To Explore or Not to Explore: Regret-Based LTL Planning in Partially-Known Environments

Jianing Zhao, Keyi Zhu, Xiang Yin and Shaoyuan Li

Abstract—In this paper, we investigate the optimal robot path planning problem for high-level specifications described by co-safe linear temporal logic (LTL) formulae. We consider the scenario where the map geometry of the workspace is partially-known. Specifically, we assume that there are some unknown regions, for which the robot does not know their successor regions a priori unless it reaches these regions physically. In contrast to the standard game-based approach that optimizes the worst-case cost, in the paper, we propose to use regret as a new metric for planning in such a partially-known environment. The regret of a plan under a fixed but unknown environment is the difference between the actual cost incurred and the best-response cost the robot could have achieved if it realizes the actual environment with hindsight. We provide an effective algorithm for finding an optimal plan that satisfies the LTL specification while minimizing its regret. A case study on firefighting robots is provided to illustrate the proposed framework. We argue that the new metric is more suitable for the scenario of partially-known environment since it captures the trade-off between the actual cost spent and the potential benefit one may obtain for exploring an unknown region.

I. INTRODUCTION

Path planning is one of the central problems in autonomous robots. In this context, one needs to design a finite or infinite path for the robot, according to its dynamic and the underlying environment, such that some desired requirements can be fulfilled. In many robotics applications such as search and rescue, persistent surveillance or warehouse delivery, the planning tasks are usually complicated evolving spatial and/or temporal constraints. Therefore, in the past years, robot path planning for high-level specifications using formal logics has been drawing increasingly more attentions in the literature; see, e.g., [1]–[5].

Linear temporal logic (LTL) is one of the most popular languages for describing high-level specifications, which supports temporal operators such as “always”, “eventually” or “next”. In the context of robotic applications, path planning and decision-making for LTL specifications have been investigated very extensively recently. For example, [6], [7] studied how to generate an optimal open-loop plan, in the so-called “prefix-suffix” structure, such that a given LTL formula is fulfilled. When the results of control actions are non-deterministic, algorithms for synthesizing reactive strategies have been developed using two-player games [8], [9]. The LTL path planning problem has also been studied for stochastic systems [10], [11] to provide probabilistic guarantees and for multi-robot systems [12]–[14] under both global and local tasks.

The aforementioned works on LTL path planning all assume that the environment is known in the sense that the map geometry and the semantic structure are both available at the planning stage. In practice, however, the environment may be partially-known such that the robot needs to explore the map geometry as well as the region semantics on-the-fly. To this end, in [15], the authors provided a re-planning algorithm based on the system model updated online. In [16], the authors proposed an iterative planning algorithm in uncertain environments where unknown obstacles may appear. A learning-based algorithm is proposed in [17] for LTL planning in stochastic environments with unknown transition probabilities. Recently, [18] investigated the LTL planning problem under environments with known map geometries but with semantic uncertainties.

In this paper, we also investigate the LTL path planning for robots in partially-known environments. Specifically, here we assume that the location of each region in the map is perfectly known but, for some regions, the robot does not know their successor regions a priori unless it reaches these regions physically. For example, in Figure 1, the dashed line between regions 2 and 5 denotes a possible wall that may prevent the robot from reaching region 5 directly from region 2. Initially, the robot knows the possibility of the wall, but it will actually know the (non-)existence of the wall only when reaching region 2. Here, we distinguish between the terminologies of non-deterministic environments and partially-known environments. Specifically, the former is referred to the scenario where the outcome of the environment is purely random in the sense that even for the same visit, the environment may behave differently. However, the partially-known environment is referred to the case where the robot has information uncertainty regarding the true world.
initially, but the underlying actual environment is still fixed and deterministic.

To solve the path planning problem in partially-known environments, a direct approach is to follow the same idea for planning in non-deterministic environments, where game-based approaches are usually used to minimize the worst-case cost. Still, let us consider Figure 1, where the robot aims to reach target region 5 with shortest distance. Using a worst-case-based approach, the robot will follow the red trajectory. This is because the short-cut from regions 2 to 5 may not exist; if it goes to region 2, then in the worst-case, it will spend additional effort to go back. However, by taking the red trajectory, the robot may heavily regret by thinking that it should have taken the short-cut at region 2 if it knows with hindsight that the wall does not exist. Therefore, a more natural and human-like plan is to first go to region 2 that the wall does not exist. Therefore, a more with hindsight may not exist; if it goes to region 2, then it should have taken the short-cut at region 2.

Section [III] we present the mathematical model for partially-known environments and introduce regret as the performance metric. In Section [IV] we transfer the planning problem as a two-player game and solve the problem. A case study on firefighting robot is provided in Section [V]. Finally, we conclude the paper in Section [VI].

II. LTL PLANNING IN FULLY-KNOWN ENVIRONMENTS

In this section, we briefly review some necessary preliminaries and the standard approach for solving the LTL planning problem in a fully-known environment.

A. Weighted Transition Systems

When the environment of the workspace is fully-known, the mobility of the agent (or map geometry) is usually modeled as a weighted transition system (WTS)

\[ T = (X, x_0, \delta_T, w_T, \mathcal{AP}, L), \]

where \( X \) is a set of states representing different regions of the workspace; \( x_0 \in X \) is the initial state representing the starting region of the agent; \( \delta_T : X \rightarrow 2^X \) is the transition function such that, starting from each state \( x \in X \), the agent can move directly to any of its successor state \( x' \in \delta_T(x) \). We also refer \( \delta_T(x) \) to as the successor states of \( x \); \( w : X \times X \rightarrow \mathbb{N} \) is a cost function such that \( w(x, x') \) represents the cost incurred when the agent moves from \( x \) to \( x' \); \( \mathcal{AP} \) is the set of atomic propositions representing some basic properties of our interest; \( L : X \rightarrow 2^{\mathcal{AP}} \) is a labeling function that assigns each state a set of atomic propositions. Given a WTS \( T \), an infinite path of \( T \) is an infinite sequence of states \( \rho = x_0x_1x_2 \cdots \in X^{\omega} \) such that \( x_{i+1} \in \delta_T(x_i), i \geq 0 \). A finite path is defined analogously. We denote by \( \text{Path}^{\omega}(T) \) and \( \text{Path}^*(T) \) the sets of all infinite paths and finite paths in \( T \), respectively. Given a finite path \( \rho = x_0x_1\cdots x_n \in \text{Path}^*(T) \), its cost is defined as the sum of all transition weights in it, which is denoted by \( \text{cost}(\rho) = \sum_{i=0}^{n-1} w(x_i, x_{i+1}) \). The trace of an infinite path \( \rho = x_0x_1x_2 \cdots \in X^{\omega} \) is an infinite sequence over \( 2^{\mathcal{AP}} \) denoted by \( L(\rho) = L(x_0)L(x_1) \cdots \). Analogously, we denote by \( \text{Trace}^{\omega}(T) \) and \( \text{Trace}^*(T) \) the sets of all infinite traces and finite traces in \( T \), respectively.

B. Linear Temporal Logic Specifications

The syntax of general LTL formula is given as follows

\[ \phi = \top | a | \neg \phi | \phi_1 \land \phi_2 | \bigcirc \phi | \phi_1 U \phi_2, \]

where \( \top \) stands for the “true” predicate; \( a \in \mathcal{AP} \) is an atomic proposition; \( \neg \) and \( \land \) are Boolean operators “negation” and “conjunction”, respectively; \( \bigcirc \) and \( U \) denote temporal operators “next” and “until”, respectively. One can also derive other temporal operators such as “eventually” by \( \phi = \bigcirc \top \phi \) and “always” by \( \square \phi = \neg \bigcirc \neg \phi \). LTL formulae are evaluated over infinite words; the readers are referred to [24] for the semantics of LTL. Specifically, an infinite word \( \tau \in (2^{\mathcal{AP}})^{\omega} \) is an infinite sequence over alphabet \( 2^{\mathcal{AP}} \). We write \( \tau \models \phi \) if \( \tau \) satisfies LTL formula \( \phi \).
In this paper, we focus on a widely used fragment of LTL formulae called the co-safe LTL (scLTL) formulae. Specifically, an scLTL formula requires that the negation operator $\neg$ can only be applied in front of atomic propositions. Consequently, one cannot use “always” $\Box$ in scLTL. Although the semantics of LTL are defined over infinite words, it is well-known that any infinite word satisfying a co-safe LTL formula has a finite path (a.k.a. a plan). A good prefix is a finite word $\tau' = \tau_1 \cdots \tau_n \in (2^{AP})^*$ such that $\tau' \tau'' = \phi$ for any $\tau'' \in (2^{AP})^\omega$. We denote by $L_{\phi}^{pref}$ the set of all finite good prefixes of scLTL formula $\phi$.

Furthermore, for any scLTL formula $\phi$, its good prefixes $L_{\phi}^{pref}$ can be accepted by a deterministic finite automaton (DFA). Formally, a DFA is a 5-tuple $A = (Q, q_0, \Sigma, f, Q_f)$, where $Q$ is the set of states; $q_0 \in Q$ is the initial state; $\Sigma$ is the alphabet; $f : Q \times \Sigma \rightarrow Q$ is a transition function; and $Q_f \subseteq Q$ is the set of accepting states. The transition function can also be extended to $f : Q \times \Sigma^* \rightarrow Q$ recursively. A finite word $\tau \in \Sigma^*$ is said to be accepted by $A$ if $f(q_0, \tau) \in Q_f$; we denote by $L(A)$ the set of all accepted words. Then for any scLTL formula $\phi$ defined over $AP$, it is known that we can always build a DFA over alphabet $\Sigma = 2^{AP}$, denoted by $A_\phi = (Q, q_0, 2^{AP}, f, Q_f)$, such that $L(A_\phi) = L_{\phi}^{pref}$.

C. Path Planning for scLTL Specifications

Given a WTS $T$ and an scLTL formula $\phi$, the path planning problem is to find an finite path (a.k.a. a plan) $\rho \in Path^*(T)$ such that $L(\rho) \in L_{\phi}^{pref}$ and, at the same time, its cost $\text{cost}(\rho)$ is minimized.

To solve the scLTL planning problem, the standard approach is to build the product system between WTS $T = (X, x_0, \delta_T, w, AP, L)$ and DFA $A_\phi = (Q, q_0, 2^{AP}, f, Q_f)$, which is a new (unlabeled) WTS $P = T \times A_\phi = (S, s_0, \delta_P, w_P, S_P)$, where $S = X \times Q$ is the set of states; $s_0 = (x_0, q_0)$ is the initial state; $\delta_P : S \times \Delta \rightarrow S$ is the transition function defined by: for any $s = (x, q) \in S$, we have $\delta_P(s) = (x', q') \in S$ if $x' \in \delta_T(x) \land q' = f(q, L(x))$; $w_P : S \times \Delta \rightarrow \mathbb{N}$ is the weight function defined by: for any $s = (x, q), s' = (x', q') \in S$, we have $w_P(s, s') = w(x, x')$; and $S_P = X \times Q_F$ is the set of accepting states. By construction, for any path $\rho = (x_0, q_0)(x_1, q_1) \cdots (x_n, q_n)$ in the product system, $(x_n, q_n) \in S_P$ implies $\rho = x_0x_1 \cdots x_n \in Path^*(T)$ and $L(\rho) \in L_{\phi}^{pref}$. Therefore, to solve the scLTL planning problem, it suffices to find a path with minimum weight from the initial state to accepting states $S_P$ in the product system.

III. PLANNING IN PARTIALLY-KNOWN ENVIRONMENTS

The above reviewed shortest-path-search-based LTL planning method crucially depends on that the mobility of the robot, or the environment map $T$ is perfectly known. This method, however, is not suitable for the case of partially-known environments. To be specific, in this paper, we consider a partially-known environment in the following setting:

A1 The agent knows the existence of all regions in the environment as well as their semantics (atomic propositions hold at each region);

A2 The successor regions of each region are fixed, but the agent may not know, a priori, what are the actual successor regions it can move to;

A3 Once the agent physically reaches a region, it will know the successor regions of this region precisely.

In this section, we will provide a formal model for such a partially-known environment using the new structure of partially-known weighted transition systems and use regret as a new metric for evaluating the performance of the agent’s plan in a partially-known environment.

A. Partially-Known Weighted Transition Systems

Definition 1 (Partially-Known WTS): A partially-known weighted transition system (PK-WTS) is a 6-tuple $T = (X, x_0, \Delta, w, AP, L)$, where, similar to a WTS, $X$ is the set of states with initial state $x_0 \in X$, $w : X \times X \rightarrow \mathbb{N}$ is the cost function and $L : X \rightarrow 2^{AP}$ is a labeling function that assigns each state a set of atomic propositions in $AP$. Different from the WTS, $\Delta : X \rightarrow 2^X$ is called a successor-pattern function that assigns each state $x \in X$ a family of successor states.

The intuition of the PK-WTS $T$ is explained as follows. Essentially, PK-WTS is used to describe the possible world from the perspective of the agent. Specifically, under assumptions A1-A3, the agent has some prior information regarding the successor states of each unknown region but does not know which one is true before it actually visits the region. Therefore, in PK-WTS $T$, for each state $x \in X$, we have $\Delta(x) = \{o_1, \ldots, o_{|\Delta(x)|}\}$, where each $o_i \in 2^X$ is called a successor-pattern representing a possible set of actual successor states at state $x$. Hereafter, we will also refer each $o_i \in \Delta(x)$ to as an observation at state $x$ since the agent “observes” its successor states when exploring state $x$. Therefore, for each state $x \in X$, we say $x$ is a

- known state if $|\Delta(x)| = 1$; and
- unknown state if $|\Delta(x)| > 1$.

We assume that the initial state $x_0$ is known since the agent has already stayed at $x_0$ so that it has the precise information regarding the successor states of $x_0$. Therefore, we can partition the state space as $X = X_{\text{kno}} \cup X_{\text{un}}$, where $X_{\text{kno}}$ is the set of known states and $X_{\text{un}}$ is the set of unknown states.

In reality, the agent is moving in a specific environment that is compatible with the possible world $T$, although itself does not know this a priori. Formally, we say a WTS $T = (X, x_0, \delta_T, w, AP, L)$ is compatible with PK-WTS $T$, denoted by $T \in T$, if $\forall x \in X : \delta_T(x) \in \Delta(x)$. Clearly, if all states in $T$ are known, then its compatible WTS is unique.
B. History and Knowledge Updates

In the partially-known setting, the agent cannot make decision only based on the finite sequence of states it has visited. In addition, it should also consider what it observed (successor-pattern) at each state visited. Note that, when the agent visits a known state \( x \in X_{kn} \), it will not gain any useful information about the environment since \( \Delta(x) \) is already a singleton. Only when the agent visits an unknown state, it will gain new information and successor-pattern at this state will become known from then on. Therefore, we refer the visit to an unknown state to as an exploration.

To capture the result of an exploration, we call a tuple \( \kappa = (x, o) \in X \times 2^X \), where \( o \in \Delta(x) \), a knowledge obtained when exploring state \( x \), which means the agent knows that the successor states of \( x \) are \( o \). For each knowledge \( \kappa \), we denote by \( \kappa(x) \) and \( \kappa(o) \), respectively, its first and second components, i.e., \( \kappa = (\kappa(x), \kappa(o)) \). We denote by

\[
Kw = \{ \kappa \in X \times 2^X \mid \kappa(o) \in \Delta(\kappa(x)) \},
\]

(1)

the set of all possible knowledges.

A history in \( T \) is a finite sequence of knowledges

\[
h = \kappa_0 \kappa_1 \cdots \kappa_n = (x_0, o_0)(x_1, o_1) \cdots (x_n, o_n) \in Kw^*
\]

(2)

such that

1) for any \( i = 0, \ldots, n-1 \), we have \( x_{i+1} \in o_i \); and
2) for any \( i, j = 1, \ldots, n \), we have \( x_i = x_j \Rightarrow o_i = o_j \).

Intuitively, the first condition says that the agent can only go to one of its actual successor states in \( o_i \). The second condition captures the fact that the actual environment is partially-known but fixed; hence, the agent will observe the same successor-pattern for different visits of the same state. For history \( h = \kappa_0 \kappa_1 \cdots \kappa_n \in Kw^* \), we call \( \kappa_0(x) \kappa_1(x) \cdots \kappa_n(x) \) its path. We denote by \( \text{Path}^*(T) \) and \( \text{Hist}^*(T) \) the set of all paths and histories of \( T \), respectively.

Along each history \( h = \kappa_0 \kappa_1 \cdots \kappa_n \in Kw^* \), the agent obtain a set of knowledges (or simply, a knowledge-set)

\[
\mathcal{K} = \{ \kappa_i \mid i = 0, \ldots, n \} \subseteq Kw,
\]

(3)

which is an unordered set of knowledges. We define

\[
\mathbb{K}W = \{ \mathcal{K} \in 2^{Kw} \mid \forall \kappa, \kappa' \in \mathcal{K} : \kappa(x) = \kappa'(x) \Rightarrow \kappa(o) = \kappa'(o) \}
\]

(4)

as the set of knowledge-sets. Therefore, given a knowledge-set \( \mathcal{K} \in \mathbb{K}W \), we say state \( x \in X \) has been explored in \( \mathcal{K} \), if \( (x, o) \in \mathcal{K} \) for some \( o \); we denote by \( X(\mathcal{K}) \) the set of explored states in \( \mathcal{K} \). If \( x \) has been explored in \( \mathcal{K} \), we denote by \( o_\kappa(x) \in 2^X \) the unique observation such that \( \langle x, o_\kappa(x) \rangle \in \mathcal{K} \).

Then the agent can maintain a finer possible world by incorporating with the knowledges it obtained. Specifically, by having knowledge-set \( \mathcal{K} \in \mathbb{K}W \), the agent can update the PK-WTS \( T = (X, x_0, \Delta, w, \mathcal{A}P, L) \) to a finer PK-WTS

\[
T' = \text{update}(T, \mathcal{K}) = (X, x_0, \Delta', w, \mathcal{A}P, L),
\]

where for any \( x \in X \), we have

\[
\Delta'(x) = \begin{cases} 
\{ o_\kappa(x) \} & \text{if } x \in X(\mathcal{K}) \\
\Delta(x) & \text{if } x \notin X(\mathcal{K}) 
\end{cases}
\]

Note that, the above update function is well-defined since conflict knowledges \( (x, o), (x, o') \in Kw \) such that \( o \neq o' \) cannot belong to the same knowledge-set by the definition of history and Equation (4).

Remark 1: Note that in the domain of knowledges as defined in Equation (1), we can omit those tuples \((x, o)\) when \( x \in X_{kn} \) is a known state since \( o \) here does not provide any additional information. Here, we still leave this reduction information when constructing a knowledge-set for the sake of unified description. One can easily omit this part when implementing our algorithm.

C. Strategy and Regret

Under the setting of partially-known environment, the plan is no longer an open-loop sequence. Instead, it is a strategy that determines the next state the agent should go to based what has been visited and what has known, which are environment dependent. Formally, a strategy is a function

\[
\xi : \text{Hist}^*(T) \rightarrow X \cup \{ \text{stop} \}
\]

such that for any \( h = \kappa_0 \kappa_1 \cdots \kappa_n \), where \( \kappa_i = (x_i, o_i) \), either (i) \( \xi(h) \in o_n \), i.e., it decides to move to some successor state; or (ii) \( \xi(h) = \text{stop} \), i.e., the plan is terminated. We denote by \( \text{Str}(T) \) the set of all strategies for \( T \).

Although a strategy is designed to handle all possible actual environments in the possible world \( T \), when it is applied to an actual environment \( T' \in T \), the outcome of the strategy can be completely determined. We denote by

\[
\rho_\xi^T = x_0 x_1 \cdots x_n \in X^*
\]

the finite path induced by strategy \( \xi \) in environment \( T' \in T \), which is the unique path such that

• \( \forall i < n : \xi(x_0, \delta_T(x_0)) \cdots (x_i, \delta_T(x_i)) = x_{i+1} \); and
• \( \xi(x_0, \delta_T(x_0)) \cdots (x_n, \delta_T(x_n)) = \text{stop} \).

Note that the agent does not know a priori which \( T \in T \) is the actual environment. To guarantee the accomplishment of the LTL task, a strategy \( \xi \) should satisfy

\[
\forall T' \in T : \rho_\xi^T \in L_{\text{pref}}.
\]

(5)

We denote by \( \text{Str}_a(\xi) \) the set of all strategies satisfying (5).

To evaluate the performance of strategy \( \xi \), one approach is to consider the worst-case cost of the strategy among all possible environment, i.e., \( \text{cost}_{\text{worst}}(\xi) := \max_{T' \in T} \text{cost}(\rho_\xi^T) \). However, as we have illustrated by the example in Figure 1, this metric cannot capture the potential benefit obtained from exploring unknown states and the agent may regret due to the unexplored. To capture this issue, in this work, we adopt the notion of regret as the metric to evaluate the performance of a strategy.

Definition 2 (Regret): Given a partially-known environment described by PK-WTS \( T \) and a task described by an
applying this strategy to this specific environment, while  

\[ \text{as follows. For each strategy } \xi \text{ and each actual environment } T, \text{ cost}(\rho^T_\xi) \text{ is the actual cost incurred when applying this strategy to this specific environment, while } \min_{\xi' \in \text{Str}_{a}(T)} \text{cost}(\rho^T_{\xi'}) \text{ is cost of the best-response strategy the agent should have taken if it knows the actual environment } T \text{ with hindsight. Therefore, their difference is the regret of the agent when applying strategy } \xi \text{ in environment } T. \] 

\[ \text{Note that, the agent does not know the actual environment } T \text{ precisely a priori. Therefore, the regret of the strategy is considered as the worst-case regret among all possible environments } T \in \mathbb{T}. \]

D. Problem Formulation

After presenting the PK-WTS modeling framework as well as the regret-based performance metric, we are now ready to formulate the problem that we solve in this work.

**Problem 1 (Regret-Based LTL Planning):** Given a possible world represented by PK-WTS \( T \) and an scLTL task \( \phi \), synthesize a strategy \( \xi \) such that

(i) \( \rho^T_\xi \in \mathcal{L}_{\text{pref}}^\phi \) for any \( T \in \mathbb{T} \); and

(ii) \( \text{reg}_T(\xi) \) is minimized.

IV. GAME-BASED SYNTHESIS ALGORITHM

In this section, we solve the regret-based LTL planning problem. Our approach is to first build a knowledge-based game arena that is consistent with all possible histories. Then, based on the game arena, an effective value iteration algorithm is developed, which provides the optimal strategy with minimum regret.

A. Knowledge-Based Game Arena

Given PK-WTS \( T = (X, x_0, \Delta, w, AP, L) \), its skeleton system is a WTS

\[ T = (X, x_0, \delta_T, w, AP, L), \]

where for any \( x \in X \), we have \( \delta_T(x) = \bigcup \{ o \in \Delta(x) \} \), i.e., the successor states of \( x \) is defined as the union of all possible successor-patterns. To incorporate with the task information, let \( A_\phi = (Q, q_0, \Sigma, f, Q_F) \) be the DFA that accepts all good-prefixes of scLTL formula \( \phi \). We construct the product system between \( T \) and \( A_\phi \), denoted by

\[ \mathcal{P} = T \otimes A_\phi = (S, s_0, \delta_P, wp, SF), \]

where the product “\( \otimes \)” has been defined in Section II-C and recall that its state-space is \( S = X \times Q \).

However, the state-space of \( \mathcal{P} \) is still not sufficient for the purpose of decision-making since the explored knowledge along the trajectory are missing. Therefore, we further incorporate the knowledge-set into the product state-space and explicitly split the movement choice of the agent and the non-determinism of the environment. This leads to the following knowledge-based game arena.

**Definition 3 (Knowledge-Based Game Arena):** The knowledge-based game arena is a bipartite graph

\[ G = (V = V_a \cup V_e, v_0, E), \]

where

- \( V_a = X \times Q \times KW \) is the set of agent vertices;
- \( V_e = X \times Q \times KW \times X \) is the set of environment vertices;
- \( v_0 = (x_0, q_0, K_0) \in V_a \) is the initial (agent) vertex, where \( K_0 \in KW \) is the initial knowledge of the agent, i.e., \( \kappa_0(x) = x_0 \) and \( \Delta(x_0) = \{ \kappa_0(o) \} \);
- \( E \subseteq V \times V \) is the set of edges defined by: for any \( v_a = (x_a, q_a, K_a) \in V_a \) and \( v_e = (x_e, q_e, K_e, \hat{x}_e) \in V_e \), we have

- \( \langle v_a, v_e \rangle \in E \) whenever
  - (i) \( (x_e, q_e, K_e) = (x_a, q_a, K_a) \); and
  - (ii) \( \hat{x}_e \in o_{K_a}(x_a) \).

- \( \langle v_e, v_a \rangle \in E \) whenever
  - (i) \( x_a = \hat{x}_e \); and
  - (ii) \( (x_a, q_a) \in \delta_P(x_e, q_e) \); and
  - (iii-1) if \( x_a \in X(K_e) \), then \( K_a = K_e \);
  - (iii-2) if \( x_a \notin X(K_e) \), then we have

\[ K_a = \{ K_e \cup \{ (x_a, o) \} \mid o \in \Delta(x_a) \}. \]

The intuition of the knowledge-based game arena \( G \) is explained as follows. The graph is bipartite with two types of vertices: agent vertices from which the agent chooses a feasible successor state to move to and environment vertices from which the environment chooses the actual successor-pattern in the possible world. More specifically, for each agent vertex \( v_a = (x_a, q_a, K_a) \), the first component \( x_a \) represents its physical state in the system, the second component \( q_a \) represents the current DFA state for task \( \phi \) and the third component \( K_a \) represents the knowledge-set of the agent obtained along the trajectory. At each agent vertex, the agent chooses to move to a successor state. Note that since \( x_a \) is the current state, it has been explored and we have \( x_a \in X(K_a) \), i.e., we know that the actual successor states of \( x_a \) are \( o_{K_a}(x_a) \). Therefore, it can move to any environment state \( v_e = (x_e, q_e, K_e, \hat{x}_e) \) by “remembering” the successor state \( \hat{x}_e \in o_{K_a}(x_a) \) it chooses. Now, at each environment state \( v_e = (x_e, q_e, K_e, \hat{x}_e) \), the meanings of the first three components are the same as those for agent state. The last component \( \hat{x}_e \) denotes the state it is moving to. Therefore, \( v_e \) can reach agent state \( v_a = (x_a, q_a, K_a) \), where the first two components are just the transition in the product system synchronizing the movements of the WTS and the DFA. Note that we have \( x_a = \hat{x}_e \) since the movement has been decided by the agent. However, for the last component of knowledge-set \( K_a \), we need to consider the following two cases:

- If state \( x_a = \hat{x}_e \) has already been explored, then the agent must observe the same successor-pattern as before. Therefore, the knowledge-set is not updated;
- If state \( x_a = \hat{x}_e \) has not yet been explored, then the new explored knowledge \( \langle x_a, o \rangle \in KW \) should be added to the knowledge-set \( K_a \). However, since this is the
first time the agent visits $x_a$, any possible observations $o \in \Delta(x_a)$ consistent with the prior information are possible. Therefore, the resulting knowledge-set $K_e$ is non-deterministic.

B. Strategies and Plays in the Game Arena

We call a finite sequence of vertices $\pi = v_0v_1 \cdots v_n \in V^*$ a play on $G$ if $(v_i, v_{i+1}) \in E$. We call $\pi$ a complete play if $\text{last}(\pi) \in V_a$, where $\text{last}(\pi)$ denotes the last vertex in $\pi$. Then for a complete play $\pi = v_0v_1 \cdots v_2n \in V^*V_a$, where $v_2n = (x_1, q_1, K_e)$, it induces a path denoted by $\pi_{\text{path}} = x_0x_1 \cdots x_n$ as well as a history

$$\pi_{\text{his}} = \langle x_0, 0K_e(x_0) \rangle \langle x_1, 0K_e(x_1) \rangle \cdots \langle x_n, 0K_e(x_n) \rangle.$$

Note that, in the above, we have $K_0 \subseteq K_1 \subseteq \cdots \subseteq K_n$ and the knowledge-set constructed along history $\pi_{\text{his}}$ is exactly $K_n$. On the other hand, for any history $h = K_0K_1 \cdots K_n \in K^*$, there exists a unique complete play in $G$, denoted by $\pi_h$, such that its induced history is $h$.

Since the first two components of $G$ are from the product of $\mathcal{T}$ and $A_{\phi}$, for any complete play $\pi$, we have $L(\pi_{\text{path}}) \in L_{\text{pref}}$ iff the second component of $\text{last}(\pi)$ is an accepting state in the DFA. Therefore, we define

$$V_F = \{ (x_a, q_a, K_a) \in V_a | q_a \in Q_F \}$$

the set of accepting vertices representing the satisfaction of the scLTL task. Also, since only edges from $V_c$ to $V_a$ represent actual movements, we define a weight function for $G$ as $w_G : V \times V \rightarrow \mathbb{N}$, where for any $v_c \in (x_c, q_c, K_c, x_c)$, $q_c = (x_c, q_c, K_c, x_c)$, we have $w_G(v_c, v_c) = 0$ and $w_G(v_c, v_a) = w(x_c, x_a)$. The cost of a play $\pi = v_0v_1 \cdots v_n \in V^*$ is defined as $\text{cost}_G(\pi) = \sum_{k=0}^{n-1} w_G(v_{i+1}, v_{i+1})$.

A strategy for the agent-player is a function $\sigma_a : V^*V_a \rightarrow V_c \cup \{ \text{stop} \}$ such that for any $\pi \in V^*V_a$, either $(\text{last}(\pi), \sigma_a(\pi)) \in E$ or $\sigma_a(\pi) = \text{stop}$. Analogously, a strategy for the environment-player is a function $\sigma_e : V^*V_c \rightarrow V_a$ such that for any $\pi \in V^*V_c$, we have $(\text{last}(\pi), \sigma_e(\pi)) \in E$. We denote by $\mathfrak{S}_a(G)$ (resp. $\mathfrak{S}_e(G)$) the set of all strategies for the agent (resp. environment) on $G$. Given strategies $\sigma_a \in \mathfrak{S}_a(G)$ and $\sigma_e \in \mathfrak{S}_e(G)$, the outcome play, denoted by $\pi_{\sigma_a, \sigma_e}$, is the unique sequence $v_0v_1 \cdots v_n \in V^*V_a$ s.t.

- $i < n : v_i \in V_a \Rightarrow \sigma_a(v_0v_1 \cdots v_i) = v_{i+1}$; and
- $i < n : v_i \in V_c \Rightarrow \sigma_e(v_0v_1 \cdots v_i) = v_{i+1}$; and
- $\sigma_a(v_0v_1 \cdots v_n) = \text{stop}$.

We say strategy $\sigma_a$ is winning if for any $\sigma_e \in \mathfrak{S}_e(G)$, we have $\text{last}(\pi_{\sigma_a, \sigma_e}) \in V_F$. We denote by $\mathfrak{S}_a^F(G) \subseteq \mathfrak{S}_a(G)$ the set of all winning strategies. Similarly, we can also define the regret of strategy $\sigma_a \in \mathfrak{S}_a^F(G)$ in arena $G$ by

$$\text{reg}_G(\sigma_a) = \max_{\sigma_e \in \mathfrak{S}_e(G)} \left( \text{cost}_G(\pi_{\sigma_a, \sigma_e}) - \min_{\sigma'_e \in \mathfrak{S}_e^F(G)} \text{cost}_G(\pi_{\sigma_a, \sigma'_e}) \right).$$

A strategy $\sigma_a$ is said to be positional if $\forall \pi, \pi' : \text{last}(\pi) = \text{last}(\pi') \Rightarrow \sigma_a(\pi) = \sigma_a(\pi')$. Therefore, a positional strategy can be represented of form $\sigma_a : V_a \rightarrow V_c$.

Essentially, an agent-player’s strategy $\sigma_a \in \mathfrak{S}_a^F(G)$ uniquely defines a corresponding strategy in $\mathcal{T}$, denoted by $\xi_{\sigma_a} \in \text{Stra}_a(T)$ as follows: for any $h \in \text{Hist}^*(T)$, we have $\xi_{\sigma_a}(h) = \sigma_a(\pi_h)$. The environment-player’s strategy $\sigma_e \in \mathfrak{S}_e(G)$ essentially corresponds to a possible actual environment $T \in T$ since it needs to specify an observation $o \in \Delta(x)$ for each unexplored $x$, and once $x$ is explored, the observation is fixed based on the construction of $G$. Since $\text{cost}_G(\cdot)$ is defined only according to its first component, for any play $\pi \in V^*V_a$, we have $\text{cost}_G(\pi) = \text{cost}(\pi_{\text{path}})$.

In summary, in order to solve Problem 1, it suffices to find a winning strategy $\sigma_a \in \mathfrak{S}_a^F(G)$ of the agent-player in the knowledge-based game arena $G$, such that $\text{reg}_G(\sigma_a)$ as defined in (7) is minimized. Then, based on the optimal strategy $\sigma_a \in \mathfrak{S}_a(G)$, we can induce a strategy $\xi_{\sigma_a} \in \text{Stra}_a(T)$ for PK-WTS $T$. Therefore, hereafter, we will only focus on the game graph $G$ without considering $T$.

C. Synthesis via Function Iterations

Now we present an algorithm for finding winning strategy $\sigma_a \in \mathfrak{S}_a^F(G)$ such that $\text{reg}_G(\sigma_a)$ is minimized. Our approach is to iteratively update the following three functions:

- strategy function $\sigma^{(k)} : V_a \rightarrow V_c$;
- cooperative value function $c\text{Val}^{(k)} : V \rightarrow \mathbb{N}$;
- antagonistic value function $a\text{Val}^{(k)} : V \rightarrow \mathbb{N}$.

Intuitively, for each vertex $v \in V_a$, $\sigma^{(k)}(v)$ denotes the positional strategy at $v$ (which successor vertex the agent should move to) after $k$th iteration. Values $c\text{Val}^{(k)}(v)$ and $a\text{Val}^{(k)}(v)$ denote, respectively, the best-case cost (resp. the worst-case costs) the agent may achieve from $v$ under a cooperative (resp. antagonistic) environment.

Based on the above functions, for each edge $(v_a, v_e) \in V_a \times V_c$, we define $\text{Reg}^{(k)}(v_a, v_e)$ as the regret of moving to environment vertex $v_e$ from agent vertex $v_a$ as

$$\text{Reg}^{(k)}(v_a, v_e) = a\text{Val}^{(k)}(v_e) - \min_{v'_e \in \text{Suc}(v_e) \setminus \{v_e\}} c\text{Val}^{(k)}(v'_e).$$

Intuitively, $a\text{Val}^{(k)}(v_e)$ is the worst-case cost by choosing $v_e \in \text{Suc}(v_e) \setminus \{v_e\}$, while $c\text{Val}^{(k)}(v'_e)$ is the best-case cost under other alternative choices. Therefore, the regret of choosing $v_e$ is their difference.

Functions $\sigma^{(k)}$, $c\text{Val}^{(k)}$ and $a\text{Val}^{(k)}$ are iterated according to Algorithm 1. Initially, for each accepting vertex $v_a \in V_F$, the c-value and the a-value are both 0 since the task has been complete, and the corresponding strategy is to stop. At iteration of $k + 1$, for each agent vertex $v_a \in V_a \setminus V_F$, we update the strategy at $v_a$ by moving to state $v_e$ that minimizes its regret based on the information of the $k$th iteration. The c-value and the a-value are also updated, respectively, as the c-value and the a-value of its successor state chosen by the strategy in the last round. However, recall that, $w_G$ has non-zero cost when moving from $V_c$ to $V_a$. Therefore, for each environment vertex $v_e \in V_c$, its c-value and a-value are updated, respectively, as the minimum c-value and maximum a-value among all its successor states plus the moving cost.

Now, let us denote by $\sigma^*$, $c\text{Val}^*$ and $a\text{Val}^*$, respectively, the limit of $\sigma^{(k)}$, $c\text{Val}^{(k)}$ and $a\text{Val}^{(k)}$. Then by taking strategy $\sigma^*$, the regret of this strategy is actually the regret of its first
Algorithm 1: Iterations of $\sigma^{(k)}, cV a l^{(k)}$ and $aV a l^{(k)}$

**Initialization:**
- For each $v_0 \in V_P$, we define
  \[ \sigma^{(0)}(v_0) = \text{stop} \]  \hspace{1cm} (9)
  \[ cV a l^{(0)}(v_0) = aV a l^{(0)}(v_0) = 0 \]  \hspace{1cm} (10)
- For each $v \notin V_P$, we define
  \[ \sigma^{(0)}(v) = \text{arbitrary vertex in } \text{Succ}(v) \]  \hspace{1cm} (11)
  \[ cV a l^{(0)}(v) = aV a l^{(0)}(v) = \infty \]  \hspace{1cm} (12)

**Iteration:**
- For each $v_0 \in V_P$, we define
  \[ \sigma^{(k+1)} = \sigma^{(k)}, cV a l^{(k+1)} = cV a l^{(k)}, aV a l^{(k+1)} = aV a l^{(k)} \]  \hspace{1cm} (13)
- For each $v_0 \in V_A \setminus V_P$, we define
  \[ \sigma^{(k+1)}(v_0) = \arg\min_{v_c \in \text{Succ}(v_0)} \text{Reg}^{(k)}(v_0, v_c) \]  \hspace{1cm} (14)
  \[ cV a l^{(k+1)}(v_0) = cV a l^{(k)}(\sigma^{(k)}(v_0)) \]  \hspace{1cm} (15)
  \[ aV a l^{(k+1)}(v_0) = aV a l^{(k)}(\sigma^{(k)}(v_0)) \]  \hspace{1cm} (16)
- For each $v_c \in V_c$, we define
  \[ cV a l^{(k+1)}(v_c) = \min_{v_0 \in \text{Succ}(v_c)} \{ uG_c(v_c, v_0) + cV a l^{(k)}(v_0) \} \]  \hspace{1cm} (17)
  \[ aV a l^{(k+1)}(v_c) = \max_{v_0 \in \text{Succ}(v_c)} \{ uG_c(v_c, v_0) + aV a l^{(k)}(v_0) \} \]  \hspace{1cm} (18)

\[
\text{choice of movement at the initial state } v_0 \in V_A, \text{ i.e.}, \text{we have}
\]
\[ \text{reg}_{G}^{C}(\sigma^*) = \text{Reg}^*(v_0, \sigma^*(v_0)), \]
where
\[
\text{Reg}^*(v_0, v_c) = aV a l^*(v_c) - \min_{v_0' \in \text{Succ}(v_0)} cV a l^*(v_0')
\]

Furthermore, due to Equation (14), the regret is iteratively minimized by improving the strategy. Therefore, we have
\[ \min_{\sigma \in \mathcal{G}_k^C(G)} \text{reg}_{G}^{C}(\sigma) = \text{Reg}^*(v_0, \sigma^*(v_0)). \]  \hspace{1cm} (20)

Overall, we know that $\sigma^* \in \mathcal{G}_k^C(G)$ is the optimal strategy minimizing $\text{reg}_{G}^{C}(\sigma^*)$, which means that its induced strategy $\xi^*$ solves Problem 1.

V. CASE STUDY: A TEAM OF FIREFIGHTING ROBOTS

In this section, we present a case study to illustrate the proposed framework. We consider a team of firefighting robots consisting of a ground robot and a UAV working in an urban district shown in Figure 2(a). Specifically, the blue regions are rivers, the black regions are bridges, the grey regions are squares, the green regions are parks, the brown regions are buildings and the yellow region is the base of the team of robots.

The firefighting mission in this district is undertaken by the collaboration of the UAV and the ground robot. Specifically, we assume that the district map is completely unknown to the robotic system initially. When a fire alarm is reported, the UAV takes off first and reconnoiters over the district, which allows the system to obtain some rough information of the distinct and leads to a possible world map. More detailed connectivities for some unknown regions in the possible world still remain to be explored by the ground robot.

In order to accomplish the firefighting mission, the ground robot needs to first go to some regions with extinguisher to get fire-extinguishers and then move to the region with fire. Let $\mathcal{AP} = \{\text{fire, extinguisher}\}$. The mission can be described by the following scLTL formula:
\[
\phi = (\neg\text{fire} \cup \text{extinguisher}) \land \phi
\]

Suppose that, after the reconnaissance, the UAV will get a look down picture of the entire district as shown in Figure 2(b). Based on the distinct picture, the system will know the map geometry and the semantics. Specifically, it knows that there is a fire in Square 4 and there are extinguishers in Parks 1-3. The connectivities of all open regions including rivers, bridges, squares, parks and the base are known. However, the UAV cannot tell if each building has corresponding doors connecting with its adjacent open regions. In order to figure out the (non-)existence of those potential doors, the ground robot has to move to the adjacent areas to explore. Therefore, the possible world model $\mathcal{T}$ of the robots is shown in Figure 2(c) where the dashed arrows denote some potential doors, whose existences are unknown.

Now, the environment is partially-known in the sense that the accessibility of the buildings are unknown to the robotic system until the ground robot reaches their adjacent regions. Then based on the possible world model $\mathcal{T}$ and the scLTL $\phi$, we can synthesize an strategy $\xi^*$ that minimizes the regret while achieving $\phi$. We have implemented our algorithm in robot simulator V-REPH. As shown in Figure 3 we consider two different actual environments $T_1, T_2 \in \mathcal{T}$ compatible to the possible world $\mathcal{T}$ when applying the same strategy $\xi^*$.

To minimize its regret, the ground robot needs to first go to Square 2 to explore if there exists a door connecting

\[ 1 \text{ Videos are available at https://github.com/hai12xp/regret_minimize} \]
Building 3. Environment $T_1$ in Figure 3(a) actually corresponds to the case of the existence of such a door. Then by passing through this door, the ground robot can easily find a extinguisher in Park 3 and then quench the fire in Square 4. This actual path is shorter than the path planned based on the worst-case, i.e., assuming there exists no such a door.

However, environment $T_2$ in Figure 3(b) corresponds to the case where there is no door between Square 2 and Building 3. Note that, the ground robot will still first go to Square 2. However, when it realizes that there is no such a door, it will turn back and go to Park 1, where it finds a extinguisher and luckily, there is a door to Building 2. Then the ground robot will cross through Building 2 and finally reaches Square 4 to quench the fire. Although this actual path is longer than the path planned based on the worst-case, the robot will not regret that much since it does not know, a priori, the non-existence of such a door.

VI. CONCLUSIONS

In this paper, we proposed a new approach for optimal path planning for sLTL specifications under partially-known environments. We adopted the notion of regret to evaluate the trade-off between cost incurred in an actual environment and the potential benefit of exploring unknown regions. A knowledge-based model was developed to formally describe the partially-known scenario and an effective algorithm was proposed to synthesize an optimal strategy with minimum regret. In the future, we would like to extend our results to multi-agent systems with general LTL specifications.
