Abstract

Self-supervised learning (SSL) to learn high-level speech representations has been a popular approach to building Automatic Speech Recognition (ASR) systems in low-resource settings. However, the common assumption made in literature is that a considerable amount of unlabeled data is available for the same domain or language that can be leveraged for SSL pre-training, which we acknowledge is not feasible in a real-world setting. In this paper, as part of the Interspeech Gram Vaani ASR challenge, we try to study the effect of domain, language, dataset size and other aspects of our upstream pre-training SSL data on the final performance low-resource downstream ASR task. We also build on the continued pre-training paradigm to study the effect of prior knowledge possessed by models trained using SSL. Extensive experiments and studies reveal that the performance of ASR systems is susceptible to the data used for SSL pre-training. Their performance improves with an increase in similarity and volume of pre-training data. We believe our work will be helpful to the speech community in building better ASR systems in low-resource settings and steer research towards improving generalization in SSL-based pre-training for speech systems.

Index Terms: low-resource data, self-supervised learning, automatic speech recognition, spontaneous telephone speech

1. Introduction

The task of Automatic Speech Recognition (ASR) involves building systems that can transcribe spoken utterances in isolation. One major problem with building efficient ASR systems is that they are data-hungry [1] and with the introduction of deep learning to build ASR systems, this problem has amplified. Though English has more than 100k hours of human transcribed data freely available online, for languages beyond English, data is scarce, with some languages even lacking professional annotators and existing only in spoken form. Transcribing data is both an expensive and time-consuming affair. With researchers and businesses finding the true potential of ASR systems in various Natural Language Understanding (NLU) systems, there has been an increasing demand for building such systems in languages beyond English.

To address these problems, researchers have resorted to semi-supervised [2,3] and self-supervised [4,5] learning approaches. First, the semi-supervised learning paradigm proposes using both transcribed and un-transcribed data and learns by first training a seed model and generating pseudo-labels for the unlabeled data using that model, and then training the model using these pseudo-labels.

Self-supervised learning or SSL is the task of learning representations solely from unlabelled data wherein the model tries to learn useful features by solving different upstream tasks. On the other hand, self-supervised speech representation learning is the process of learning from raw speech signals to downstream speech tasks like Automatic Speech Recognition (ASR), Speaker Verification (SV), Speech Emotion Recognition (SER), etc. In the past decade, SSL in deep neural models has successfully alleviated the need for human-annotated data and has closed the gap and sometimes even performed better than models trained with supervision. Beyond speech, researchers have also leveraged SSL to push the state-of-the-art in low-resource data settings in modalities of vision [6,7] and text.

Very recently, [8] pointed out that though self-supervised learning models learn better task-agnostic features, a comprehensive study of which can be found in [9]. They are not robust to changes in the domain between pre-training and ASR fine-tuning and get biased toward the domain from which the unlabelled data come. [10] has shown that SSL pre-training from the same language helps improve ASR performance. This boils down to the need for huge amounts of unlabeled data with a high source similarity to the final downstream low-resource data in terms of accent, language, or domain. This introduces another problem of computing when pre-trained using SSL from scratch, and as correctly pointed out by [11], SSL would be more accessible if it could be trained with lesser compute.

This paper builds on our curiosity to answer the following question. “Can we use existing models available online, pre-trained on thousands of hours of data, to improve performance on a rather low-resource ASR task with minimal pre-training and fine-tuning steps?” and if so, “How would a shift in the domain, or language in our labeled fine-tuning data, compared to the original pre-training unlabeled data, affect the performance of our model for ASR?”. Thus, building on the continued pre-training paradigm, we use 1000 hours of unlabelled data from the Interspeech Gram Vaani ASR challenge to pre-train existent models already available online. We also use pre-trained models on a dataset of considerably larger size but originating from a different domain, or language. This pre-trained model is then used as an upstream feature encoder. Feature representations are fed to a task-specific downstream model to learn the task of solving ASR. Our setup is very similar to [12], which was one of the first works to explore speech-based SSL pre-trained as an upstream feature encoder from raw speech. This paradigm of training and feature generation has been relatively under-explored, and our work makes a considerable contribution to exploring this at more depths.

Beyond just achieving considerable improvements over our baselines, contradictory to [8] where the analysis was done on a combined data setup, we do the first of its kind analysis on the
2. Related Work

The past decade has seen an incremental increase in research in SSL in all 3 modalities of speech [4][5][13], text [14] and vision [6][7].

SSL in speech can be divided into 3 major categories. All these categories, irrespective of the objective function they try to optimize, solve some kind of Masked Acoustic Modelling (MAM) task. The first and the most common in this space is contrastive learning which minimizes the InfoNCE loss [15] to learn rich feature representations [4][16][17]. The second learns by minimizing a masked prediction loss wherein each input frame is assigned a pseudo-label either using quantization [18][19] or clustering [5][13][14]. The third paradigm, which has also been gaining attention lately due to its compute-friendly nature is solving a reconstruction-based objective function [20][21][22].

A comprehensive study of all these SSL techniques on various Spoken Language Processing (SLP) downstream tasks can be found in [9].

With research in this field drawing huge attention, it has been of utmost importance to analyze the properties of these learned features and look towards the generalizability of domain, accent, and language and therefore expand their capabilities to building systems beyond native English. Very recently, researchers have made sound efforts to analyze the intrinsic properties of features learned through SSL at various layers of the deep neural networks [23][24][25]. [8] on the other hand, shows that wav2vec-2.0 tends to get biased to the pre-training data domain and domain similarity in the unlabelled data helps the final downstream ASR task. Along similar lines, in this work, we try to analyze the effect of domain and multilinguality, and dataset size of SSL pre-training unlabelled data on our low-resource downstream ASR task. Different from [8], we build on the continued pre-training paradigm [25] which we acknowledge is more sensible in a real-world setup than pre-training from scratch by combining the data.

3. Proposed Methodology

3.1. Problem Formulation

Suppose we have a $I$ high-resource Out of or In Domain/Language datasets from a different source, denoted as $X$ = \{ ($X^1_t$, ..., $X^I_t$) $\}$ where $X^i_t$ = dataset of size $N$ and $X^i_r$ = dataset of size $H$. $X^i_t$ is a dataset of size $H$ from a similar source, where $X = \{ (x^1, ..., x^I, x^J) \}$ and $J = \{ (x^j_t, x^j_r, y^j_t, y^j_r, x^j_h, y^j_h) \}$ where $y$ is the text transcript for utterance $x$. Our primary task here is to use labelled data $J$ to build an End-to-End ASR system. We might want to optionally use $D$ or $L$ in isolation to pre-train a contextualized speech encoder from scratch or first pre-train with unlabelled data from $L$ and continue pre-training it with $D$ upon convergence of $L$. 

3.2. Model Architecture

In this section, we briefly describe our End-to-End (E2E) ASR training setup, including our upstream and downstream setups. Our experiments, including our baselines, use either a non-contextualized feature extractor (Filter-Banks) or a contextualized feature extractor (wav2vec-2.0) as our upstream. We use the conformer-based [26] Encoder-Decoder model as our downstream, which takes as input the features from our upstream and learns the task of ASR.

3.2.1. Upstream

We resort to log-compressed mel Filter-Banks (F-Banks) as our non-contextualized feature extractor upstream. Previous to the self-supervised pre-training era, F-Banks were among the most common low-level feature extractor choices for building efficient ASR systems [28][29]. Thus, as shown in Fig. [1] the F-Bank features extracted from raw audio are directly fed to the downstream model for training on the ASR task.

With the recent dawn of SSL, the use of SSL pre-trained models trained using MAM have shown to be a better alternative to low-level features like F-Banks [12]. As seen in Fig. [1] our setup is similar to [12], where a well-trained SSL model is used as our raw contextualized feature encoder, features from which, similar to our F-Bank setup, are fed into the downstream model for ASR. We resort to wav2vec-2.0 (either of base or large) as our feature encoder for our model, and for a fair comparison to use it just like a F-Bank feature extractor, we don’t fine-tune our upstream model parameters while training on ASR. We acknowledge that fine-tuning the upstream might benefit the ASR task and remains part of our future work. It is to be noted that Context representations from the transformer encoder are used as the upstream features from the wav2vec-2.0 models. The exact SSL training details of wav2vec-2.0 is beyond the scope of this paper, and we refer our readers to [4] for more details.

3.2.2. Downstream

As shown in Fig. [1] our downstream ASR training is based on a joint CTC/attention-based encoder-decoder architecture [27] and conduct all our downstream experiments on the ESPnet toolkit [28]. Our encoder is made up of multiple conformer encoder blocks. While transformer models are well known for capturing global information and data interactions, CNNs effectively capture the local features. A conformer block is made up of a feed-forward module, followed by a self-attention module, a convolution module, and a second feed-forward module [26]. Also, conformer blocks use swish activations [29] which leads to faster convergence of the model. As the Gramvaani Hindi dataset is a corpus of spontaneous telephonic speech data, we believe that the conformer models are better suited to capture the local and global information of the data. Our downstream decoder uses generic transformer blocks and the CTC and attention losses are weighted by hyper-parameters $\alpha$ and $\beta$. 

4. Experiments

4.1. Dataset

The Interspeech Gram Vaani ASR challenge data is a corpus of 1108 hours of real-world, spontaneous telephone speech recordings in multiple dialects of the Hindi language. Of this 1108 hours of data, 1000 hours is unlabelled, 100 hours is the labeled training data, and 5 hours of development data. Blind test data
of 3 hours has been released for evaluation. The audio files were recorded at different sampling rates ranging from 8 kHz to 48 kHz in the mp3 format.

We re-sample all the audios to 16 kHz and convert them to the wav format for our experiments. For the upstream pre-training / continued pre-training of the wav2vec-2.0 models, we use 10 hours of the unlabelled data as a validation set and train on the rest of the 990 hours of unlabelled data. The labeled data from the corpus is used for the downstream ASR training.

4.2. Baselines

As mentioned in section 3.2.2, all of the experiments have been carried out with the same downstream E2E model configuration, the structural details of which will be mentioned in section 4.3. The baseline models differ from the rest of the systems in terms of the upstream used. For the first baseline system, we use 80-dimensional F-BANKs as the features coming from the upstream part of the model. As a second baseline system, we pre-train the wav2vec-2.0 model from scratch on the 1000 hours of unlabelled data and use it as the upstream feature extractor.

4.3. Experimental Setup

4.3.1. Upstream wav2vec-2.0 models

The wav2vec 2.0 models used as the front-end feature extractors have been pre-trained on data from various languages, domains, and datasets of various sizes. Following are descriptions of the datasets used in these pre-trained models.

- XLSR-53: This is a large model pre-trained on 56k hours of data from 53 different languages [30]. The datasets used include Multilingual LibriSpeech (MLS), CommonVoice, and Babel. However, the model could be biased towards the data from European languages as the 50.7k hours of pre-training data comes from 8 European languages.
- LV-60: This is a large model pre-trained on 60k hours of Libri-Light which is a corpus of spoken English audiobook data [3].
- CLSRIL-23: This is a base model pre-trained on 10k hours of raw audio data from 23 Indic languages [31].
- Mono Ekstep: This is a base model pre-trained on 4.2k hours of Hindi data [31].
- LV-60+CV+SWBD+FISH: This is a large model pre-trained on pooled multi-domain data coming from Libri-Light, CommonVoice, Switchboard and Fisher datasets.

- IndicWav2Vec: This is a large model pre-trained on 17k hours of multilingual data from 40 Indian languages [32]. Also, the data used has been sourced from varied domains, including education, news, technology, and finance.

While using these models as upstream feature extractors, we get representations of different dimensions (1024 for large models and 768 for base models). These representation vectors are passed through a linear layer to obtain 80-dimensional features, which are then passed to the downstream End-to-End ASR training system.

4.3.2. Downstream configuration

As mentioned earlier, our downstream model is a conformer-based encoder-decoder model. Our encoder has 12 conformer blocks with 8 attention heads and outputs a 512 dimensional vector representation for each frame which it passes to the decoder. Our decoder has 8 transformer blocks with 8 attention heads too. Best values for $\alpha$ and $\beta$ were found to be 0.3 and 0.1 respectively. For decoding, we don’t use an LM to keep our setup simple and analyze the effect of various upstreams independent of the effect of the LM. While inference we do beam search decoding with a beam size of 20. All optimal hyper-parameters were found via grid-search.

4.3.3. Continued Pre-training

To adapt the openly available pre-trained models mentioned in Sec. to the Gram Vani data, we allow these models to continue pre-training on 1000 hours of Gram Vani unlabelled data. First introduced in [25], continued pre-training (CP) has been proven to be quite effective for unsupervised domain adaptation in NLP.

Other hyper-parameters include a batch size of 1.2m samples per GPU for LARGE models (24 transformer layers and 16 attention heads) and 1.4m samples per GPU for the BASE models (12 transformer layers and 8 attention heads). All pre-training and fine-tuning experiments were conducted on the Fairseq and ESPnet toolkits respectively, with 4 A100 gpus for pre-training and 1 for fine-tuning.

5. Results and Analysis

In this section, we analyze individually, how the factors of language, domain, and dataset size affect the usefulness of feature representations obtained from a pre-trained SSL model, pre-trained on $\mathbf{X} \in \mathbf{I}$, and optionally allowed to continue to pre-train on $\mathbf{L}$, for our final downstream task of learning an ASR using low-resource labeled dataset $\mathbf{J}$. $\mathbf{I}$ here is from a similar source as $\mathbf{J}$, whereas $\mathbf{X}$ is from a different source. Table 1 reports results for all our setups. Our best setups achieve an improvement of 5.3% and 42.1% WER over our F-Bank baselines for 100hrs and 10hrs GramVani fine-tuning respectively, and 4.3% and 6.1% when the model pre-trained from scratch acts as our baselines, over continued pre-training setups. Further, we discuss some of our primary observations w.r.t. the evaluation results on development set, which are as follows:

- **Quality over Quantity**: LV-60+CV+SWBD+FISH performs worse with or w/o continued pre-training than IndicWav2Vec pre-trained with about 1/5th the total amount of unlabelled data. IndicWav2Vec is pre-trained with languages with a similar phonetic structure

6. Conclusion and Future Work

In this paper, we study the effect of upstream pre-training domain, language, dataset size and other aspects like multilingual pre-training and phonetic information sharing in an upstream-downstream ASR fine-tuning setup both with and without CP on source data. We think our work will be useful to the speech community, guiding the use of openly available pre-trained models better, and promote model re-use thereby decreasing carbon footprint. As part of future work, we would like to devise better language and domain adaptation methods for low-resource (both data and compute) pre-training regimes.

- **High-level features from SSL show better effectiveness in ultra-low-resource data regimes:** For our 10hrs GramVani fine-tuning setup, we get an absolute improvement of over 40% WER from our F-Bank baseline, which is better jump than our 100hrs fine-tuning setup.
- **More domains generalize better:** From Wav2Vec2.0-LV-60+CV+SWBD+FSH performs better than Wav2Vec2.0-LV-60 and IndicWav2Vec performs better than CILSIL-23, which conclude that models that see more domains during pre-training learn better domain-agnostic features.

Finally, as mentioned earlier, since we use the weighted sum of all the layers of our upstream model for our downstream ASR fine-tuning, we try to analyze the weights given to each layer by our ASR task for each individual upstream setup with the help of work done in [23]. In lines with the observation made by [23], that representation from layers 16-21 of a wav2vec-2.0 large model has the highest phonetic information, for setups with upstream models pre-trained on Indian languages, our downstream gives maximum attention to these layers and this improves for all models on CP. Additionally, following our results, setups that give the best performance also pay the highest attention to these layers with IndicWav2Vec paying the most thus again re-confirming the advantages of multilingual Indian language pre-training. Consistent with observations in literature [12], the lower (0-7) and higher layers (21-24) play a minimal role throughout all upstream setups.

- **Continued pre-training on source data always helps:** Continued SSL pre-training on L, already converged on X, always helps to improve the effectiveness of feature representations for ASR irrespective of model or dataset size or shift in domain or language of X compared to J. As also seen in Table 1, all models which were allowed to continue to pre-train on the GramVani un-labelled data showed improvement over the ones which were not pre-trained.
- **Language plays a key role in this setup:** Language plays one of the most important roles and it benefits to have a smaller X from the same language than extremely high-resource X from a completely different language with a different phonetic structure. As evident from Table 1, models pre-trained on Indian Languages perform better on ASR fine-tuning with GramVani than models trained on 10× the data but from a different language.
- **Multilingual upstream pre-training helps monolingual downstream fine-tuning for Indian languages:** Indian languages have a similar phonetic structure and pre-training on multilingual Indian data X always helps over monolingual X even if the monolingual is from the same language. A similar observation was also made in [10]. As evident from Table 1, IndicWav2Vec performs better than Mono Ekstep. However, contrary to this, we would like to point out that multilingual pre-training doesn’t help if X is dominant of other languages with a completely different phonetic structure even if X has more hours of data. This is evident from the fact that XLSR-53 performs worse than IndicWav2Vec which pre-trained on both more hours and more languages.
