Abstract
Recent neural network-based language models have benefited greatly from scaling up the size of training datasets and the number of parameters in the models themselves. Scaling can be complicated due to various factors including the need to distribute computation on supercomputer clusters (e.g., TPUs), prevent bottlenecks when infeeding data, and ensure reproducible results. In this work, we present two software libraries that ease these issues: t5x simplifies the process of building and training large language models at scale while maintaining ease of use, and seqio provides a task-based API for simple creation of fast and reproducible training data and evaluation pipelines. These open-source libraries have been used to train models with hundreds of billions of parameters on datasets with multiple terabytes of training data. Along with the libraries, we release configurations and instructions for T5-like encoder-decoder models as well as GPT-like decoder-only architectures.

I:5x and seqio are open source and available at https://github.com/google-research/t5x and https://github.com/google/seqio, respectively.

Keywords: Large language models, data parallelism, model parallelism, data processing
1. Introduction

Neural network models are highly scalable. In particular, Transformers (Vaswani et al., 2017) have been scaled up to hundreds of billions of parameters, demonstrating significant improvements on tasks of interest along the way. However, training models at these sizes is challenging and often demands specialized and hand-tuned software systems, making it difficult to quickly iterate over experimental research ideas. Furthermore, downstream usage and evaluation of these models requires either finetuning or prompting, which must be applied consistently across competing models.

These requirements motivate the development of a framework that enables easy model scaling while remaining research-friendly. JAX (Bradbury et al., 2018; Frostig et al., 2018) is uniquely positioned to provide such benefits; its NumPy-like (Harris et al., 2020) API makes it easy to understand and develop, while the \texttt{jax.pjit} API backed by XLA GSPMD (Xu et al., 2021) provides a powerful and efficient compiler-based programming model for parallelism. In this paper, we present \texttt{t5x}, a JAX-based open-source library that is focused on building Transformer models at a wide range of scales.

As model sizes grow, it becomes increasingly important to train them on larger datasets. We therefore additionally introduce \texttt{seqio}, a fully-featured library for efficiently managing data pipelines and model evaluation with a simple, task-based API. \texttt{seqio} builds off of \texttt{tensorflow.data} with additional support for SPMD-based data parallelism, making it compatible with many modeling frameworks including JAX, TensorFlow (Abadi et al., 2015), and PyTorch (Paszke et al., 2019). \texttt{seqio} includes an option to create deterministic data pipelines, which we have found to be an indispensable tool for optimizing training performance, fairly comparing models, and diagnosing issues during training.

2. \texttt{t5x}

\texttt{t5x} is a library for training, evaluating, and inferring with JAX models across many scales, with a focus on Transformer-based language models. The typical usage involves either pretraining from scratch or finetuning an existing language model implemented in Flax—a JAX-based neural network library (Heek et al., 2020)—and then running inference for evaluations and/or downstream applications. GPU and CPU acceleration are supported, but \texttt{t5x} is optimized for TPU.

In the following subsections, we discuss the design of \texttt{t5x} including how it wraps \texttt{jax.pjit} to provide a high-level interface to XLA GSPMD for simple yet efficient scaling via parameter, activation, and data partitioning.

2.1 Overall structure

Figure 1 illustrates the modular structure of \texttt{t5x}, in particular how \texttt{t5x} uses open-source libraries to implement different functionalities. We briefly describe each of these below.
Figure 1: Overall structure of t5x, showing which dependencies are used to implement the principal functionalities contained in darker boxes.

- **Datasets and Evaluation** - By default, we use seqio to create reproducible “tasks”, which we cover in detail in Section 3. Note that t5x provides a modular structure and may be used without seqio.

- **Checkpointing** - For large models, straightforward tasks like checkpointing can be challenging, especially when using parameter and optimizer partitioning. In order to efficiently manage checkpoints from multiple hosts with distributed parameters, we built our own checkpointing library utilizing TensorStore¹ as a tool for scalably reading and writing sliced tensors.

- **Configuration** - For fast iterations over research ideas, it is important for the code-base to be easily configurable. In particular, researchers should be able to control function arguments and even use custom components without needing to modify the core library code. We use Gin² for this dependency injection. As a typical example, users can inject hyperparameters or a custom model object as function arguments for training. More advanced users can replace entire modules (e.g., a custom checkpointer) in a similar manner.

- **Models** - To actually implement the modeling layers, we use Flax (Heek et al., 2020), a high-level library built on JAX. Section 2.3 discusses a few specialized features in Flax that are required by t5x to enable model parallelism.

- **Partitioning** - One of the key features of t5x is its ability to parallelize over data, parameters, and activations. We use the XLA GSPMD partitioner (Xu et al., 2021) to automatically shard the computation graph and use jax.pjit as a frontend to interact with GSPMD, providing our own high-level API to simplify configuration. Section 2.2 will discuss this component in further detail.

2. https://github.com/google/gin-config
2.2 XLA GSPMD partitioning with jax.pjit

Many different kinds of parallelism are useful for scaling large models. In data parallelism, the input data and intermediate activations are split over devices (“partitioned”) along the global batch axis. In (tensor) model parallelism, the model computation for a single example, and the model parameters themselves, are split across devices.

These two kinds of parallelism are orthogonal, in that a system with \( N = M \times D \) devices can use \( M \)-way model parallelism and \( D \)-way data parallelism at the same time. t5x assumes such a decomposition of the devices in the system into a model parallel axis (specified in multidimensional TPU networks as a “model parallel submesh”) and a data parallel axis or submesh.

t5x has built-in support for multiple variants of data and model parallelism, i.e., multiple ways to use these two orthogonal axes:

- **Data parallelism** is parallelism in the batch dimension. It can also involve either replicating the parameters and optimizer state or sharding them over the data parallel axis. The former is also termed “1D parameter partitioning”, since parameters are only subject to model parallel partitioning over one array axis, while the latter is “2D parameter partitioning” since a second array axis in each parameter is also partitioned.

- **Model parallelism** involves partitioning model computation over axes other than the batch dimension. In Transformers, it involves partitioning parameters and some intermediate activations along axes like the MLP hidden dimension and the heads dimension. Other intermediate activations (those with an embedding/model axis but not hidden/heads) can either be replicated over the model parallel axis (“1D activation partitioning”) or sharded (“2D activation partitioning”).

These options correspond to previously described parallelism techniques: 2D parameter partitioning is also known as ZeRO-3 (Rajbhandari et al., 2020) or fully sharded data parallelism; 1D activation partitioning is also known as Megatron (Shoeybi et al., 2019) and is the default in the Mesh TensorFlow Transformer (Shazeer et al., 2018); and 2D activation partitioning is the “fully sharded” case described in Xu et al. (2021).

t5x supports flexible partitioning configurations, including these built-in options, using the Flax APIs described in the following section.

2.3 Model Implementation

**t5x** is compatible with Flax-based model implementations with some minor caveats. In order to support flexible configurations for parameter and activation partitioning, **t5x** requires these tensors to be annotated with user-defined logical named axes when they are defined in the model implementation, via `flax.partitioning.param_with_axes`. These logical axes are used to group tensor dimensions that one would expect to always partition in the same way in various settings, for example “batch” (for partitioning across examples in a batch), “kv” (for partitioning across the dimensions of key-value matrices in Transformer self-attention layers), or “head” (for partitioning across heads in multi-headed attention). While XLA GSPMD will automatically select matching partitions for the intermediate activations produced by these parameters, users may also provide overrides by
naming their axes as well via `flax.partitioning.with_sharding_constraint` to better optimize memory usage and between-device communication.

At runtime, the user provides a mapping from each logical axis name to one of the two hardware axes (model and data). Alternatively, the logical axis can be mapped to None to specify that it should be replicated across all devices.

Given a `flax.nn.module` module implemented as described above, one must simply wrap it in a subclass of `t5x.BaseModel` to define its loss, evaluation, and inference methods to make it compatible with the core `t5x` interface.

With its modular design, the model implementations in `t5x` can be flexible. Layers and modules can be written directly with Flax (e.g., the “Minimal” implementations discussed in Section 4) or using a higher-level library such as Flaxformer. Dependency injection with Gin allows users to easily swap the module implementation in their configuration. Even when implemented in different libraries, the model checkpoints can be made compatible. Additionally, models trained with the legacy T5 codebase based on Mesh TensorFlow can be read directly by `t5x`. They can also be converted to the native `t5x` format resulting in faster reading based on how `t5x` leverages TensorStore.

3. seqio

`seqio` is a library for processing data to be fed into models for training, inference, and evaluation. It uses `tensorflow.data` to create scalable data pipelines but requires minimal use of TensorFlow. In particular, with one line of code, the returned dataset can be transformed to a NumPy iterator and hence it is fully compatible with other frameworks such as JAX or PyTorch.

3.1 Task-based API

```
def preprocess(dataset):
    ...
    ...
    return preprocessed_dataset

def metric_fn(predictions, targets):
    ...
    ...
    return metrics
```

Figure 2: Structure of a `seqio` Task, highlighting customizable use of APIs.

A key differentiator of `seqio` from most other dataset frameworks is its use of a task-based API, which is illustrated in Figure 2. The Task object associates raw data sources

with preprocessing steps—to define the inputs and targets—and evaluation metrics—to create consistent benchmarks. Feature converters are used to convert task features into the raw values that will be fed into the model itself. This way the same task can be made compatible with various architectures (e.g., encoder-decoder or decoder-only).

Multiple Tasks can also be combined into a Mixture for multi-task training, with user-provided mixing rates.

3.2 Deterministic Pipelines

`seqio` also provides the ability to generate deterministic data pipelines with following key features:

- **Reproducibility** - Data read from a deterministic Task/Mixture is always in the same order, which is important for dataset debugging and inspection. It also allows the dataset to be held constant for more accurate benchmarking or when debugging training issues.

- **Recoverability** - A deterministic dataset can be continued from an arbitrary point in training. This avoids repeating data on intentional or unintentional (e.g., due to preemption) training restarts, which can lead to reduced performance and memorization (Lee et al., 2022). We have also found it useful for manually skipping batches of a dataset that produce instabilities during training.

- **Sharding** - Data can be arbitrarily sharded across any number of readers to enable efficient distributed reads from data-parallel workers.

- **Global Shuffling** - Deterministic datasets are prepared by an offline job that ensures data is well-shuffled. This is particularly important when examples are correlated (e.g., they are based on the same source document) or multiple epochs are used.

To achieve these requirements, once a Deterministic Task/Mixture is defined, a distributed caching job (implemented in Apache Beam\(^5\)) loads the raw data, preprocesses and shuffles the examples, assigns ordered indices, and writes the data to sharded files. Importantly, the examples are sharded by the modulo of their index to the number of files. This enables each set of data parallel hosts to sequentially read an interleaved exclusive set of files at train time, helping to optimize throughput and greatly reducing the chance of an input bottleneck.

We have found these four features to be beneficial when training extremely large models. They increase throughput, protect against overfitting, ease debugging, and provide fine-grained control over the examples seen during training in order to avoid instabilities. We expect this control to also be useful for researchers interested in understanding how specific aspects of the dataset (e.g., order and repeats) might affect the model’s ability to generalize or memorize.

4. Example Models

With t5x, we provide well-tested\(^6\) “Minimal” model implementations with checkpoints:

- T5 from Raffel et al. (2020) and T5.1.1 (introduced after the paper).
- Scalable T5
- mT5 (Xue et al., 2021)
- ByT5 (Xue et al., 2022)

These model implementations are minimal in the sense that they only use Flax with limited abstractions as opposed to using higher-level libraries built on top of Flax (e.g., Flaxformer). They closely mimic the pedagogical Flax examples\(^7\).

Scalable T5 is an implementation of T5.1.1 using \texttt{jax.scan} to significantly reduce compilation time and provide finer-grained control over activation memory.

We also provide a model configuration (without any checkpoints) for a decoder-only architecture that is compatible with LaMDA (Thoppilan et al., 2022).

5. Related Work

There are many open source libraries for training sequence models. Previous Google-released systems based on TensorFlow include Tensor2Tensor (Vaswani et al., 2018), Lingvo (Shen et al., 2019), and the Mesh TensorFlow (Shazeer et al., 2018)-based T5 (Raffel et al., 2020).

Comparable projects from other research groups include model libraries such as fairseq (Ott et al., 2019), large-scale parallelism libraries such as FairScale (Baines et al., 2021), and libraries that include both kinds of functionality such as DeepSpeed (Rasley et al., 2020) and Megatron (Smith et al., 2022).

Some major differentiators of t5x are its use of JAX and Flax for model expression, its support for TPU (including TPU v4), and its Gin-based configuration system that allows users to modify nearly everything about the model and training procedure. t5x also doesn’t support pipeline parallelism, a major component of systems like DeepSpeed. This is because the inter-chip network of TPUs has performance similar to within-node GPU interconnects but scales to thousands of chips, so model and data parallelism are sufficient to train efficiently at large scale.

6. Project Status and Adoption

We started the project in the fall of 2020 and open sourced the library code in October 2021. During that time, t5x and seqio achieved widespread adoption by teams across Google: t5x has been launched on TPU hundreds of thousands of times at Google, and the total number of internal t5x and seqio users exceeds 1,000. Teams are using these libraries for research projects (from small-scale research to the largest language models trained at Google) and user-facing products. External adopters include academic and commercial users of Cloud TPUs, such as portions of the the Big Science project (Wang et al., 2022).

---

\(^6\) We validated these models by reproducing the T5 models from Raffel et al. (2020), originally implemented in Mesh TensorFlow Transformer.

\(^7\) \url{https://github.com/google/flax/tree/main/examples}
Users of t5x and seqio cite the usability and research-friendliness of the libraries as reasons for adoption. We are continuing to actively develop both libraries, prioritizing future work based on researcher needs and feedback.

7. Contributions

Adam Roberts founded and leads the project, designed and wrote much of seqio and t5x, and co-authored the paper. Hyung Won Chung designed and wrote much of t5x, led its open sourcing, and co-authored the paper. Anselm Levskaya built the initial prototype for t5x and wrote much of the code. Gaurav Mishra leads seqio, implemented deterministic pipelines, and co-authored the paper. James Bradbury implemented partitioning in t5x and co-wrote the paper.

Noah Fiedel is a member of the leadership team, contributed to the high level design and roadmap, and co-wrote the paper. Mark Omernick, Brennan Saeta, Ryan Sepassi, Alexander Spiridonov (Product Manager), and Josh Newlan (Technical Program Manager) are members of the leadership team and co-wrote the paper. Andrea Gesmundo is a member of the leadership team and contributed to the internal infrastructure component.

Thanks to Douglas Eck and Zoubin Ghahramani for sponsoring the project.
