(Dated: April 1, 2022/ Received date / Accepted date)

In the binary-driven hypernova (BdHN) scenario, long gamma-ray bursts (GRBs) originate in a cataclysmic event that occurs in a binary system composed of a carbon-oxygen (CO) star and a neutron star (NS) companion in close orbit. The collapse of the CO star generates at its center a newborn NS (νNS), and a supernova (SN) explosion. Matter from the ejecta is accreted both onto the νNS because of fallback and onto the NS companion, leading to the collapse of the latter into a black hole (BH). Each of the ingredients of the above system leads to observable emission episodes in a GRB. In particular, the νNS is expected to show up (hereafter νNS-rise) in the early GRB emission, nearly contemporary or superimposed to the ultrarelativistic prompt emission (UPE) phase, but with a different spectral signature. Following the νNS-rise, the νNS powers the afterglow emission by injecting energy into the expanding ejecta leading to synchrotron radiation. We here show that the νNS-rise and the subsequent afterglow emission in both systems, GRB 180720B and GRB 190114C, are powered by the release of rotational energy of a Maclaurin spheroid, starting from the bifurcation point to the Jacobi ellipsoid sequence. This implies that the νNS evolves from a triaxial Jacobi configuration, prior to the νNS-rise, into the axially symmetric Maclaurin configuration observed in the GRB. The triaxial νNS configuration is short-lived (less than a second) due to a copious emission of gravitational waves, before the GRB emission, and it could be in principle detected for sources located at distances closer than 100 Mpc. This appears to be the sole process of emission of gravitational waves in long GRBs.

I. INTRODUCTION

The progenitor of long gamma-ray bursts (GRBs) in the binary-driven hypernova (BdHN) model is a binary system composed of a carbon-oxygen (CO) star and a neutron star (NS) companion (see, e.g., Refs. \[1\]–\[7\]). The gravitational collapse of the iron core of the CO star leads to the formation of a newborn NS (νNS) at its center and to a supernova (SN) explosion that ejects the outer layers of the star. Some part of the ejecta is accreted by the NS companion and also by the νNS via matter fallback accretion. Both accretion processes proceeds at hypercritical (i.e., highly super-Eddington) rates thanks to a copious neutrino emission \[6, 8\]. In compact binaries with orbital periods of a few minutes, the hypercritical accretion onto the NS companion brings it the critical mass inducing its gravitational collapse and forming a rotating (Kerr) BH. These systems have been called BdHN I. In less compact binaries, the NS companion does not reach the critical mass and hold stable as a more massive, fast rotating NS. These systems have been called BdHN II.

The fallback accretion onto the νNS spins it up to a millisecond rotation period. In this early phase, the huge νNS rotational energy of up to a few $10^{45} \text{erg}$, powers what we have called the νNS-rise that is the first observed emission from the νNS. Subsequently, the νNS fuels the synchrotron radiation at the SN ejecta that leads to the afterglow observed in the X-rays, optical and radio energy bands following a power-law luminosity \[9\]–\[10\]. The accretion onto the companion NS leads to the BH formation that leads to the ultrarelativistic prompt emission (UPE) phase \[11\] and the GeV emission \[12\]–\[16\].

In \[14\], 380 BdHNe I were identified and it was there shown that all of them show an X-ray afterglow, observed by the Neil Gehrels Swift satellite \[17\]–\[19\], with a luminosity in the cosmological source rest-frame that decreases with time as a power-law \[14\], i.e.

$$L_X = A_X t^{-\alpha_X},$$

where $A_X$ and $\alpha_X$ depend on the source. In this article, we confine our attention to the BdHN I prototypes GRB 180720B, with $A_X = (2.5 \pm 0.4) \times 10^{53} \text{erg s}^{-1}$ and $\alpha_X = 1.44 \pm 0.01$, and GRB 190114C, with $A_X = (5.14 \pm 2.03) \times 10^{52} \text{erg s}^{-1}$ and $\alpha_X = 1.37 \pm 0.05$. Figure 1 shows the νNS-rise and the X-ray afterglow of GRB...
180720B and GRB 190114C, in the cosmological rest-frame of the sources. In GRB 180720B, the \( \nu NS \)-rise is observed at 6.05–9.06 s, and in GRB 190114C at 1.12–1.68 s from the Fermi-GBM trigger. The afterglow in the optical and radio energy bands also shows a similar power-law but much less luminous, so the X-ray luminosity is an excellent proxy of the total afterglow power-law luminosity.

The backward extrapolation of the power-law fit of the X-ray afterglow joins the \( \nu NS \)-rise emission, which confirms the expectation that both emissions are powered by the \( \nu NS \) energy. Therefore, the \( \nu NS \)-rise is the first release of the \( \nu NS \) energy gained during the fallback accretion process, and it continues to release it at the pace given by the power-law luminosity inferred from the X-ray afterglow. Therefore, we assume that the evolution of the \( \nu NS \) is driven by the energy balance equation

\[
E = -L_x , \tag{2}
\]

which we use to calculate the evolution of the \( \nu NS \) structure. We shall model the \( \nu NS \) as a Maclaurin spheroid and show that the \( \nu NS \)-rise and the afterglow emission energetics require that the initial parameters of the Maclaurin spheroid be the ones of the bifurcation point to the Jacobi sequence of ellipsoids. Therefore, the \( \nu NS \) before the GRB emission evolves from a Jacobi ellipsoid into a Maclaurin spheroid by emission of gravitational waves. We also estimate the entropy of this emission.

II. \( \nu NS \) STRUCTURE EVOLUTION

We turn now to evaluate the \( \nu NS \) parameters and their evolution during the \( \nu NS \)-rise and the afterglow emissions. For this task, we assume the \( \nu NS \) evolves along the sequence of equilibrium of Maclaurin spheroids, i.e., Newtonian configurations of self-gravitating, oblate, homogeneous (uniform density), uniformly rotating objects (see [20] for details). From the solution of the gravitational Poisson equation, it turns out that given a density \( \rho \), all the properties of the spheroid are function of the eccentricity, \( e^2 = (a^2 - b^2)/a^2 \), where \( a \) and \( b \) are, respectively, the semi-major (equatorial) and semi-minor (polar) axis. The angular velocity is given by (e.g., [21])

\[
\Omega^2 = 2\pi G \rho g(e), \tag{3}
\]

\[
g(e) = \frac{(3 - 2e^2)(1 - e^2)^{1/2}\arcsin(e) - 3(1 - e^2)}{e^3}. \tag{4}
\]

The angular momentum, \( J \), and moment of inertia, \( I \), are given by

\[
J = I\Omega, \quad I = I_0(1 - e^2)^{-1/3}, \quad I_0 = \frac{2}{5}Ma_0^3, \tag{5}
\]

where the mass and equatorial radius are

\[
M = \frac{4\pi}{3}pa^3(1 - e^2)^{1/2}, \quad a = a_0(1 - e^2)^{-1/6}, \tag{6}
\]

being \( a_0 \) the radius of the homogeneous, non-rotating (i.e. spherical) star of mass \( M \), density \( \rho \), and with the same volume of the spheroid, so it is defined by \( \rho = 3M/(4\pi a_0^3) \). The total energy is the sum of the kinetic rotational (\( T \)) and gravitational (\( W \)) energy

\[
E = T + W, \quad W = \frac{3GM^2}{5a}\arcsin(e), \quad T = \frac{1}{2}I\Omega^2, \tag{7}
\]

Following the BdHN scenario, the \( \nu NS \) must cover the energy released in the \( \nu NS \)-rise and the subsequent afterglow emission. This is confirmed by the backward extrapolation of the X-ray afterglow power-law emission to the time of the \( \nu NS \)-rise, which shows the connection between the two emissions (see Fig. 1).

By integrating analytically Eq. (2), and equating it to Eq. (7), we obtain the following algebraic, nonlinear implicit equation whose solution gives the eccentricity as a function of time

\[
\pi GI_0 \rho F(e) = \frac{A_X}{1 - \alpha_x}t^{1 - \alpha_x}, \tag{8}
\]

\[
F \equiv -2 + \frac{3(1 - e^2)^{2/3}}{e^2} + \frac{(4e^2 - 3)(1 - e^2)^{1/6}}{e^3}\arcsin(e), \tag{9}
\]

Figure 1. Luminosity of the \( \nu NS \)-rise (red point) and the X-ray afterglow (black points) of GRB 180720B (left panel) and GRB 190114C (right panel) observed by Swift-XRT, measured in the cosmological rest-frame. The dashed yellow line is the power-law fit given by Eq. (1).
and rotation period at $t_0$ are, respectively, $e_0$ and $P_0$.

where we have used the asymptotic condition $e(\infty) = 0$.

As for the initial conditions, we must specify a value for the density $\rho$ and radius $a_0$ of the spherical configuration of reference, and at the initial time of evolution, $t_0$, which is the time of the occurrence of the $\nu$NS-rise, a value for the eccentricity, $e(t_0)$. We here adopt $a_0 = 10^9$ cm, and seek for the density and initial eccentricity of the spheroid that allow to explain the $\nu$NS-rise and afterglow emission, which are specified by the values of $A_X$ and $\alpha_X$.

We have found that the high luminosity and energy released at the $\nu$NS-rise requires the $\nu$NS to have the fast spin and the maximum (or very close to it) eccentricity allowed by the axially symmetric Maclaurin spheroid, namely the values of the bifurcation point to the sequence of Jacobi ellipsoids (triaxial configurations), i.e., $e(t_0) = 0.813$ [20]. Table I summarizes the initial conditions of the Maclaurin spheroid modeling the $\nu$NS in GRB 180720B and GRB 190114C. Figure 2 shows the evolution of the eccentricity (upper row) and the contribution of the rotational and gravitational power (lower row) to the total power released during the evolution. The gravitational energy is relevant at the beginning of the evolution when $e \gtrsim 0.3$ while, at lower eccentricities, the rotational energy dominates the emission.

### III. CONCLUDING REMARKS

We have calculated the evolution of the $\nu$NS in BdHN I assuming that it powers the $\nu$NS-rise and the afterglow emission. By modelling the $\nu$NS as a Maclaurin spheroid, we have shown that its parameters (rotation period and eccentricity) have to be very close (or equal to) to the ones of the transition point to the Jacobi sequence of ellipsoids (see Table I).

Therefore, the $\nu$NS could have evolved from a triaxial body (Jacobi-like ellipsoid) into an axially symmetric body (Maclaurin spheroid) by emission of gravitational waves as anticipated in early models of pulsars (e.g. [22, 24]) and verified by [25, 26]. The gravitational-wave emission drives the evolution of the ellipsoid to the Maclaurin sequence in relatively short time [24, 26]. This emission carries out angular momentum which plays a role in bringing the $\nu$NS to the observed short-rotation period: the ellipsoid spins up while it loses angular momentum because the gravitational-wave-driven evolution occurs along the Riemann-S sequence conserving circulation [26]. The gravitational-wave power released by the triaxial configuration with equatorial ellipticity $\epsilon$ and moment of inertia $I$ about the rotation axis is $E = (32/5)(G/c^5)I^2\Omega^5$ [23]. For instance, assuming a rotation frequency of 1 kHz, and the moment of inertia inferred for the $\nu$NS in GRB 180720B, we obtain $E \sim 1.5 \times 10^{53}(\epsilon/0.1)^2$ erg s$^{-1}$, and the characteristic timescale $E/\dot{E} \lesssim 1$ s, where $E \sim 10^{53}$ erg is the gravitational energy of the triaxial configuration, where we are assuming that the ellipticity can be as large as 0.1 at early post-birth times. The associated characteristic strain at a detector of gravitational waves is $h_c \sim 4G/(c^4D)\epsilon\Omega^2 \sim 1.6 \times 10^{-23} (\epsilon/0.1) (100$ Mpc$/D)$, where $D$ is the distance to the source (e.g. [27]). This strain is comparable to the detectability threshold of Advanced LIGO and Virgo interferometers at these frequencies (e.g. [28]). In view of the above, and the possible enhancement of the strain depending upon the number of cycles of the signal in the detector [27], there is a chance for gravitational-wave interferometers to calibrate their detectors [29] observing this radiation before the GRB prompt emission for sources located at $D \lesssim 100$ Mpc.
