then fine-tuned on $D_{valid}$ and is used to generate examples for the validation classes. The classifier pretrained on $D_{train}$ is now fine-tuned on $D_{valid}^{(k)}$ and the GAN-generated examples and the goal is to maximise performance on $D_{valid}$. At the end of evaluation, the same GAN + classifier fine-tuning steps must be repeated on $D_{test}$ which has its own support set $D_{test}^{(k)}$, but hyperparameter tuning is not allowed on this split. Note that this evaluation protocol is cumbersome, and the next iteration of our work will simply make the validation and test classes the same (but with the latter containing held-out examples not seen by any model).

Figure S11: Illustration of how the dataset is split according to MatchingGAN (Hong et al., 2020a). The training set (1) is used to train the GAN, and validation set (2) is used to monitor GAN training (tune GAN training hyperparameters via FID?). What we call the ‘support set’ they have called the ‘training set of unseen categories’ (3), and this is what the GAN uses to generate additional examples. The classifier pre-trained on (1) is now fine-tuned on (3) + the GAN-generated examples and is used to predict accuracy on (4). As we mentioned in Section 4, hyperparameter tuning of the generation process / classifier can lead to biased estimates of performance on (4), since there is no additional held-out test set. Furthermore, in F2GAN (Hong et al., 2020b) no validation set appears to be mentioned.
Figure S12: Illustration of how the dataset is split according to DAGAN (Antoniou et al., 2017). Some details regarding the evaluation were not clear, but from what can be gathered, DAGAN is trained on the source domain (training set). A baseline classifier is also trained (from scratch, not fine-tuned) on the validation domain, and hyperparameter tuning is done for $n_s$ to determine how many DAGAN-generated samples per class are optimal. The final evaluation is then training a classifier from scratch on the target domain with the optimal $n_s$ found via hyperparameter tuning. The test accuracy is averaged over five independent runs (dataset seeds).

S7.3 SEMI-SUPERVISED EXPERIMENTS

Figure S13: Projection discriminator from Miyato & Koyama (2018). Recall from Section 5 that the output of the discriminator is $d(x, y) = d(y|x) + d(x) = y^T V \cdot \phi(f_D(x)) + \psi(\phi(f_D(x)))$. The fact that $d(x, y)$ partly decomposes into $d(x)$ means that the projection discriminator can be leveraged in a semi-supervised manner.
