Abstract

We exploit a new theory of gravity proposed by Finzi, which gives stronger interaction at large scales, to study the thermodynamic description of galaxy clusters. We employ a statistical model to deduce various thermodynamics equations of state. In addition, we analyze the behavior of clustering parameter in comparison to its standard (Newtonian) counterpart. The general distribution function and its behavior with varying strength of clustering parameter are also studied. The possibility of phase transition is also investigated and observed that a phase transition is possible though hierarchically.

Keywords: Finzi gravity; Distribution function of galaxies; Phase transition.

I. INTRODUCTION

The large scale distribution of the matter is mainly described by the gravitational interaction. It is believed that the large scale structure of the universe is a gravitationally amplified descendant of a faint noise field believed to be seeded by quantum fluctuations in the early universe. A linear theory for initial perturbations to the present observed matter distribution has been developed extensively [1]. The formation of first structures in the universe took place at a red-shift of $10^{-30}$ in the dark matter halos of masses, $M > 10^5 - 10^8 M_\odot$ [2]. This structure formation took place on the imprints of small matter density perturbations in the primordial matter density field. Present day $N$-body simulations have confirmed that the initial density perturbations have the potential to grow to the present day observed structure [3].

It is well-known that the velocity of galaxies in a cluster doesn’t agree well with the total mass of the visible matter. The estimated mass was $200 - 400$ times less than the mass required to prevent the rupture of the galaxies from the cluster [4]. This led to the concept of dark matter. Although there is a strong support to the dark matter hypothesis but the identification of the particles that compose this matter is yet under discussion. One explanation to this could be a strong correlation between baryonic matter [5] and dark-matter. The other intriguing idea could be a relevance of modified Newtonian dynamics (MoND) at large scales.

The formation and distribution of galaxy clusters are crucial to understand the evolution of the structure formation in the universe. Saslaw and Hamilton developed a thermodynamic model for nonlinear regime of the clustering of galaxies in an expanding universe [6]. The theoretical predictions of this model involve the distribution of voids as well as galaxies corresponding to under-dense and over-dense regions, respectively, in the initial density field. The probability distribution function predicted by this theory for $N$ number of galaxies in volume $V$ is given by

$$ f(N) = e^{-N(1-b)-N_b} \frac{\bar{N}(1-b)}{N!} \left[ \bar{N}(1-b) + Nb \right]^{N-1}, \quad (1) $$
where $\bar{N}$ is the average number of particles found in volume $V$ and $b$ is clustering parameter.

It is established that the force accounting for the flat rotation curve of galaxy clusters requires an enhancement at larger distances than predicted by Newtonian gravity. In recent past, there have been a number of modifications to general relativity [7] to account for this discrepancy. For instance, in $f(R)$ gravity, an additional term having function $f(R)$ of Ricci curvature is added to account for the enhanced gravitational force on large scales. The force field that governs the large scale structure formation also governs the distribution of mass at this scale. We can employ statistical methods to find the statistical distribution of matter at largest possible scales [8]. Recently there has been a lot of progress on the study of the effect of modified gravity theories on the clustering of galaxies through statistical methods [9–18]. The effect of the modifications incorporated has been anticipated in the strength of the clustering parameter $b$. For instance, in [13], the modified clustering parameter has been studied as a function of the modification factor.

In 1963, Finzi proposed a law of gravitation that gives a stronger interaction at relatively larger distances than predicted by Newton’s law of gravity [19]. This force form can explain the larger velocities of galaxies in clusters without involving the concept of dark matter. The potential energy function proposed by Finzi is given by

$$\Phi(r) = G_* m^2 \left( \frac{1}{r^{1/2}} \right),$$

(2)

where $G_* = -2k/\rho^{1/2}$, $k$ is a constant (equivalent to gravitational constant $G$) and $\rho$ is a characteristic length beyond which the potential becomes significant. This potential reduces to the usual Newtonian potential at distances $\rho \approx r$. The correlation and distribution function of galactic cluster are not studied for Finzi approximation. Here, we try to bridge this gap and also make a comparison of the effect of this model to the already studied theories.

Our investigations are presented systematically as following. First, we construct the partition function under Finzi potential for the system of galaxies in section III. Here, in order to avoid divergence, we consider extended nature of galaxies. In section III...
we derive the various thermodynamic equations of state along with their behavior under different circumstances, e.g., Helmholtz free energy, pressure, internal energy, entropy and chemical potential. In section [IV] we compare the clustering parameters with increasing radial distance corresponding to Newtonian and Finzi gravity. In section [V] we study the effects of this new force form on the statistical distribution of the galaxy clusters. The power-law behavior for the correlation function is presented in section [VI]. Finally we investigate the possibility of phase transition in section [VII]. We conclude the results and their importance in the last section.

II. THE PARTITION FUNCTION

In this section, we develop the partition function by taking into consideration a system of particles interacting gravitationally through Finzi gravity. We assume the clustering of galaxies in the expanding background to be in quasi-equilibrium state forming an ensemble of co-moving cells. We consider our system consists of a larger number of cells (ensemble of cells) of equal volume $V$ with an average number density $\bar{N}$. The partition function for such a system of pairwise interacting particles having correlation energy $\Phi$ and average temperature $T$ is given by \[ Z_N(T, V) = \frac{1}{N!} \left( \frac{2\pi mT}{\lambda^2} \right)^{\frac{3N}{2}} Q_N(T, V). \] (3)

Here, $N!$ takes care of distinguishability of the system and $\lambda$ is a normalization factor. Boltzmann’s constant is set to unity here. The configuration part of the equation (3) can be written as

\[
Q_N(T, V) = \int \cdots \int \exp \left[ -T^{-1} \Phi(r_1, r_2, \ldots r_N) \right] d^{3N}r.
\] (4)

The gravitational potential energy function $\Phi(r_1, r_2, \ldots r_N)$ is a function of the relative positions $r = |r_i - r_j|$ and is summed over all the pairs of particles. In our system of gravitating bodies, the potential energy $\Phi(r_1, r_2, \ldots r_N)$ of the system is due to all pairs of
particles of the system, i.e.

$$\Phi(r_1, r_2, ... r_N) = \sum_{1 \leq i \leq j \leq N} \Phi_{ij}(r).$$  \hspace{1cm} (5)

With this simplification (5), equation (4) can now be written as

$$Q_N(T, V) = \int ... \int \prod_{1 \leq i \leq j \leq N} \exp \left[ -T^{-1} \Phi_{ij}(r) \right] d^3r_i, \hspace{1cm} (6)$$

where $\Phi_{ij}$ is the two point interaction energy between the $i^{th}$ and $j^{th}$ particle. The configuration integral can be written in terms of two-point function $f_{ij} (= e^{-\frac{\Phi_{ij}}{T}} - 1)$ defined as:

$$Q_N(T, V) = \int ... \int (1 + f_{12})(1 + f_{13})(1 + f_{23})(1 + f_{14})...(1 + f_{N-1,N})d^3r_1d^3r_2...d^3r_N. \hspace{1cm} (7)$$

Here, we note that the two-point function $f_{ij}$ is non-zero only when there are interactions present. The Finzi potential (2) diverges for the point-particle nature of galaxies. Therefore, we need to express potential (2) by considering the extended nature of galaxies (galaxies with halos). This is done by introducing the softening parameter $\epsilon$ ($0.01 \leq \epsilon \leq 0.05$) in the potential as

$$\Phi(r) = \frac{G_s m^2}{(r + \epsilon)^{1/2}}. \hspace{1cm} (8)$$

By substituting the two-point function corresponding to potential (8) in equation (7), the values of $Q_N$ for different values of $N$ can be calculated. For $N = 1$, we have

$$Q_1(T, V) = V. \hspace{1cm} (9)$$

For $N = 2$, the integral is evaluated by fixing the position of $r_1$ and evaluating over all the other particles. In this way the integral simplifies to

$$Q_2(T, V) = V^2[1 + X\alpha],$$

where $X = \frac{2G_s m^2}{T \epsilon^{1/2}}$ and $\alpha = \sqrt{1 + \frac{2}{\epsilon}[3 - 4(\epsilon/r) + 8(\epsilon/r)^2 - (\sqrt{\epsilon/r}8(\epsilon/r)^2)]}$. 

Proceeding in similar fashion, the values of $Q_N$ for $N = 3, 4, 5, ..., N$ can be obtained. E.g., for $N = 3$, we get

$$Q_3(T, V) = V^3 \left[ 1 + X\alpha \right]^2.$$  

In general the above equation for $N$ number of particles takes the form,

$$Q_N(T, V) = V^N \left[ 1 + X\alpha \right]^{N-1}. \quad (10)$$

Finally, substituting equation (10) into equation (3), we obtain the general partition function for a gravitating system of $N$ pairwise interacting particles (galaxies) as

$$Z_N(T, V) = \frac{1}{N!} \left( \frac{2\pi mT}{\Lambda^2} \right)^{\frac{3N}{2}} V^N \left[ 1 + \alpha X \right]^{N-1}. \quad (11)$$

Equation (11) is the standard form of canonical partition function for a system of $N$ particles interacting through the new gravity law (2). The modification is inherent in the parameter $\alpha$.

III. THERMODYNAMIC EQUATIONS OF STATE

The partition function equation (11) contains all the necessary information about the macroscopic variable (free energy, entropy, internal energy, pressure, chemical potential) of the system. The Helmholtz free energy for the system of galaxies can be deduced from the partition function via the general statistical relation $F = -T \ln Z_N(T, V)$. For our system of galaxies the free energy takes the following form:

$$F = NT \ln \left( \frac{N V T^{-\frac{3}{2}}}{\Lambda^2} \right) - NT - \frac{3}{2} NT \ln \left( \frac{2\pi mT}{\Lambda^2} \right) - NT \ln[1 + X\alpha],$$

$$= NT \ln \left( \frac{N V T^{-\frac{3}{2}}}{\Lambda^2} \right) - NT - \frac{3}{2} NT \ln \left( \frac{2\pi mT}{\Lambda^2} \right) + NT \ln[1 - b_n]. \quad (12)$$

Here, we approximated $N - 1 \approx N$. In equation (12), the parameter $b_n$ is defined as

$$b_n = \frac{\alpha X}{1 + \alpha X}. \quad (13)$$

This is the new clustering parameter which estimates the strength of correlation that governs the evolution of the galaxy cluster and can take values between 0 and 1.
FIG. 1: Variation of the free energy of the system with particle number for different values of the $\alpha$ and unit value for the rest of parameters.

Once the free energy is known, other thermodynamic equations of state can be estimated easily. For example, the entropy of the system of galaxies can be obtained using the relation, $S = -\left(\frac{\partial F}{\partial T}\right)_{V,N}$. Utilizing equation (12), the entropy of the system takes the following form:

$$S = N \ln \left(\frac{V}{NT}^{3/2}\right) + N \ln[1 + X\alpha] - 3N \frac{X\alpha}{1 + X\alpha} + \frac{5}{2} N + \frac{3}{2} N \ln \left(\frac{2\pi m \lambda^2}{\alpha^2}\right).$$

(14)

Entropy per particle of the system correspond to equation (13) can be written as

$$\frac{S}{N} = \ln \left(\frac{V}{NT}^{3/2}\right) - \ln[1 - b_n] - 3b_n + \frac{5}{2} N + \frac{3}{2} \ln \frac{2\pi m}{\lambda^2},$$

(15)

The total internal energy of the system of galaxies can be calculated using the basic definition, $U = F + TS$. Substituting the values of free energy (12) and entropy (13), the relation for internal energy in terms of the new clustering parameter takes the form

$$U = \frac{3}{2} NT \left[1 - 2 \frac{X\alpha}{1 + X\alpha}\right]$$

$$= \frac{3}{2} NT [1 - 2b_n].$$

(16)

The graphical representation of the effect of the New clustering parameter on the internal
FIG. 2: The variation of entropy \((S - S_0)\) with an increasing particle number for different values of clustering parameter \(b_n\).

FIG. 3: The variation of internal energy \(U\) as a function of particle number for different values of correlation parameter \(b_n\).

energy function for the system of galaxies can be visualized in Fig. 3

Similarly we can calculate the pressure caused by the particles within the system utilizing the fundamental definitions \(P = -\left(\frac{\partial F}{\partial V}\right)_{T,N}\). The pressure of the system takes the form:
\[ P = \frac{NT}{V} \left[ 1 - \frac{X\alpha}{1 + X\alpha} \right], \]
\[ = \frac{NT}{V} [1 - b_n]. \tag{17} \]

Finally, we can deduce the relation for the chemical potential of the system using,
\[ \mu = \left( \frac{\partial F}{\partial N} \right)_{T,V} \] as
\[ \mu = T \left( \ln \frac{N}{V} T^{-1/2} \right) + T \ln \left[ 1 - \frac{X}{1 + X} \right] - T \frac{X}{1 + X} - \frac{3}{2} T \ln \left( \frac{2\pi m}{\lambda^2} \right), \]
\[ = T \left( \ln \frac{N}{V} T^{-3/2} \right) + T \ln [1 - b_n] - T b_n - \frac{3}{2} T \ln \left( \frac{2\pi M}{\chi^2} \right). \tag{18} \]

The graphical representation of the variation of the chemical potential with an increase in the particle number can be seen in figure (5).

IV. A COMPARISON OF NEW AND OLD CLUSTERING PARAMETER

In this section the clustering parameter \( b_n \) developed in this work based on the Finzi model of gravity is compared with the standard parameter \( b \) defined in \[8\]. The clustering
FIG. 5: The graph shows the behavior of the chemical potential $\mu(N)$ of the system as a function of particle number for different values of clustering parameter $b_n$. Parameter $b_n$ gives the strength of correlation and will in turn decide the time-length of clustering. From the graph (Fig. (6)) it can be seen the new clustering parameter is more stronger than the standard one. This is due to the effect of the increased strength of the potential energy function at large distances as defined in the Finzi model.

FIG. 6: A comparison of the standard clustering parameter $b$ with the new parameter $b_n$
V. GENERAL DISTRIBUTION FUNCTION

The general form of the distribution function \( f(N) \), which characterizes the galaxy clustering, contains the distribution of voids as well as the number of galaxies in fixed volume cells distributed throughout the system. Here we let the system particles to cross the cell boundaries which in turn can change the particle number in each cell. Thus we derive the grand canonical partition function defined as

\[
Z_G(T, V, z) = \sum_{N=0}^{\infty} \exp \left( \frac{N\mu}{T} Z_N(T, V) \right).
\]

(19)

The probability distribution function of finding \( N \) particles contained in a cell of volume \( V \) in a grand canonical ensemble is given by

\[
F(N) = \sum_{i=0}^{N} \exp \frac{N\mu}{T} \frac{\exp -U}{Z_G(T, V, z)},
\]

\[
= \frac{\exp \frac{N\mu}{T} Z_N(T, V)}{Z_G(T, V, z)}.
\]

(20)

Here, the factor \( z = \exp \mu \) (fugacity) determines the activity of the system. From this basic relation equation (20), we can determine the general form of distribution function for our system of galaxies. Using the partition function (19) with chemical potential equation (11) the distribution function takes the following form:

\[
F(N) = \frac{\bar{N}}{N!} (1 - b_n) \left[ \bar{N}(1 - b_n) + Nb_n \right]^{N-1} \exp -Nb_n - \bar{N}(1 - b_n).
\]

(21)

Till here

From equation (21) we confirm the basic structure of the distribution function is same for Finzi model of gravity as has been derived by Saslaw and Hamilton for Newtonian gravity \([6, 12]\). The graphical representation of the probability distribution function as a function of particle number \( N \) in is shown in figure 7. From the figure, it is clearly visible that the peak of the distribution function has flattens as the value of the clustering parameter shifts to higher values.
VI. POWER LAW FOR TWO-POINT CORRELATION FUNCTION

Here we study the behavior of the two-point correlation function in the new model of gravity. We write the clustering parameter in the form [20]

\[ b_n = \frac{G_s \bar{\rho}}{6T} \int \left[ \frac{1}{(r + \epsilon)^{1/2}} \right] \xi_2(\rho, r, T) dV, \]  

(22)

where \( \bar{\rho} \) is the number density and \( \xi_2 \) is the two-point correlation function.

Differentiating with respect to \( V \), equation (22) yields

\[ \frac{\partial b_n}{\partial V} = \frac{G_s \bar{\rho}}{6T} \frac{\partial}{\partial V} \int \left[ \frac{1}{(r + \epsilon)^{1/2}} \right] \xi_2(\rho, r, T) dV \]

\[ + \frac{G_s}{6T} \left( - \frac{\partial \bar{\rho}}{\partial V} \right) \int \left[ \frac{1}{(r + \epsilon)^{1/2}} \right] \xi_2(\rho, r, T) dV, \]  

(23)

where we have used \( \frac{\partial V}{\partial \bar{\rho}} \rho = - \frac{\bar{\rho}}{V} \).

Using the relation \( \frac{\partial b_n}{\partial \bar{\rho}} = \frac{b_n (1 - b_n)}{\rho} \) and equation (23), we obtain the following expression for the power law

\[ \xi_2(r) = \frac{9T b_n^2}{2\pi G_s \bar{\rho}} \left( \frac{1}{(r + \epsilon)^{1/2}} \right). \]  

(24)

The graphical representation of the two point correlation function can be visualized from the figure (8). We can see the strength of the correlation function decreases with increasing...
radius. This leads us to an important result about the correlation of system points in different cells. The galaxies within a cell are more correlated than the galaxies in the adjacent cells. Thus the transfer of system points from cell to cell are less likely although not negligible.

![Graphical representation of the two point correlation function \( \xi(r) \) with increasing radial distance, \( r \), for different values of clustering parameter \( b_n \).]

**FIG. 8**: Graphical representation of the two point correlation function \( \xi(r) \) with increasing radial distance, \( r \), for different values of clustering parameter \( b_n \).

**VII. POSSIBILITY OF PHASE TRANSITION**

If an interaction is introduced in a system characterized by Poisson distribution the system has a high chance of changing phase from less correlated to highly correlated. The possibility of phase transition in case of our system of galaxies interacting gravitationally can not be ignored. Here we will try to find out if the Finzi interaction can cause a phase transition in the system of gravitationally interacting point particles. The result is important as the possible phase transition can break the homogeneity of the system and cause lumpiness in the structure. Among many indicators of phase transition, specific heat is an important candidate to track.

The specific heat (at constant volume) \( C_V \) is defined as

\[
C_V = \frac{1}{N} \left( \frac{\partial U}{\partial T} \right)_{N,V}.
\]
Using the relation for internal energy \((16)\), the specific heat of the system takes the following form
\[
C_V = \frac{3}{2} \left[ \frac{1 + 6\alpha X - 4\alpha^2 X^2}{(1 + \alpha X)^2} \right].
\]
\((26)\)

As \(b_n \to 0, C_V \to 3/2\), this corresponds to no interaction among the system particles. As \(b_n \to 1, C_V \to -3/2\), which means the system is fully virialized. Between these two extreme values lies the maximum values of specific heat at some critical value of temperature. This extreme value of specific heat indicates a possible phase transition at \(T = T_C\).

\[
\left. \frac{\partial C_V}{\partial T} \right|_{T=T_C} = 0.
\]

This gives an expression for the critical temperature as
\[
T_C = \left[ \frac{3}{\bar{N} V} (GM^2)^3 \alpha \right]^{1/3}.
\]
\((27)\)

In terms of critical temperature the specific heat \(C_V\) given in \((26)\) can be expressed as
\[
C_V = \frac{3}{2} \left[ 1 - \frac{1 - 4 (T/T_C)^3}{1 + 2 (T/T_C)^3} \right]^2.
\]
\((28)\)

At \(T = T_C, C_V = 5/2\), a property of a diatomic gas. This is an indication of system symmetry breaking due to the formation of binaries. The phase transition is hierarchical and not spontaneous as observed in many other physical systems. The graphical behavior of the specific heat can be visualized in figure \((9)\).

\section*{VIII. CONCLUSION}

The velocities of galaxies in a cluster are much higher than depicted by the visible matter that brings in the concept of gravitating non-visible matter called dark matter. While the hunt for the exact description is underway, it is plausible to reconsider Newtonian dynamics and modify it to fit the observed data. A proposition of a new gravity law applicable at higher scales is also not vague.
FIG. 9: The behavior of specific heat $C_V$ with changing system temperature $T/T_C$. We observe that the system symmetry breaks around the critical temperature, $T = T_C$.

In this work, we have considered a gravitational potential proposed by Finzi and, by using statistical methods, we deduced various thermodynamic quantities along with correlation function. The graphical analysis of various thermodynamic equations of state was also done. A new clustering parameter was deduced based on this theory which shows a greater strength as compared to the standard one. We have also made a graphical comparison of the the clustering parameters for Finzi and Newtonian gravity. From the behavior of the clustering parameter, it is obvious that the Finzi model of gravity at larger scale is more significant. The power-law of correlation function for Finzi model is also discussed. We also studied possible phase transition within the system.

Society, 204(3), 891-907.
