Abstract

We consider unsupervised domain adaptation (UDA), where labeled data from a source domain (e.g., photographs) and unlabeled data from a target domain (e.g., sketches) are used to learn a classifier for the target domain. Conventional UDA methods (e.g., domain adversarial training) learn domain-invariant features to improve generalization to the target domain. In this paper, we show that contrastive pre-training, which learns features on unlabeled source and target data and then fine-tunes on labeled source data, is competitive with strong UDA methods. However, we find that contrastive pre-training does not learn domain-invariant features, diverging from conventional UDA intuitions. We show theoretically that contrastive pre-training can learn features that vary substantially across domains but still generalize to the target domain, by disentangling domain and class information. Our results suggest that domain invariance is not necessary for UDA. We empirically validate our theory on benchmark vision datasets.

1 Introduction

Machine learning models often underperform when the train and test data are drawn from different distributions. This is especially problematic in performance-critical applications such as image recognition for self-driving cars (Yu et al., 2020; Sun et al., 2020) or medical image diagnosis (AlBadawy et al., 2018; Dai & Gool, 2018). In this work, we study the unsupervised domain adaptation (UDA) setting where we have access to labeled data from a source domain and unlabeled data from a target domain, and the goal is to get high accuracy on the target domain.

Conventional algorithms for UDA focus on learning domain-invariant features (Tzeng et al., 2014; Ganin et al., 2016; Tzeng et al., 2017; Shu et al., 2018; Sun et al., 2019)—intuitively, if the features for the source and target domains are indistinguishable and the accuracy is high on the source, then the accuracy should be high on the target as well. This is supported by theoretical notions such as $\mathcal{H} \Delta \mathcal{H}$-divergence, which measures the distinguishability of source and target feature spaces (Ben-David et al., 2010). If the source and target domains are difficult to distinguish in feature space, then the corresponding generalization bound given by $\mathcal{H} \Delta \mathcal{H}$-divergence is tighter.

We find that a surprisingly simple and effective method for UDA is out-of-the-box contrastive pre-training on source and target unlabeled data, followed by fine-tuning on source labeled data. In our experiments, contrastive pre-training achieves comparable or better results to strong UDA methods based on domain adversarial neural networks (Ganin et al., 2016; Shu et al., 2018) and self-training (Prabhu et al., 2021) on visual adaptation benchmarks including DomainNet, BREEDS Living-17, BREEDS Entity-30, and STL-10→CIFAR-10 (results in Table 2).

However, unlike conventional UDA methods, contrastive pre-training does not produce domain invariant features; for example in the learned feature space in DomainNet, we can predict which domain an image came from with only an 8% error, which is much lower than in the input space (27%) or in the DANN feature space (14%)—see Table 1 in Section 4. In fact, in the contrastive pre-trained feature space for DomainNet, it is as easy to distinguish between two domains as it is to distinguish between two classes.

How does contrastive pre-training learn features that generalize to the target domain without domain invariance? To theoretically analyze contrastive pre-training, we consider a graph where input examples are nodes and the edge weight

*Equal contribution.
between two inputs is the probability that they are generated by sampling two views of the same original input via data augmentation. By considering the weights of all the edges between two class-domain pairs (e.g., all edges connecting a dog photo to a cat sketch), we can define class-domain connectivities. These connectivities describe how much overlap to expect amongst the randomly augmented inputs from two class-domain pairs. Our key assumption for these connectivities is that the probability that an augmentation changes just the domain (keeping the class constant) or just the class (keeping the domain constant) is larger than the probability that it changes both. Intuitively, this states that augmentations of dog photos should be more similar to dog sketches and cat photos than to cat sketches. Using a standard randomized model for the edges of the graph (known as the stochastic block model), we prove that contrastive pre-training achieves good target accuracy without domain invariance—by learning representations that disentangle the domain and class information (Theorem 1). Importantly, in our analysis the source and target domains can be very far apart, and the features can be easily distinguished (Proposition 2).

We empirically validate our theory on benchmark UDA datasets. We first estimate the connectivities between different class-domain pairs (e.g., dog photos and cat sketches) on Living-17 (Santurkar et al., 2020) and DomainNet (12 domain pairs) (Peng et al., 2019), showing that they satisfy our theoretical condition for contrastive pre-training to learn transferable features. Next, we find that the target accuracy of contrastive pre-training on DomainNet can be well-explained ($R^2 = 0.78$) using the terms that appear in our theory: the ratios of the estimated connectivities. Furthermore, removing a selected subset of the pre-training data to adversely change the connectivities consistently hurts the target accuracy more than randomly removing data. Finally, we give evidence that contrastive pre-training learns features that disentangle the class and domain information, allowing the features to be transferable across domains while not being domain-invariant. Our results suggest that, even without knowledge about distribution shifts, contrastive pre-training is a promising UDA method. We provide a first step for theoretically understanding contrastive pre-training for UDA, which can be used to improve data augmentation and selection strategies.

2 Related work

Conventional domain adaptation methods bring source and target domains together. Ben-David et al. (2010) prove generalization bounds for domain adaptation that rely on small $\mathcal{H}\mathcal{D}\mathcal{H}$-divergence between the domains. Typically, $\mathcal{H}\mathcal{D}\mathcal{H}$-divergence is estimated by training a classifier that distinguishes between the source and target domains, where more distinguishable domains have higher $\mathcal{H}\mathcal{D}\mathcal{H}$-divergence. Many methods such as domain adversarial training (Tzeng et al., 2014; Ganin et al., 2016; Tzeng et al., 2017) and moment matching (Peng et al., 2019) have objectives that aim to
minimize $\mathcal{H}_\Delta \mathcal{H}$-divergence between the source and target features, such that the source and target feature distributions become indistinguishable. Recent works address shortcomings of these conventional methods (Xiao & Zhang, 2021), propose alternate measures of domain divergence to minimize (Li et al., 2021), and improve on prior work that uses optimal transport to bring the domains together (Li et al., 2020).

**Contrastive learning for self-supervised learning.** Contrastive learning methods (Chen et al., 2020a; He et al., 2020; Caron et al., 2020) perform self-supervised learning of a feature encoder on unlabeled data. Broadly, the contrastive learning objective aims to learn an encoder that maps views of the same input (generated by data augmentation) to similar features and views of random inputs to distinguishable features. The pre-trained encoder is then used as a feature extractor or as a good parameter initialization for downstream learning on a task like ImageNet (Russakovsky et al., 2015), where the downstream train and test examples come from the same distribution. Several theoretical works provide guarantees on the performance of contrastive learning in this setting of identical train and test distributions (Arora et al., 2019; Tosh et al., 2021; HaoChen et al., 2021). In contrast, we consider contrastive pre-training for domain adaptation, where the downstream training data are the labeled source domain data and the test data are from the target domain (so there is distribution shift).

**Domain adaptation with self-supervision.** Prior works have explored the application of self-supervision to UDA. However, to the best of our knowledge they have all used domain distance either as part of their objective (Kang et al., 2019; Wang et al., 2021; Thota & Leontidis, 2021) or for model selection (Sun et al., 2019).

**Assumptions about distribution shift.** A classical assumption is covariate shift (Shimodaira, 2000), a setting in which the marginal distribution over $X$ can change between domains but the label conditioned on $x$ is fixed. However, if the source and target have disjoint support then covariate shift is trivially satisfied, and therefore recent works have proposed alternative definitions. Kumar et al. (2020) handle this issue by assuming the shift is gradual in a Wasserstein metric and does not explicitly assume covariate shift. Wei et al. (2021) analyze UDA with two assumptions: 1) the source classifier has reasonable accuracy on the target, and the target satisfies an “expansion” condition. Cai et al. (2021) assume that expansion is satisfied between the source and target domains and analyzes self-training for UDA. They assume that distinct class populations have very little overlap (even after augmentations are applied), while our framework assumes the augmentations may bring together a nontrivial proportion of examples within the same domain but from different classes (an assumption substantiated by our empirical observations in Section 6). Our theoretical connectivity model is an alternative method for describing distribution shift so that contrastive pre-training adapts even when the $\mathcal{H}_\Delta \mathcal{H}$-divergence is large.

## 3 Setup

### 3.1 Unsupervised Domain Adaptation (UDA)
We consider a classification problem from an input space $\mathcal{X} \subseteq \mathbb{R}^d$ to a label space $\mathcal{Y} = \{1, \ldots, r\}$.

**Data, model, and metrics.** Each $x \in \mathcal{X}$ has a deterministic label $y_x \in \mathcal{Y}$ and domain $d_x \in [2]$ (where domain 1 is the source and domain 2 is the target). We note that this setup implies the covariate shift setting. Let $P_S$ and $P_T$ denote the source and target input distributions respectively (both over $\mathcal{X}$). We additionally have labels $y_x$ for source examples $x \sim P_S$ (but not for target examples $x \sim P_T$). Let $P_U = \theta P_S + (1 - \theta) P_T$ for some $\theta \in [0, 1]$ be a mixture of the source and target domains. This mixture distribution serves as the unlabeled data distribution over both source and target domains. The goal is to learn a classifier $h : \mathcal{X} \to \mathcal{Y}$ with low classification error on the target distribution $L_{0-1}(h) = \mathbb{E}_{x \sim P_U} [1[h(x) \neq y_x]]$.

**Augmentations.** Modern ML models are trained with augmentations such as crops and color distortions (Krizhevsky et al., 2012; Chen et al., 2020a). For any input $x \in \mathcal{X}$, let $A(\cdot \mid x)$ be the distribution of its augmentations (also over $\mathcal{X}$).
3.2 Methods

**Empirical risk minimization** (ERM) minimizes a loss over augmentations \(x'\) of source examples \(x \sim P_S\) and the original labels \(y_x\):

\[
\mathcal{L}_{\text{ERM}}(h) = \mathbb{E}_{x \sim P_S, x' \sim A(\cdot | x)}[\ell(h(x'), y_x)],
\]

where \(\ell\) is a loss function (e.g., cross-entropy loss or squared loss)—ERM learns a minimizer \(\hat{h}_{\text{erm}} \in \arg \min_h \mathcal{L}_{\text{ERM}}(h)\). Augmentations improve the target accuracy of ERM and our results also hold without augmentations.

**Domain adversarial neural networks** (DANN) (Ganin et al., 2016) optimizes the sum of two terms: a source classification loss, and a “domain confusion” loss that makes it difficult to predict the domain \(d\):

\[
\mathcal{L}_{\text{DANN}}(f, g, \xi) = \mathbb{E}_{x \sim P_S, x' \sim A(\cdot | x)}[\ell(g(f(x')), y_x)] - \lambda \mathbb{E}_{x \sim P_U, x' \sim A(\cdot | x)}[\ell(\xi(f(x')), d_x)],
\]

where \(\lambda > 0\) is a tradeoff parameter between the two losses and \(\xi\) is a domain classifier. The classifier \(\hat{h}_{\text{dann}} = \hat{f}_{\text{dann}} \circ \hat{g}_{\text{dann}}\) is learned by minimizing the loss: \(\hat{f}_{\text{dann}}, \hat{g}_{\text{dann}} \in \arg \min_{f, g} \max_{\xi} \mathcal{L}_{\text{DANN}}(f, g, \xi)\).

**Contrastive pre-training** aims to learn useful features on the unlabeled data from both source and target by training an encoder which maps data-augmented views of the same input to similar features (the “positive pairs”) and data-augmented views of random pairs of inputs to dissimilar features (the “negative pairs”). Formally, let \(S_+\) be the distribution (on \(X \times X\)) of “positive pairs” (augmentations of a single input \(\bar{x}\)), given by:

\[
S_+(x, x^+) = \mathbb{E}_{x \sim P_U} [A(x \mid \bar{x})A(x^+ \mid \bar{x})].
\]

We apply contrastive pre-training to UDA—we pretrain an encoder on source and target unlabeled data, and then fine-tune a classifier on only labeled data from the source.

1. (Pre-train on unlabeled source and target data) We first pre-train an encoder \(f\) to minimize a distance \(d_+\) over augmentations of the same input, and maximize a distance \(d_-\) over random pairs of inputs

\[
\mathcal{L}_{\text{pretrain}}(f) \triangleq \mathbb{E}_{(x, x^+) \sim S_+}[d_+(f(x), f(x^+))] - \mathbb{E}_{x \sim P_U, x' \sim P_U}[d_-(f(x), f(x'))],
\]

where we learn a pretrained feature map \(\hat{f} = \arg \min_f \mathcal{L}_{\text{pretrain}}(f)\).

2. (Fine-tune on labeled source data) We learn a head \(g\) on pretrained features \(\hat{f}(x)\) and their labels \(y_x\):

\[
\mathcal{L}(g) \triangleq \mathbb{E}_{x \sim P_S}[\ell(g(\hat{f}(x)), y_x)],
\]

where we learn a head \(\hat{g} = \arg \min_g \mathcal{L}(g)\), and the final classifier is \(\hat{g} \circ \hat{f}\). For our theory we consider only linear classifiers \(g\) (trained with fixed \(\hat{f}\)), but in our experiments we fine-tune both the head \(\hat{g}\) and encoder \(\hat{f}\).

4 Intuitions and Analysis

In this section, we explain why contrastive pre-training can learn transferable features—i.e., simply training a classifier on labeled source inputs leads to good predictions on the unlabeled target domain—despite keeping the source and target features very different. We extend the spectral contrastive learning framework (HaoChen et al., 2021) to incorporate distribution shift—we give intuitions in Section 4.2, a proof for the stochastic block model setting in Section 4.3, and a setting where contrastive pre-training outperforms domain adversarial neural networks (Ganin et al., 2016) (even when both use the same data augmentations), in Section 4.4.
### Table 1: Average error of classifying augmented images of two class-domain pairs (as a proxy for connectivity) on Living-17 and DomainNet in the input space and in the feature spaces learned by DANN+strong-augs and SwAV. The classes are very distinguishable in the feature spaces learned by both algorithms, but the domains are much more difficult to distinguish in the DANN feature space than in the contrastive pre-training feature space.

4.1 Theoretical setup

Spectral contrastive learning. HaoChen et al. (2021) theoretically analyzed contrastive learning from the perspective of an augmentation graph in which the inputs $x$ from $X$ constitute the nodes and the edge weight between $x, x'$ represents the probability of the inputs being selected as a positive pair. As in HaoChen et al. (2021), we analyze the spectral contrastive learning objective, which achieves similar empirical results to other contrastive learning methods but is more amenable to theoretical analysis:

$$L_{\text{pretrain}}(f) = -2 \cdot \mathbb{E}_{(x, x') \sim S_+} \left[ f(x)^T f(x') \right] + \mathbb{E}_{x, x' \sim P_U} \left[ \left( f(x)^T f(x') \right)^2 \right].$$

(5)

The pre-training step learns the encoder $\hat{f} : \mathcal{X} \rightarrow \mathbb{R}^k$ by minimizing (5).

Linear classification. After pre-training, we train a linear probe on source domain features with parameters $B \in \mathbb{R}^{r \times k}$ (where $k$ is the feature dimension and $r$ is the number of classes). We learn the parameters $\hat{B}$ by minimizing

$$L(B) = \mathbb{E}_{x \sim P_S} \left[ \ell(\hat{B} \hat{f}(x), y_x) \right] + \eta \|B\|_F^2,$$

(6)

where $\ell$ is the squared loss. The resulting classifier is $\hat{h}(x) = \arg \max_{i \in [r]} (\hat{B} \hat{f}(x))_i$.

4.2 Simple example

To build intuition about when spectral contrastive pre-training generalizes to the target domain, we first consider the simple example of binary classification between clocks and butterflies before presenting formal results in the next section. The input space $\mathcal{X}$ consists of 4 points: [clock sketch, butterfly sketch, clock photo, butterfly photo], where the $i$-th input refers to the $i$-th element in the list. The label space $\mathcal{Y}$ contains two classes, clock ($y_x = 1$) and butterfly ($y_x = 2$). The source distribution $P_S$ has support on the sketches ($d_x = 1$) and the target distribution has support on photos ($d_x = 2$)—see Figure 2 left. We only have labeled data for the source inputs (sketches, $d_x = 1$), and the goal is to have high accuracy on the target inputs (photos, $d_x = 2$). The unlabeled distribution $P_U$ is the uniform distribution over both sketch and photos.

Connectivities. We focus on the following four types of class-domain connectivities across all pairs of inputs $x, x'$:

1. $\rho := S_+(x, x')$, if $y_x = y_{x'}$ and $d_x = d_{x'}$ (x, x' have the same domain and class)
2. $\alpha := S_+(x, x')$, if $y_x = y_{x'}$ and $d_x \neq d_{x'}$ (across-domain; x, x' have same class but different domain)
3. $\beta := S_+(x, x')$, if $y_x \neq y_{x'}$ and $d_x = d_{x'}$ (across-class; x, x' have same domain but different class)
Figure 2: **(Left)** Illustrative example in binary classification, where each class-domain pair is a single node in the graph. Edge weights denote connectivity (probability of sampling the endpoints as a positive pair). The self-loop weight $\rho$ denotes the probability of sampling a pair of the same domain and class. **(Middle)** When $\alpha$ (same class, different domain) and $\beta$ (different class, same domain) are greater than $\gamma$ (different domain, different class), the features are oriented so that a source-trained linear classifier generalizes to the target. The class and domain information are disentangled along the vertical and horizontal axes, respectively. **(Right)** When $\alpha < \gamma$, the target features are flipped and the source-trained classifier does not generalize.

4. $\gamma := S_+(x, x')$, if $y_x \neq y_{x'}$ and $d_x \neq d_{x'}$ (across-both; $x, x'$ are from both a different class and domain, for example (sketch, clock) and (real, butterfly))

Figure 2 (left) shows the different class-domain connectivities in the simple example as a graph.

**Key condition for contrastive pre-training in the UDA setting.** We explain in our simple example how contrastive pre-training achieves zero target error when $\min\{\alpha, \beta\} > \gamma$, and we formally prove a more general version in Section 4.3. This condition is satisfied when data augmentation is less likely to change both the domain and class of an image than just one of domain or class. For example, an augmentation is less likely to connect a clock photo with a butterfly sketch, since it involves changing both the style (sketch vs. real) and the semantic content (butterfly vs. clock).

**Warm up (augmentations that preserve class, $\beta = \gamma = 0$).** Suppose that augmentations can change the domain ($\alpha > 0$) but never change the class of an image ($\beta = \gamma = 0$) (we will shortly relax this assumption). To minimize the spectral contrastive objective (Equation 5), contrastive pre-training learns an encoder that maps inputs of the same class to the same feature vector. Thus, a classifier trained on these features trivially generalizes between source and target. This warm-up reflects a similar intuition to domain invariance methods (Ganin et al., 2016; Tzeng et al., 2014) which collapse the features of different domains. However, we show next that this view cannot provide the full picture when considering the strong augmentations used in contrastive pre-training.

**Strong augmentations can change the class.** Some of the connectivity quantities (across-class and across-both) connect inputs from different classes. We consider these connectivites because in practice, contrastive pre-training involves aggressive augmentations such as cropping a small piece of an image and applying large amounts of noise. These augmentations may often change the class, perhaps even more often than they change the domain. In Table 1, we find that it is more difficult to discriminate between augmented inputs from two different classes (33% error) than it is to discriminate between augmented inputs from two different domains (27% error). This suggests that augmentations used in practice often blur the lines between classes. Thus, we must consider all the connectivity quantities when analyzing contrastive pre-training.

**Simple example with augmentations that change the class and domain.** We show in a simple 2-class, 2-domain example that contrastive pre-training learns features that allow a linear classifier trained on the source domain to extrapolate to the target domain, despite augmentations that can change the class and domain. Consider a 4-node graph $G$ where the nodes are input examples in $\mathcal{X}$ and where the edge weight between $x, x'^+ \in \mathcal{X}$ is the probability of sampling the positive pair: $S_+(x, x'^+)$. We illustrate this graph in the left panel of Figure 2.
Let $A$ denote the weighted adjacency matrix for $G$. The entries of the adjacency matrix correspond to the connectivities:

$$
A = \begin{bmatrix}
\rho & \beta & \alpha & \gamma \\
\beta & \rho & \gamma & \alpha \\
\alpha & \gamma & \rho & \beta \\
\gamma & \alpha & \beta & \rho \\
\end{bmatrix}.
$$

(7)

HaoChen et al. (2021) show that the features that minimize the spectral contrastive loss ((5)) are given by the top $k$ eigenvectors and eigenvalues of the adjacency matrix, where $k$ is the feature dimensionality (we use $k = 3$). Below, the $j$-th column of the matrix $F$ contains the $j$-th eigenvector of the adjacency matrix $A$, scaled by the square root of the $j$-th eigenvalue:

$$
F = \begin{bmatrix}
1 & 1 & 1 & 1 \\
1 & 1 & -1 & -1 \\
1 & -1 & 1 & -1 \\
1 & -1 & -1 & 1 \\
\end{bmatrix} \cdot \text{diag}\left(\sqrt{\lambda_1}, \sqrt{\lambda_2}, \sqrt{\lambda_3}, \sqrt{\lambda_4}\right)
$$

(8)

where the eigenvalue $\lambda_j$ associated with the $j$-th eigenvector is:

$$
\lambda_1 = \alpha + \beta + \gamma + \rho, \quad \lambda_2 = -\alpha + \beta - \gamma + \rho, \quad \lambda_3 = \alpha - \beta - \gamma + \rho, \quad \lambda_4 = -\alpha - \beta + \gamma + \rho.
$$

(9)

The matrix $F$ contains a superset of the features $\widehat{F}$ learned by contrastive pre-training. We consider feature dimension $k = 3$ in this example, so that the contrastive pre-trained features $\widehat{F}$ contain the top 3 columns of $F$, excluding the column corresponding to the smallest eigenvalue. The $i$-th row of the learned feature matrix $\widehat{F}$ (and $F$) is the feature vector for the $i$-th input (ordered as class sketch, butterfly sketch, class photo, butterfly photo).

Recall that our key condition is that the probability of changing only one of the class and domain (across-class or across-domain) is larger than the probability of changing both (across-both), so: $\beta > \gamma$ and $\alpha > \gamma$. Inspecting the eigenvalues in this case,

1. $\lambda_1 > \lambda_4$ since all the connectivities are nonnegative,
2. $\lambda_2 > \lambda_4$ when $\beta - \gamma > -\beta + \gamma$, which is implied by $\beta > \gamma$,
3. $\lambda_3 > \lambda_4$ when $\alpha - \gamma > -\alpha + \gamma$, which is implied by $\alpha > \gamma$.

Thus, contrastive pre-training learns features $\widehat{F}$ where the eigenvector corresponding to $\lambda_4$ is excluded. Furthermore, the first feature dimension is constant and therefore not useful. We visualize the remaining 2-D features in the middle panel of Figure 2. We see that the features nicely disentangle the domain and class information—the second feature dimension can be used to distinguish domains while the third feature can distinguish classes. Therefore, training a max-margin classifier $\widehat{h}$ on only labeled sketch images (first two rows of the feature matrix $\widehat{F}$) produces a classifier that uses only the third feature, which extrapolates to photos correctly (such that $L_{0-1}(\widehat{h}) = 0$). The key difference from conventional intuitions in domain adaptation is that contrastive pre-training does not learn domain-invariant features—the source and target are perfectly distinguishable but the domain and class information are disentangled, enabling generalization.

On the other hand, if the condition does not hold, e.g., $\alpha < \gamma$ but $\gamma < \beta$, then the learned features $\widehat{F}$ exclude the eigenvector corresponding to $\lambda_3$ as the smallest. Again, the first feature is constant and not useful. In the visualization (Figure 2 right), we show the features learned by contrastive pre-training (corresponding to the second and fourth eigenvectors). In this case, a max-margin classifier $\widehat{h}$ trained on sketch images (red line) mislabels the photos ($L_{0-1}(\widehat{h}) = 1$) because the orientation of the classes is flipped between domains.

4.3 Theory for multi-class stochastic block model

We extend and prove the intuitions in Section 4.2 in a stochastic block model setting with $r$ classes and many data points per class. We assume each class-domain pair contains $n$ data points and that $P_U$ is the uniform distribution over $\mathcal{X}$. 

7
The stochastic block model (SBM) (Holland et al., 1983) is a random graph model widely used in theoretical computer science to model communities, networks, and topic models in NLP (Bouveyron et al., 2016; Abbe, 2018; Mehta et al., 2019). The graph $G = (\mathcal{X}, E)$ is generated as follows (beginning with $E = \emptyset$): for each pair of nodes $x, x' \in \mathcal{X}$, the corresponding edge (undirected, unweighted) is in the edge set $E$ with probability:

$$
\begin{cases}
\rho & \text{if } y_x = y_{x'}, d_x = d_{x'}, \\
\alpha & \text{if } y_x = y_{x'}, d_x \neq d_{x'}, \\
\beta & \text{if } y_x \neq y_{x'}, d_x = d_{x'}, \\
\gamma & \text{if } y_x \neq y_{x'}, d_x \neq d_{x'},
\end{cases}
$$

and all edges are sampled independently. The distribution of positive pairs $S_+$ is the uniform distribution over $E$.

Our key condition is that 1) augmentations are less likely to change both the domain and class ($\min\{\alpha, \beta\} > \gamma$) and 2) augmentations are more likely to keep both class and domain unchanged than to change either one of the two ($\rho > \max\{\alpha, \beta\}$). Assuming this and using a feature dimension $r + 1$, the following result shows that contrastive pre-training on unlabeled source and target data learns transferable features so that a linear head trained on the source features achieves high accuracy on the target.

**Theorem 1.** In the SBM setting above, let $\rho > \max\{\alpha, \beta\}$ and $\min\{\alpha, \beta\} > \gamma$ and let the pre-training feature dimension be $r + 1$. Then, for any $n \geq \Omega\left(\frac{1}{\min\{\alpha - \gamma, \beta - \gamma\}^2 \cdot n}\right)$ and regularization strength $\eta \in \left(0, \frac{\sqrt{\rho}}{8\rho}\right)$, with probability at least 0.999, we have

$$
L_{0-1}(\hat{h}) \leq O\left(\frac{1}{\eta^m \cdot \min\{\alpha - \gamma, \beta - \gamma\}^2 \cdot n}ight) \cdot \text{poly}(r).
$$

where $\hat{h}(x)$ is the linear classifier trained on source domain pre-trained features (Section 4.1).

The rate at which the error decreases with the number of samples $n$ (per class-domain pair) is controlled by the gap between the across-class/ across-domain connectivities $\beta, \alpha$ and the across-both connectivity $\gamma$. Thus, augmentations that tend to change only one of class or domain will improve the downstream transferability of the learned features.

**Proof sketch.** The features learned by contrastive pre-training are given by the top $k$ eigenvectors of the adjacency matrix $A$, which is a random matrix defined by the SBM. For the expected adjacency matrix $E[A]$, similarly to the simple example, we can compute the eigenvectors in closed form and show that the linear head learned on the source data achieves low error on the target. The main challenge is to show an analogous result for the sampled graph, where each of the data points per class-domain pair can have a different set of edges. We use matrix concentration bounds to concentrate the top eigenvectors of $A$ to those of $E[A]$ and use matrix perturbation analysis to show that the predictor learned using $A$ is close to the “ideal” one learned using $E[A]$. This shows that contrastive pre-training on the random graph defined by $A$ also learns transferable features with high probability, which gives the result. 

The full proof is in Appendix A.1, where we show that the result holds even when we have more than 2 domains. This suggests that we can pre-train one model on the unlabeled data of many domains and the features can transfer across all of them. Our bound in the appendix also holds with probability arbitrarily close to 1.

As discussed earlier, contrastive pre-training does not merge source and target features. Our next result mirrors this observation theoretically in the SBM setting, showing that a linear classifier on top of the pre-trained features can classify the domain with low error. Letting $g_d : \mathbb{R}^k \to \{1, 2\}$ be a domain classifier, we define the 0-1 loss for domain classification as $L_{0-1}^D(g_d \circ \hat{f}) = \mathbb{P}_x \cdot \mathbb{P}_{y|x}[1(g_d(f(x)) \neq d_x)].$

**Proposition 2.** In the setting of Theorem 1, with probability at least 0.999, there exists a linear classifier $g_d : \mathbb{R}^k \to \{1, 2\}$, such that $g_d$ composed with the encoder $\hat{f}$ can distinguish the domains:

$$
L_{0-1}^D(g_d \circ \hat{f}) \leq O\left(\frac{1}{\min\{\alpha - \gamma, \beta - \gamma\}^6 \cdot n}\right) \cdot \text{poly}(r).
$$

The proof is in Appendix A.1 and is similar to Theorem 1.
4.4 Setting where ERM/DANN underperform contrastive pre-training

We theoretically show a simple setting in which contrastive learning on unlabeled data can have higher target extrapolation accuracy than both ERM and DANN (Equations 1 and 2, respectively). The main intuition of our construction is that ERM and DANN may underperform when there are subsets of the target data distribution that are unreachable via data augmentation on any labeled source input—in other words, inputs $x \in T$ such that $A(x | x') = 0$ for all $x' \in S$. This makes the problem underconstrained for both ERM and DANN, while contrastive pre-training better leverages the connectivity information from unlabeled source and target inputs to learn transferable features.

**Proposition 3.** There exists a set $X$, a distribution $P_U$ and data augmentation $A$, such that for some feature dimension $k \in \mathbb{Z}^+$, a linear classifier trained on contrastive pre-trained features achieves 0 target error: $L_{0-1}(\hat{h}) = 0$. However, for all $k \in \mathbb{Z}^+$, there exist minimizers $\hat{h}_{\text{erm}}$ and $\hat{h}_{\text{dann}}$ of the ERM and DANN objectives, respectively, that have non-zero error: $L_{0-1}(\hat{h}_{\text{erm}}) = L_{0-1}(\hat{h}_{\text{dann}}) = 1/3$.

The proof is in Appendix A.2. For ERM, an optimal predictor that minimizes the ERM objective (1) can make arbitrary predictions on unseen target examples. For DANN, simply matching the marginal input distributions (even with augmentations) across domains can potentially swap the classes of the unreachable target data—this is consistent with the well-known drawback that DANN with an expressive feature extractor can learn domain-invariant features by arbitrarily pairing the source and target examples (Shu et al., 2018; Zhao et al., 2019). Conversely, contrastive pre-training learns features that enable perfect transferability.

5 Contrastive pre-training is a strong domain adaptation method

Our theory gives conditions for which contrastive learning produces effective features for domain adaptation. We now empirically validate contrastive pre-training as a competitive domain adaptation method. We observe that contrastive pre-training achieves comparable performance to strong UDA methods on four standard domain adaptation datasets.

**Datasets.** We conduct experiments on DomainNet (Peng et al., 2019; Prabhu et al., 2021), which contains 40 classes and 4 domains, the BREEDS Living-17 and Entity-30 tasks (Santurkar et al., 2020), which are subpopulation shift benchmarks derived from ImageNet, and STL-10 $\rightarrow$ CIFAR-10 (Coates et al., 2011; Krizhevsky, 2009; French et al., 2018), which are two classical image recognition datasets often paired together for domain adaptation.

**Contrastive pre-training algorithm.** We use SwAV (Caron et al., 2020), a contrastive pre-training algorithm with high accuracy on ImageNet, for our ImageNet-like datasets (BREEDS and DomainNet). SwAV uses a multi-crop data augmentation strategy with several crops of different sizes, followed by horizontal flipping, color distortion, and Gaussian blurring. We pre-train on the combined source and target unlabeled data and fine-tune the entire model (pre-trained encoder and randomly initialized linear classification head) on the source using the same augmentation pipeline used during pre-training. For STL$\rightarrow$CIFAR, we use a publicly available SimCLR (Chen et al., 2020a) model that is pre-trained on CIFAR. SimCLR applies random cropping, color distortions, and Gaussian blur for data augmentation.

**Baselines.** We compare contrastive pre-training with standard ERM on the labeled source data and two strong domain adaptation methods: DANN (Ganin et al., 2016) and SENTRY (Prabhu et al., 2021). SENTRY achieves SoTA results on DomainNet when initialized with ImageNet-pretrained models. To ensure the methods all use the same data, we initialize the domain adaptation methods with the ERM baseline. For STL$\rightarrow$CIFAR, we compare to Dirt-T (Shu et al., 2018), a SoTA domain adaptation algorithm for this task. For a more complete comparison, we consider not only using each method’s default augmentations, but also applying the contrastive pre-training data augmentation pipeline to all baselines (denoted +strong-augs).

5.1 Results

**Main comparison (Table 2).** Contrastive pre-training improves over the best baseline (SENTRY+strong-augs) by 6% on Living-17 and over the best baseline (DANN+strong-augs) by 6% on Entity-30. On DomainNet, SwAV achieves...
Table 2: Test accuracy (%) of baselines, contrastive pre-training, and SwAV+extra on 4 benchmark visual adaptation datasets. The pre-training algorithm is SwAV for DomainNet, Living-17, and Entity-30, and SimCLR for STL→CIFAR. On DomainNet, SwAV is comparable with DANN+strong-augs (the best baseline). On Living-17, SwAV is 6% higher than SENTRY+strong-augs and on Entity-30 it is 6% higher than DANN+strong-augs (the best baselines). On STL→CIFAR, simply fine-tuning SimCLR on the source attains higher target accuracy than Dirt-T, the previous state-of-the-art (75.3% as reported in the original paper). The first and second highest numbers for each dataset are bolded and underlined, respectively. SwAV+extra is not bolded as it uses additional data and is therefore not directly comparable.

Comparable accuracy on average over all pairs to the best baseline, DANN+strong-augs (44.91% vs. 45.00%). On STL→CIFAR, the target accuracies of Dirt-T and SimCLR are very close (SimCLR is 0.1% better). We find that replacing the default data augmentation used by each baseline with the augmentations used by contrastive pre-training consistently boosts performance for DANN but only sometimes boosts performance for SENTRY. Table 4 provides the individual results for each pair of domains on DomainNet, and tables 4 and 6 contain results of additional contrastive pre-training methods: MoCo-V2 (Chen et al., 2020b) and MoCo-V3 (Chen et al., 2021).

Extra unlabeled data from related domains. We also consider adding extra unlabeled data from other (related) domains in DomainNet, Living-17, and Entity-30. In particular, we pre-train once on an unlabeled dataset consisting of a superset of the domains we want to adapt to, fine-tune on labeled data from one of the domains, and evaluate on all other domains. While this is not a fair comparison to other domain adaptation methods, the ability to scale to large unlabeled datasets by pre-training on all domains simultaneously is a natural advantage of pre-training. This method, which we denote as SwAV+extra, gives further improvements over SwAV (7% on DomainNet, 7% on Living-17, 3% on Entity-30). In Table 6 we show results from pre-training on different splits of the BREEDS data, as well as using additional pre-training methods: DINO+extra (Caron et al., 2021) and Barlow Twins+extra (Zbontar et al., 2021).

6 Evaluating connectivity on real datasets

Recall that our theory (Theorem 1) proves conditions on connectivities between classes and domains for which contrastive pre-training has good target accuracy. We empirically evaluate the connectivity measures on Living-17 and DomainNet to verify the predictions from our theory in Section 4. We show that the empirical connectivities satisfy our theoretical conditions for contrastive pre-training to learn transferable features (e.g., across-domain > across-both connectivity) and that connectivity ratios (e.g., across-domain / across-both) correlate well with target accuracy of contrastive pre-training.

Estimating connectivity on benchmark datasets. To verify whether real datasets and augmentation schemes satisfy the connectivity requirements for Theorem 1, we compute empirical estimates of the connectivity measures. For example, to estimate across-domain connectivity, we train a classifier to distinguish between augmented images from class-domains pairs of the same class and different domain. Other types of connectivities are analogously estimated. The estimates are in Table 1 (see Appendix C for full details). We find that connectivity ratios satisfy our theoretical conditions in all cases—this makes sense: data augmentation should be more likely to connect class-domain pairs where only the domain differs than to bridge differences across both the domain and the class.
Predicted accuracy gain

Actual accuracy gain

$R^2 = 0.78$

Figure 3: (Left) True target accuracy of SwAV (gain over the worst source/target pair with the same target) vs. the predicted accuracy using the connectivity ratios on 12 pairs of DomainNet domains. The predictions have a high coefficient of determination with the observed ($R^2 = 0.78$). (Right) Ablation of connectivity: selective removal of inputs near the margin of a domain classifier consistently degrades target accuracy more than random removal.

</table>

Table 3: Cosine similarity of class and domain classifiers trained on SwAV representations on Living-17 and DomainNet (average over all classes). Class classifiers trained on the source and target individually learn similar linear weights and are nearly orthogonal to the linear weights learned by domain classifiers.

**Connectivity ratios correlate with target accuracy.** Section 4 suggests that when the across-domain ($\alpha$) and across-class ($\beta$) connectivities are larger than the across-both ($\gamma$) connectivity (i.e., $\alpha/\gamma$ and $\beta/\gamma$ are large), contrastive pre-training learns features with good target accuracy. To investigate the relation between the connectivity ratios and target accuracy, we consider fitting the following function, with parameters $\epsilon$ and $\delta$, to the SwAV target accuracy on the 12 pairs of DomainNet domains:

$$\text{target accuracy} \approx (\alpha/\gamma)^\epsilon \cdot (\beta/\gamma)^\delta.$$  \hspace{1cm} (10)

Since our theory predicts that target accuracy is high when both ratios are large, we multiply them to express the logical “and”. To normalize by the differing intrinsic difficulties of transferring to each target domain of DomainNet, we fit Eq. 10 to the improvement over the worst pair over all source/target pairs with the same target domain. A linear regression fit of Eq. 10 in log space yields $\epsilon = 14.9$ and $\delta = 2.7$, with a strong coefficient of determination ($R^2 = 0.78$) between the predicted and observed accuracies (left panel of Figure 3). Thus, the target accuracy can be well-explained using the connectivity ratios alone.

Figures 5 and 6 show that the predicted target accuracies using this method are also accurate for MoCo-V2 (Chen et al., 2020b) ($R^2 = 0.79$) and MoCo-V3 (Chen et al., 2021) ($R^2 = 0.60$), but much less accurate for DANN+strong-augs and SENTRY ($R^2 = 0.18$ and 0.14, respectively).

**Ablating connectivity.** We find that the across-domain connectivity is very important, as those examples “bridge” the domains—for instance, our linear regression fit puts the largest weight on the across-domain connectivity ratio. We verify this intuition by removing subsets of Living-17 that contribute most to across-domain connectivity and investigating the resulting target accuracy. Specifically, we trained classifiers between source and target examples of each class and kept only the $n$ pre-training data points from each class-domain pair on which the classifier was most confident; these examples can be seen as the ones contributing least to across-domain connectivity. For several subset sizes, this confidence pruning method consistently reduces target accuracy compared to random subset removal (Figure 3 right).

**Pre-trained features disentangle class and domain.** In Section 4, we found that contrastive pre-training learns features that keeps the source and target domains apart, but are still transferable across domains. Here, we show that
contrastive pre-training learns features that disentangle class and domain information, which allows a downstream classifier to use only class or domain information.

Given a source and target dataset, we test disentanglement by training the following linear classifiers on the feature space: 1) Source classifier, which predicts classes in source; 2) Target classifier, which predicts classes in target; and 3) Domain classifier, which predicts source or target. If the class and domain information are disentangled, then the linear weights of the source/target classifier should be orthogonal to the weights of the domain classifier.

We train the linear classifiers and computing the cosine similarity between their weights on Living-17 and all pairs of domains from DomainNet (Table 8). First, we find that the domain classifier is nearly orthogonal to the source and target classifiers. The average cosine similarity between the linear weights of the source or target classifiers (corresponding to any output class) and the weights of the domain classifier is < 0.02. Second, we find that the source and target classifiers are aligned: on average over the classes, the cosine similarity of linear weights for the same class from the source and target classifiers is high (0.40 on Living-17 and average 0.19 on DomainNet). Full results are in Appendix D.

7 Conclusion

While off-the-shelf contrastive pre-training is not intentionally a domain adaptation method, we find that not only does it theoretically and empirically transfer well across distribution shifts, but it does so in a way that runs counter to conventional domain adaptation theory and practice. Given some of the practical advantages of pre-training (such as being able to pre-train once and then finetune for many different downstream tasks), we hope that our connectivity model leads to improvements for contrastive pre-training as a domain adaptation method, such as improving pre-training data selection, developing better augmentations for pre-training with distribution shift in mind, and improving fine-tuning methods that exploit the properties of the pre-trained feature space. Future work may also lead to new domain adaptation methods that focus on connectivity rather than collapsing domains.

† Although this cannot be done in practice, we only use the target labels here for exploratory analysis.

A Additional details for Section 4

A.1 Proof of Theorem 1

We first summarize the setting of the multi-domain multi-class classification problem that we will analyze.

Consider a multi-way classification problem, where \( r \) is the number of classes, \( m \) is the number of domains, \( n \) is the number of data in each class of each domain. The total number of data is \( N = rmn \). The set of all nodes is \( \mathcal{X} \).

For data \( x \in \mathcal{X} \), we use \( d_x \in [m] \) and \( y_x \in [r] \) to denote its domain and class, respectively.

We consider a stochastic block model for the graph, where the probability of existence of an edge between \( x \) and \( x' \) is:

(1) \( \rho \) if \( d_x = d_{x'} \) and \( y_x = y_{x'} \),

(2) \( \alpha \) if \( d_x \neq d_{x'} \) and \( y_x = y_{x'} \),

(3) \( \beta \) if \( d_x = d_{x'} \) and \( y_x \neq y_{x'} \),

(4) \( \gamma \) if \( d_x \neq d_{x'} \) and \( y_x \neq y_{x'} \).

Let \( A \in \mathbb{R}^{N \times N} \) be the adjacency matrix of the graph. A random positive pair \((x, x^+)\) is a uniform random edge (i.e.,

\[ p_+(x, x^+) = \frac{1}{\text{\# \text{edges}}}, \]

\[ p_{x,x'} = 0, \]

\[ p_{x,x'} = 0. \]

a negative pair \((x, x^-)\) are two uniform random nodes. Let \( k = m + r - 1 \) be the feature dimension and \( f : \mathcal{X} \to \mathbb{R}^k \) be the feature map learned by minimizing the population spectral contrastive loss:

\[
-2 \mathbb{E}_{x,x^+} [f(x)^T f(x^+)] + \mathbb{E}_{x,x^-} \left[ (f(x)^T f(x^-))^2 \right].
\]

(11)

Let \( S = \{ x \in \mathcal{X} : d_x = 1 \} \) and \( T = \{ x \in \mathcal{X} : d_x \neq 1 \} \) be source and target domains, respectively. Given the labeled source domain data, we learn the linear head

\[
\hat{b} = \arg \min_{b \in \mathbb{R}^{(k \times r)}} \sum_{x \in S} \left( \| b^T f(x) - \bar{y}_x \|^2 + \eta \| b \|_F^2 \right),
\]

(12)

where \( \bar{y}_x = e_{y_x - 1} \in \mathbb{R}^r \) is the mean-zero one-hot embedding of the label, \( \eta > 0 \) is the regularization strength.

For data \( x \in T \), we use \( \text{pred}(x) = \arg \max_i (\hat{b}^T f(x)_i) \) as the predictor.

We have the following more generalized version of Theorem 1.

**Theorem 4.** Let \( \zeta > 0 \) and \( \epsilon \in (0, \frac{1}{2}) \) be arbitrary constants. In the above stochastic block model, assume \( \rho > \max\{\alpha, \beta\} \) and \( \gamma < \min\{\alpha, \beta\} \). Then, there exists \( \tilde{\zeta} \in [1 - \epsilon, 1] \), such that for any \( n \geq \Omega \left( \frac{rm}{\min\{\alpha - \gamma, \beta - \gamma\}^2} \right) \) and regularization strength \( \eta \in \left( 0, \frac{(\alpha - \gamma)^2}{2r \rho} \right] \), with probability at least \( 1 - n^{-\zeta} \), we have

\[
\sum_{x \in T} \left\| \hat{b}^T f(x) - \tilde{\zeta} \bar{y}_x \right\|_2 \leq O \left( \frac{1}{\eta^4 \cdot \min\{\alpha - \gamma, \beta - \gamma\}^2} \right) \cdot \text{poly}(r,m).
\]

(13)

Furthermore, the target error can be bounded by

\[
\mathbb{P}_{x \sim T} \left( \text{pred}(x) \neq y_x \right) \leq O \left( \frac{1}{\eta^4 \cdot \min\{\alpha - \gamma, \beta - \gamma\}^2 \cdot n} \right) \cdot \text{poly}(r,m).
\]

(14)

Note that setting \( \epsilon = \frac{1}{4} \) and \( \zeta = 1 \) proves Theorem 1. In the rest of this subsection, we will give a proof of Theorem 4.

Let \( A_k \in \mathbb{R}^{N \times N} \) be the rank-\( k \) approximation of the adjacency matrix \( A \), which contains the top \( k \) components of \( A \)'s SVD decomposition. We use \( A_{k,(\mathcal{T}, \mathcal{S})} \) to denote the matrix by restricting \( A_k \) to the rows corresponding to the source and the columns corresponding to the target. We use \( A_{k,(\mathcal{S}, \mathcal{S})} \) to denote the matrix by restricting \( A_k \) to the rows and columns corresponding to the source.
Let \( Y \in \mathbb{R}^{N \times r} \) be the label matrix where on the \( x \)-th row it contains the label \( y_x = e_{y_x} - \frac{1}{2} \cdot 1 \). Let \( Y_S \in \mathbb{R}^{|S| \times r} \) and \( Y_T \in \mathbb{R}^{|T| \times r} \) be the matrices by restricting \( Y \) to the source and target domain, respectively.

Let \( \text{pred} \in \mathbb{R}^{N \times r} \) be the matrix with \( \hat{b}^T f(x) \) on its \( x \)-th row. Let \( \text{pred}_T \) be the matrix by restricting \( \text{pred} \) to the target domain. The following lemma gives a closed-form expression for the prediction on the target domain.

**Lemma 1.** In the setting of Theorem 4, let \( |E| \triangleq \sum_{x,x'} A_{xx'} \) be the total number of edges. Then,

\[
\text{pred}_T = A_{k,(T,S)} \left( A_{k,(S,S)} + \frac{|E|}{N^2} \cdot |S| \cdot I \right)^\dagger Y_S,
\]

where \((\cdot)^\dagger\) is the Moore–Penrose inverse, \(|S|\) is the number of data in the source domain.

**Proof of Lemma 1.** By the definition of spectral contrastive loss, we can rewrite the loss function as

\[
-2 \sum_{x,x'} \frac{A_{xx'}}{|E|} f(x)^T f(x') + \sum_{x,x'} \frac{1}{N^2} \left( f(x)^T f(x') \right)^2 \leq 0,
\]

which gives a closed-form expression for the prediction on the target domain.

\[
\text{pred}_T = \frac{N}{|E|} \cdot A - \left( \frac{1}{\sqrt{N}} \cdot F \right)^T F + \text{const},
\]

where \( F \in \mathbb{R}^{N \times k} \) is the matrix which the \( x \)-th row contains \( f(x)^T \). According to the Eckart–Young–Mirsky theorem, the minimizer of this loss function is \( F = \frac{N}{|E|} S_k \) where \( S_k \in \mathbb{R}^{N \times k} \) is a matrix such that \( A_k = S_k^\dagger S_k \).

Let \( S_{k,S} \in \mathbb{R}^{|S| \times k} \) be the matrix gotten by restricting \( S_k \) to the rows corresponding to the source data, and \( S_{k,T} \) be the matrix gotten by restricting \( S_k \) to the rows corresponding to the target data. The head learned on the source domain can be expressed as

\[
\hat{b} = \arg \min_{b \in \mathbb{R}^{(k \times r)}} \sum_{x \in S} \left( \| b^T f(x) - \tilde{y}_x \|_2^2 + \eta \| b \|_F^2 \right)
\]

\[
= \frac{\sqrt{|E|}}{N} \cdot S_{k,S}^T \left( S_{k,S} S_{k,S}^\dagger + \frac{|E|}{N^2} \cdot |S| \cdot I \right)^\dagger Y_S.
\]

Therefore, the prediction on the target domain \( \text{pred}_T \) is

\[
\text{pred}_T = F_T \hat{b} = S_{k,T} S_{k,S}^\dagger \left( S_{k,S} S_{k,S}^\dagger + \frac{|E|}{N^2} \cdot |S| \cdot I \right)^\dagger Y_S = A_{k,(T,S)} \left( A_{k,(S,S)} + \frac{|E|}{N^2} \cdot |S| \cdot I \right)^\dagger Y_S.
\]

The following lemma shows that the prediction in the expectation graph is accurate.

**Lemma 2.** Let \( \bar{A} \triangleq \mathbb{E}[A] \) be the expectation of the adjacency matrix. Then, for any \( \xi > 0 \), we have

\[
\mathbb{A}_{k,(T,S)} \left( \bar{A}_{k,(S,S)} + \xi I \right)^\dagger Y_S = \frac{\lambda_c}{\lambda_c + m \xi} \cdot Y_T,
\]

where \( k = r + m - 1 \) and \( \lambda_c \triangleq n \rho - n \beta + (m - 1) \alpha - n (m - 1) \gamma \). Furthermore, if we use \( \bar{\lambda}_i \) to denote the \( i \)-th largest eigenvalue of \( \bar{A} \), we have \( \bar{\lambda}_k - \bar{\lambda}_{k+1} = n \min \{ r (\beta - \gamma), m (\alpha - \gamma) \} \) and \( \bar{\lambda}_1 \leq n \rho m \).
Proof of Lemma 2. By the definition of the graph, every entry \( \tilde{A}_{xx'} \) is in the set of \( \{ \rho, \beta, \alpha, \gamma \} \), depending on whether \( x \) and \( x' \) belong to the same domain/class. We can index every node \( x \) as \( (d_x, y_x, id_x) \), where \( id_x \in [n] \) is the index of \( x \) within domain \( d_x \) and class \( y_x \). For any integer \( i \geq 1 \), we use \( 1_i \) to denote the \( i \)-dimensional all-one vector, and \( 1_i = 1_i / \| 1_i \| \) be its normalized unit vector. We use \( \mathbb{S}^t \) to denote the \( i \)-dimensional unit-norm sphere.

It can be verified that \( \tilde{A} \) can be decomposed into the sum of several matrix Kronecker products:

\[
\tilde{A} = (\beta - \gamma) \cdot I_m \otimes (1_n 1_n^T) \otimes (1_n 1_n^T) + (\alpha - \gamma) \cdot (1_m 1_m^T) \otimes I_r \otimes (1_n 1_n^T) + (\rho - \beta - \alpha + \gamma) \cdot I_m \otimes I_r \otimes (1_n 1_n^T) + \gamma \cdot (1_m 1_m^T) \otimes (1_r 1_r^T) \otimes (1_n 1_n^T). \tag{22}
\]

As a result, \( \tilde{A} \) has the following four sets of eigenvectors with non-zero eigenvalues:

\* \( 1_m \otimes 1_r \otimes 1_n \). The corresponding eigenvalue is \( \lambda_a \triangleq n \rho + n(r - 1) \beta + n(m - 1) \alpha + n(m - 1)(r - 1) \gamma \).

\* \( u \otimes 1_r \otimes 1_n \), where \( u \in \mathbb{S}^m \) and \( u^T 1_m = 0 \). The corresponding eigenvalue is \( \lambda_b \triangleq n \rho + n(r - 1) \beta - n \alpha - n(r - 1) \gamma \).

\* \( 1_m \otimes v \otimes 1_n \), where \( v \in \mathbb{S}^r \) and \( v^T 1_r = 0 \). The corresponding eigenvalue is \( \lambda_c \triangleq n \rho - n \beta + n(m - 1) \alpha - n(m - 1) \gamma \).

\* \( u \otimes v \otimes 1_n \), where \( u \in \mathbb{S}^m \), \( v \in \mathbb{S}^r \) and \( u^T 1_m = 0, v^T 1_r = 0 \). The corresponding eigenvalue is \( \lambda_d \triangleq n \rho - n \beta - n \alpha + n \gamma \).

Since \( \rho > \max \{ \beta, \alpha \} \) and \( \min \{ \beta, \alpha \} > \gamma \), we know that all of these eigenvalues are positive. When \( k = r + m - 1 \), \( \tilde{A}_k \) will contain exactly the first three sets of eigenvectors since they correspond to the top-\( k \) eigenvalues. This suggests that we can write \( \tilde{A}_k \) as follows:

\[
\tilde{A}_k = \lambda_a \cdot 1_m \otimes 1_r \otimes 1_n + \lambda_b \cdot (I_m - 1_m 1_m^T) \otimes 1_r \otimes 1_n + \lambda_c \cdot 1_m \otimes (I_r - 1_r 1_r^T) \otimes 1_n + \lambda_d \cdot (1_m 1_m^T) \otimes (1_r 1_r^T) \otimes 1_n. \tag{26}
\]

Restricting to the source domain, we have

\[
\tilde{A}_{k,(S,S)} = \frac{\lambda_a + (m - 1) \lambda_b}{m} \cdot 1_r 1_r^T \otimes 1_n 1_n^T + \frac{\lambda_c}{m} \cdot (I_r - 1_r 1_r^T) \otimes 1_n 1_n^T. \tag{27}
\]

By the definition of pseudoinverse, we have

\[
\left( \tilde{A}_{k,(S,S)} + \xi I \right)^\dagger = \left( \frac{\lambda_a + (m - 1) \lambda_b}{m} + \xi \right)^{-1} \cdot 1_r 1_r^T \otimes 1_n 1_n^T + \left( \frac{\lambda_c}{m} + \xi \right)^{-1} \cdot (I_r - 1_r 1_r^T) \otimes 1_n 1_n^T. \tag{28}
\]

Notice that \( Y_S \) satisfies \( (1_r 1_r^T \otimes 1_n 1_n^T) Y_S = 0 \) and \( (I_r - 1_r 1_r^T) \otimes 1_n 1_n^T) Y_S = Y_S \), we have

\[
\left( \tilde{A}_{k,(S,S)} + \xi I \right)^\dagger Y_S = \left( \frac{\lambda_a}{m} + \xi \right)^{-1} Y_S. \tag{29}
\]

We can also write \( \tilde{A}_{k,(X,S)} \) in the form of kronecker products as follows:

\[
\tilde{A}_{k,(X,S)} = \frac{\lambda_a}{m} \cdot 1_m \otimes 1_r 1_r^T \otimes 1_n 1_n^T + \lambda_b \cdot (e_1 - \frac{1}{m} 1_m) \otimes 1_r 1_r^T \otimes 1_n 1_n^T + \frac{\lambda_c}{m} \cdot 1_m \otimes (I_r - 1_r 1_r^T) \otimes 1_n 1_n^T. \tag{30}
\]
Again, using the fact that \((1, 1^T \otimes 1_n, 1_n) Y_S = 0\) and \(((I_n - 1, 1^T) \otimes 1_n, 1_n) Y_S = Y_S\), we have

\[
\hat{A}_{k,(X,S)} \left( \hat{A}_{k,(S,S)} + \xi I \right)^T Y_S = \frac{\lambda}{\lambda + m \xi} 1_m \otimes Y_S.
\] (31)

Finally, noticing that \(1_m \otimes Y_S = Y\) finishes the proof.

The following lemma shows that when a matrix \(A\) is close to \(\hat{A}\), their rank-\(k\) approximations \(A_k\) and \(\hat{A}_k\) are also close.

**Lemma 3.** Let \(\hat{A} \triangleq E[A]\) be the expectation of the adjacency matrix. Let \(A_k\) and \(\hat{A}_k\) be the rank-\(k\) approximations of \(A\) and \(\hat{A}\), respectively. Let \(\hat{\lambda}_i\) be the \(i\)-th largest eigenvalue of \(\hat{A}\), \(\|\cdot\|\) be the operator norm of a matrix or \(\ell_2\)-norm of a vector. Then, when \(\|A - \hat{A}\| < \hat{\lambda}_k - \hat{\lambda}_{k+1}\), we have

\[
\|A_k - \hat{A}_k\| \leq \left( 1 + \frac{2 \|A - \hat{A}\| + 2 \|\hat{A}\|}{(\hat{\lambda}_k - \hat{\lambda}_{k+1}) - \|A - \hat{A}\|} \right) \|A - \hat{A}\|.
\] (32)

**Proof of Lemma 3.** Let the SVD decomposition of \(A\) and \(\hat{A}\) be as follows:

\[
A = \begin{bmatrix} U_1 & U_2 \end{bmatrix} \begin{bmatrix} \Sigma_1 & 0 \\ 0 & \Sigma_2 \end{bmatrix} \begin{bmatrix} U_1^T \\ U_2^T \end{bmatrix},
\] (33)

\[
\hat{A} = \begin{bmatrix} \hat{U}_1 & \hat{U}_2 \end{bmatrix} \begin{bmatrix} \hat{\Sigma}_1 & 0 \\ 0 & \hat{\Sigma}_2 \end{bmatrix} \begin{bmatrix} \hat{U}_1^T \\ \hat{U}_2^T \end{bmatrix},
\] (34)

where \(\Sigma_1\) and \(\hat{\Sigma}_1\) contain the top \(k\) eigenvalues of \(A\) and \(\hat{A}\), respectively. By the definition of rank-\(k\) approximation, we have \(A_k = U_1 \Sigma_1 U_1^T\) and \(\hat{A}_k = \hat{U}_1 \hat{\Sigma}_1 \hat{U}_1^T\). Therefore,

\[
\|A_k - \hat{A}_k\| = \|U_1 \Sigma_1 U_1^T - \hat{U}_1 \hat{\Sigma}_1 \hat{U}_1^T\| = \max_{v \in \mathbb{R}^n: \|v\| = 1} \|(U_1 \Sigma_1 U_1^T - \hat{U}_1 \hat{\Sigma}_1 \hat{U}_1^T) v\|
\]

\[
\leq \max_{v \in \mathbb{R}^n: \|v\| = 1, v^T \hat{U}_2 = 0} \|\left(U_1 \Sigma_1 U_1^T - \hat{U}_1 \hat{\Sigma}_1 \hat{U}_1^T\right) v\| + \max_{v \in \mathbb{R}^n: \|v\| = 1, v^T \hat{U}_1 = 0} \|\left(U_1 \Sigma_1 U_1^T - \hat{U}_1 \hat{\Sigma}_1 \hat{U}_1^T\right) v\|.
\] (35)

Let \(\delta \triangleq \min\{\hat{\lambda}_k - \hat{\lambda}_{k+1}, \hat{\lambda}_k - \hat{\lambda}_{k+1}\}\). According to Weyl’s inequality, we have

\[
\|\begin{bmatrix} \Sigma_1 & 0 \\ 0 & \Sigma_2 \end{bmatrix} - \begin{bmatrix} \hat{\Sigma}_1 & 0 \\ 0 & \hat{\Sigma}_2 \end{bmatrix}\| \leq \|A - \hat{A}\|.
\] (37)

So we have \(\delta \geq \left(\hat{\lambda}_k - \hat{\lambda}_{k+1}\right) - \|A - \hat{A}\| > 0\). Now we bound \(C_1\) and \(C_2\) separately. To bound \(C_1\), we have

\[
C_1 \leq \|A - \hat{A}\| + \max_{v \in \mathbb{R}^n: \|v\| = 1, v^T \hat{U}_2 = 0} \|\left(U_2 \Sigma_2 U_2^T - \hat{U}_2 \hat{\Sigma}_2 \hat{U}_2^T\right) v\|
\]

\[
\leq \|A - \hat{A}\| + \|U_2\| \cdot \|\Sigma_2\| \cdot \|\hat{U}_2\|
\] (38)

\[
\leq \left(1 + \frac{\|\Sigma_2\|}{\delta}\right) \|A - \hat{A}\|
\] (39)

(40)
where the first line follows the triangle inequality, the second line uses $v^\top \tilde{U}_2 = 0$, and the third line uses Davis-Kahan theorem (Davis & Kahan, 1970). Similarly, to bound $C_2$, we have

$$C_2 = \max_{v \in \mathbb{R}^N : \|v\| = 1, v^\top \tilde{U}_1 = 0} \left\| U_1 \Sigma_1 U_1^\top v \right\|_2 \leq \|U_1\| \cdot \|\Sigma_2\| \cdot \left\| U_1^\top \tilde{U}_2 \right\| \leq \frac{\|\Sigma_1\| \cdot \left\| A - \tilde{A} \right\|}{\delta}. \quad (41)$$

Adding $C_1$ and $C_2$ together we have

$$\|A_k - \tilde{A}_k\| \leq \left( 1 + \frac{\|\Sigma_1\| + \|\Sigma_2\|}{\delta} \right) \cdot \left| A - \tilde{A} \right| \leq \left( 1 + \frac{2 \left\| A - \tilde{A} \right\| + 2 \left\| \tilde{A} \right\|}{\delta} \right) \cdot \left| A - \tilde{A} \right|, \quad (42)$$

where the second line again uses Weyl’s inequality.

To bound the difference between $A$ and $\tilde{A}$, we use the following lemma which is adapted from Theorem 5.2 of (Lei & Rinaldo, 2015).

**Lemma 4.** Let $A$ be the adjacency matrix of a random graph on $N$ nodes in which edges occur independently. Let $E[A] = \tilde{A} = (\tilde{A}_{ij})_{i,j=1,\ldots,N}$ be the expectation adjacency matrix and assume that $N \max_{i,j} \tilde{A}_{ij} \geq \log N$. Then, for any $\zeta > 0$ there exists a constant $C = C(\zeta)$ such that

$$\|A - P\| \leq C\sqrt{N} \quad (43)$$

with probability at least $1 - N^{-2\zeta}$.

Now we prove Theorem 4 using the above lemmas.

**Proof of Theorem 4.** By Lemma 1, we have that the prediction on the target domain is

$$\text{pred}_T = A_{k,(T,S)} \left( A_{k,(S,S)} + \frac{|E|}{N^2} \cdot \eta \cdot |S| \cdot I \right)^{\dagger} Y_S. \quad (46)$$

Let $|\tilde{E}| \triangleq 1_N^\top \tilde{A} 1_N$ be the expectation of number of edges in the graph. We define the ideal prediction as

$$\tilde{\text{pred}}_T = \tilde{A}_{k,(T,S)} \left( \tilde{A}_{k,(S,S)} + \frac{|\tilde{E}|}{N^2} \cdot \eta \cdot |S| \cdot I \right)^{\dagger} Y_S. \quad (47)$$

We will bound the difference between pred$_T$ and $\tilde{\text{pred}}_T$. For every class $c \in [r]$, define the following error vector

$$e_c \triangleq A_{k,(T,S)} \left( A_{k,(S,S)} + \frac{|E|}{N^2} \cdot \eta \cdot |S| \cdot I \right)^{\dagger} Y_S - \tilde{A}_{k,(T,S)} \left( \tilde{A}_{k,(S,S)} + \frac{|E|}{N^2} \cdot \eta \cdot |S| \cdot I \right)^{\dagger} Y_S^c, \quad (48)$$

where $Y_S^c$ is the $c$-th column of $Y_S$. 

20
Using the perturbation bound for the pseudoinverse matrix (Stewart, 1977), we have

\[
\|e\| \leq \left\| A_{k,(\tau,S)} - \tilde{A}_{k,(\tau,S)} \right\| \left\| \left( \tilde{A}_{k,(S,S)} + \frac{|E|}{N^2} \cdot \eta \cdot |S| \cdot I \right) \right\| \cdot \|Y_{\tilde{s}}\| + \|A_{k,(\tau,S)}\| \left\| \left( \tilde{A}_{k,(S,S)} + \frac{|E|}{N^2} \cdot \eta \cdot |S| \cdot I \right) \right\| \cdot \|Y_{\tilde{s}}\| \] (49)

+ \left\| A_{k,(\tau,S)} \right\| \left\| \left( \tilde{A}_{k,(S,S)} + \frac{|E|}{N^2} \cdot \eta \cdot |S| \cdot I \right) \right\| \cdot \|Y_{\tilde{s}}\| \] (50)

\[
\leq \left\| A_{k} - \tilde{A}_{k} \right\| \cdot \frac{N^2}{\eta |E| \cdot |S|} \cdot \|Y_{\tilde{s}}\| + \left\| A_{k} \right\| \cdot \frac{1 + \sqrt{5}}{2} \cdot \left( \frac{N^2}{\eta |E| \cdot |S|} \right) \cdot \left\| A_{k} - \tilde{A}_{k} \right\| \cdot \|Y_{\tilde{s}}\| . \] (51)

By lemma 4, there exists constant \( C = C(\zeta) \) such that \( \| \hat{A} - \tilde{A} \| \leq C\sqrt{N} \) with probability at least \( 1 - N^{-2\zeta} \) for any \( N > \Omega(1/\rho) \). From now on, we assume this high probability event happens. Let \( \Delta \triangleq \min \{ r(\beta - \gamma), m(\alpha - \gamma) \} \). According to Lemma 2, we know that \( \lambda_k - \lambda_{k+1} = n\Delta \). If our choice of \( N \) further satisfies \( N \geq \left( \frac{2rmC}{\Delta} \right)^2 \), we have \( \| \hat{A} - \tilde{A} \| \leq \frac{1}{2} (\hat{\lambda}_k - \lambda_{k+1}) \), so from Lemma 3 we have

\[
\| A_{k} - \tilde{A}_{k} \| \leq O \left( \frac{\hat{\lambda}_1}{\lambda_k - \lambda_{k+1}} \cdot \| \hat{A} - \tilde{A} \| \right) \leq O \left( \frac{\hat{\lambda}_1}{\lambda_k - \lambda_{k+1}} \cdot \sqrt{N} \right) . \] (52)

According to Lemma 2, we know that \( \hat{\lambda}_1 \leq nrmp \), so we have

\[
\| A_{k} - \tilde{A}_{k} \| \leq O \left( \frac{rm\rho\sqrt{N}}{\Delta} \right) . \] (53)

By Hoeffding’s inequality, with probability at least \( 1 - 2e^{-2N^2} \) we have \( \| E \| - |\tilde{E}| \leq N \). From now on, we assume this high-probability event happens. The total failure probability so far is \( N^{-2\zeta} + 2e^{-2N^2} \leq N^{-\zeta} \). By the definition of graph, we have \( |\tilde{E}| \geq \rho N^2 \). If our choice of \( N \) further satisfies \( N \geq \frac{2rm}{\rho} \), we have \( |E| \geq \frac{\rho N^2}{2rm} \), hence

\[
\frac{|E| \cdot |S|}{N^2} \geq \frac{\rho N}{2rm}. \] (54)

Substituting (53) and (54) into (51) gives:

\[
\|e\| \leq O \left( \frac{1}{\Delta \eta^2 \sqrt{N}} \right) \cdot \text{poly}(r, m) \cdot \|Y_{\tilde{s}}\| . \] (55)

Summing over all classes \( c \) and noticing that \( \|Y_{\tilde{s}}\| \leq \sqrt{N} \) leads to

\[
\|e\|_F \leq O \left( \frac{1}{\Delta \eta^2} \right) \cdot \text{poly}(r, m) \] (56)

Let \( \xi = \frac{|E|}{N^2} \cdot \eta \cdot |S| \) and \( \tilde{\xi} = \frac{|\tilde{E}|}{N^2} \cdot \eta \cdot |S| \). We have

\[
\left| \frac{\lambda_k}{\lambda_k + m\xi} - \frac{\lambda_c}{\lambda_c + m\xi} \right| \leq \frac{m}{\lambda_c} \cdot |\xi - \tilde{\xi}| \leq \frac{\eta}{N} \cdot \text{poly}(r, m). \] (57)
From Lemma 2 we have

\[
\| \hat{A}_{k,(T,S)} \left( \hat{A}_{k,(S,S)} + \frac{|E|}{N^2} \cdot \eta \cdot |S| \cdot I \right)^\dagger Y_S - \hat{A}_{k,(T,S)} \left( \hat{A}_{k,(S,S)} + \frac{|E|}{N^2} \cdot \eta \cdot |S| \cdot I \right)^\dagger Y_S \|_F,
\]

Combining (56) and (59) we have

\[
\| \text{pred}_T - \tilde{\text{pred}}_T \|_F \leq O \left( \frac{1}{\eta^2 \cdot \min(\alpha - \gamma, \beta - \gamma)} \right) \cdot \text{poly}(r, m).
\]

Notice that the \(x\)-th row of \(\tilde{\text{pred}}_T\) is \(\frac{\lambda_c}{\lambda_c + m \xi} \cdot y_{x^*}\). Since \(\lambda_c = n (r - \beta + (m - 1) \alpha - (m - 1) \gamma) \geq \frac{1}{2} nm (\alpha - \gamma)\), and \(\tilde{\xi} = \frac{|E|}{N^2} \cdot \eta \cdot |S| = \frac{n^2 \rho m + n^2 m (r - \beta + (m - 1) \alpha - (m - 1) \gamma)}{n \cdot m \cdot 2^{m-2}} \cdot \eta \cdot r n \leq \eta m \rho\), we have

\[
\frac{\lambda_c}{\lambda_c + m \xi} \geq \frac{1}{1 + \frac{2^{m-2} \rho m}{m (\alpha - \gamma)}} \geq 1 - \epsilon,
\]

where the second inequality follows our assumption on \(\eta\).

Since \(\text{pred}_T\) is incorrect on the \(x\)-th row only if its difference from the \(x\)-th row of \(\tilde{\text{pred}}_T\) has larger norm than \(\Omega(1 - \epsilon)\), we know the final total error on the target domains is bounded by \(O \left( \frac{1}{\eta^2 \cdot \min(\alpha - \gamma, \beta - \gamma)} \right) \cdot \text{poly}(r, m)\).

Collecting all the requirements of \(N\), this bound holds so long as \(N \geq \Omega \left( \left( \frac{rn}{2^{m-2} \rho m} \right)^2 \right)\), which is equivalent to

\[\begin{aligned}
\min(\alpha - \gamma, \beta - \gamma) \geq \frac{1}{4} \cdot \left( \frac{\beta - \gamma}{2^{m-2} \rho} \right)
\end{aligned}\]

Proof of Proposition 2. Notice that the roles of domain and class are the same in stochastic block model. Let \(\zeta > 0\) and \(\epsilon \in \left(0, \frac{1}{2}\right)\) be arbitrary constants. If we train a domain classifier head on class 1 with regularization strength \(\eta \in \left(0, \frac{(\beta - \gamma) \epsilon}{2^{m-2} \rho}\right)\), then following the same proof of Theorem 4, we know that when \(n \geq \Omega \left( \frac{\rho m}{\min(\alpha - \gamma, \beta - \gamma)^2} \right)\), with probability at least \(1 - n^{-\zeta}\), we have that the global error of this domain predictor is bounded by \(O \left( \frac{1}{\eta^2 \cdot \min(\alpha - \gamma, \beta - \gamma)^2} \right) \cdot \text{poly}(r, m)\). Setting \(\epsilon = \frac{1}{4}, \zeta = 1\) and \(\eta = \frac{\beta - \gamma}{8^{m-2} \rho}\) finishes the proof.

A.2 Proof of Proposition 3

Data distribution (Figure 4). In the setting of binary classification with 2 domains, let \(S = \{x \in \mathcal{X} : d_x = 1\}\) and \(T = \{x \in \mathcal{T} : d_x = 2\}\) and assume that \(P_S\) and \(P_T\) are uniform over \(S\) and \(T\), respectively. We refer to each input by its ID, so that \(\mathcal{X} = \{1, \ldots, 8\}\). The source domain \(S = \{1, 2\}\) contains 2 points while the target domain \(T = \{3, 4, 5, 6, 7, 8\}\) contains 6 points. The label space is \(\mathcal{Y} = \{-1, 1\}\). The label for \(x \in \{1, 3, 5, 7\}\) is \(y_x = 1\) and the label for \(x \in \{2, 4, 6, 8\}\) is \(y_x = -1\). The marginal distribution over unlabeled examples \(P_U\) (used by contrastive pre-training in Equation 3) is the uniform distribution over \(\mathcal{X}\). Only the inputs in the source domain \(S\) have labels for supervised learning.
We recall Proposition 3:

Proposition 3. We claim that the following classifier

\[ L \]

is defined similarly: \( \rho \) \( x \) \( \neq x' \)

By the edge structure of the graph, we have that \( \rho \), \( \alpha \), \( \beta \), and \( \gamma' \) are all distinct and obey the following inequalities: \( \rho' > \max\{\alpha', \beta'\} \) and \( \min\{\alpha', \beta'\} > \gamma' \).

**Augmentation distribution.** The augmentation distribution \( A(\cdot \mid x) \) is

\[
A(x' \mid x) = \begin{cases} 
\rho' & x = x' \\
\alpha' & y_{x'} = y_{x}, x \neq x' \\
\beta' & \{x', x\} \in \{(1, 2), (3, 4), (5, 6), (7, 8)\} \\
\gamma' & \{x', x\} \in \{(1, 4), (2, 3), (3, 6), (4, 5), (5, 8), (6, 7), (1, 8), (2, 7)\} 
\end{cases}.
\]

(62)

By the edge structure of the graph, we have that \( \rho' + 2\alpha' + \beta' + 2\gamma = 1 \). We assume that \( \rho', \alpha', \beta', \) and \( \gamma' \) are all distinct and obey the following inequalities: \( \rho' > \max\{\alpha', \beta'\} \) and \( \min\{\alpha', \beta'\} > \gamma' \).

**Distribution over positive pairs.** The augmentation distribution induces a distribution \( S_+ \) over positive pairs, which is defined similarly:

\[
S_+(x', x) = \begin{cases} 
\rho/C & x = x' \\
\alpha/C & y_{x'} = y_{x}, x \neq x' \\
\beta/C & \{x', x\} \in \{(1, 2), (3, 4), (5, 6), (7, 8)\} \\
\gamma/C & \{x', x\} \in \{(1, 4), (2, 3), (3, 6), (4, 5), (5, 8), (6, 7), (1, 8), (2, 7)\} 
\end{cases}.
\]

(63)

where the normalization is \( C = 8\rho + 16\alpha + 8\beta + 8\gamma \). The normalization ensures that the sum of \( S_+(x', x) \) over all pairs \( x', x \) is 1. At the end of this section (paragraph A.2), we show how to derive \( \rho, \alpha, \beta, \gamma \) as functions of \( \rho', \alpha', \beta', \gamma' \), respectively. We also show that the assumptions that \( \rho' > \max\{\alpha', \beta'\} \) and \( \min\{\alpha', \beta'\} > \gamma' \) imply that \( \rho > \max\{\alpha, \beta\} \) and \( \min\{\alpha, \beta\} > \gamma \).

We recall Proposition 3:

**Proposition 3.** There exists a set \( \mathcal{X} \), a distribution \( P_U \) and data augmentation \( A \), such that for some feature dimension \( k \in \mathbb{Z}^+ \), a linear classifier trained on contrastive pre-trained features achieves 0 target error: \( L_{0-1}(\hat{h}) = 0 \). However, for all \( k \in \mathbb{Z}^+ \), there exist minimizers \( \hat{h}_{erm} \) and \( \hat{h}_{dann} \) of the ERM and DANN objectives, respectively, that have non-zero error: \( L_{0-1}(\hat{h}_{erm}) = L_{0-1}(\hat{h}_{dann}) = 1/3 \).

**ERM.** We claim that the following classifier \( \hat{h}_{erm} \) is a minimizer of the ERM objective with data augmentation (Equation 1):

\[
\hat{h}_{erm}(x) = \begin{cases} 
1 & \text{if } x \in \{1, 3, 6, 7\} \\
-1 & \text{if } x \in \{2, 4, 5, 8\} 
\end{cases}.
\]

(64)

Figure 4: Example distribution of data and augmentations in which ERM and DANN generalize more poorly than contrastive learning. ERM and DANN minimizers are only guaranteed to correctly label inputs that are either in the source domain or reachable from source inputs via data augmentation, while connectivity throughout the target domain allows contrastive pre-training to generalize even to target inputs that are multiple “hops” away from the source. The orange dotted lines on the far left and far right connect to each other but are illustrated as straight dotted lines for cleanliness.
We show that \( \hat{A} \) we have that \( x \) when \( \hat{R} \) augmentation \( x \) by \( \lambda \) following encoder \( \text{DANN} \). This shows that \( \hat{f} \) for \( x \) the ERM objective will output \( 1 \) \( x \) since \( P \sim f(x') = 1 \) \( x \). Thus any minimizer of the ERM objective will correctly classify these 6 inputs (including 4/6 of the target points \( \{5, 6\} \)). Since this classifier outputs the incorrect prediction 2/6 of the target points \( \{5, 6\} \), it has a target error of 1/3. It remains to show that \( \hat{h}_{\text{erm}} \) is a minimizer of the ERM objective.

To see why, we first define the reachable set \( \mathcal{R} = \{1, 2, 3, 4, 7, 8\} \) as the inputs that are sampled with probability greater than 0 as augmentations of the labeled source data, and rewrite Equation 1 as

\[
\mathcal{L}_{\text{ERM}}(h) = \mathbb{E}_{x \sim P_S, x' \sim A(\cdot | x)}[1[h(x') \neq y_x]]
\]

where in the last step, we replace the sum over the entire input space \( \mathcal{X} \) with the reachable set \( \mathcal{R} \) since \( A(x' | x) = 0 \) when \( x' \) is not in the reachable set. Since \( x \in \{5, 6\} \) are not included in this sum, the prediction of \( h \) on \( \{5, 6\} \) can be arbitrary (and wrong). This shows that there exists a minimizer of the ERM objective with error at least 1/3, since the minimizer can classify 2/6 target inputs incorrectly.

However, all minimizers of ERM output the correct prediction for the other inputs. From above, we have

\[
\mathcal{L}_{\text{ERM}}(h) = P_S(x = 1) \left( \sum_{x' \in \mathcal{R}} A(x' | x = 1) 1[h(x') \neq 1] \right) + P_S(x = 2) \left( \sum_{x' \in \mathcal{R}} A(x' | x = 2) 1[h(x') \neq -1] \right)
\]

since \( P_S(x = 1) = P_S(x = 2) = 1/2 \). For each \( x' \in \mathcal{R} \), the minimizer will output 1 if \( A(x' | x = 1) > A(x' | x = 2) \).

For \( x' = 1 \), we have that \( A(x' | x = 1) = \rho' \), which by assumption is larger than \( A(x' | x = 2) = \beta' \). For \( x' = 3, 7 \), we have that \( A(x' | x = 1) = \alpha' \), which by assumption is larger than \( A(x' | x = 2) = \gamma' \). Therefore any minimizer of the ERM objective will output 1 for \( x \in \{1, 3, 7\} \). By symmetry, any minimizer of the ERM objective will output \(-1\) for \( x \in \{2, 4, 8\} \). Thus any minimizer of the ERM objective will correctly classify these 6 inputs (including 4/6 of the target inputs). This shows that \( \hat{h}_{\text{erm}} \) is a minimizer of the ERM objective and has target error 1/3.

**DANN.** Let \( z_1, z_{-1} \in \mathbb{R}^k \) be distinct points in the representation space such that \( z_1 \neq z_{-1} \). We claim that the following encoder \( \hat{f}_{\text{dann}} \) and classification head \( \hat{b}_{\text{dann}} \) minimize the DANN objective (Equation 2):

\[
\hat{f}_{\text{dann}}(x) = \begin{cases} z_1 & \text{if } x \in \{1, 3, 6, 7\} \\ z_{-1} & \text{if } x \in \{2, 4, 5, 8\} \end{cases} \quad \text{and} \quad \hat{b}_{\text{dann}}(z) = \begin{cases} 1 & \text{if } z = z_1 \\ -1 & \text{if } z = z_{-1} \end{cases}.
\]

The first term in the DANN objective is equivalent to the ERM objective, and the classifier \( \hat{h}_{\text{dann}} : \hat{h}_{\text{dann}} \circ \hat{f}_{\text{dann}} \) outputs the same predictions as the ERM minimizer \( \hat{h}_{\text{erm}} \). Therefore, \( \hat{f}_{\text{dann}} \) minimizes the first term of Equation 2 by the same argument from the ERM section.

We show that \( \hat{f}_{\text{dann}} \) minimizes the second term of Equation 2. First, we show that the second term is lower bounded by \(-\lambda/4\). To do this, we first consider the distribution of source inputs after augmentation. The probability that an augmentation \( x' \) of \( x \sim P_U \) is in \( S = \{1, 2\} \) is

\[
\mathbb{P}[x' \in S] = \sum_{x' \in S} P_U(x) \sum_{x' \in S} A(x' | x)
\]

\[
= 2 \cdot \frac{1}{8} (\rho' + \beta') + 4 \cdot \frac{1}{8} (\alpha' + \gamma')
\]

\[
= \frac{1}{4} (\rho' + \beta' + 2\alpha' + 2\gamma')
\]

\[
= 1/4.
\]
Let $\xi : \mathbb{R}^k \rightarrow \{1, 2\}$ be a domain classifier (from the model family of all functions from $\mathbb{R}^k$ to $\{1, 2\}$). For any encoder $f$ (from the model family of all functions from $X$ to $\mathbb{R}^k$), consider a domain classifier $\xi$ which always predicts target, so that $\xi(f(x')) = 2$ for all $x'$. This domain classifier attains error $1/4$ (for the misclassified source inputs). Therefore the second term of the DANN loss is lower bounded (i.e., the domain classification error is upper bounded):

$$-\min_{\xi} \lambda \mathbb{E}_{x \sim P_U, x' \sim A(\cdot | x)}[1[\xi(f(x')) \neq d_x]] \geq -\lambda/4.$$  \hfill (75)

where $\lambda$ is the weight of the second term in the DANN loss.

Next, we show that $\hat{f}_{\text{dann}}$ attains the optimal value $-\lambda/4$. Since $\hat{f}_{\text{dann}}(x')$ can only be one of two values, it is straightforward to see that, the minimizing domain classifier $\xi$ must predict $\xi(z_1) = 1$ and $\xi(z_{-1}) = -1$. This shows that $\hat{f}_{\text{dann}}$ achieves the optimal value of $-\lambda/4$ for the second term.

Contrastive pre-training. We show that contrastive pre-training achieves 0 target error on this example as long as $\alpha > \gamma + \beta$. Examining Figure 4, $\alpha$ intuitively corresponds to the probability that an image $x$ augments to a different image $x'$ of the same class, while $\gamma$ and $\beta$ correspond to the probability that $x$ augments to $x'$ of a different class. Roughly speaking, the condition $\alpha > \gamma + \beta$ means that augmentations should preserve the class more often than not.

We prove that contrastive pre-training achieves 0 target error by first deriving the representations learned by contrastive learning on unlabeled data $P_U$ (Equation 5), and then deriving the linear probe learned by optimizing the squared loss on source examples $S$ (Equation 6) and examining its accuracy on target examples $T$.

Step 1 (Pretraining): During the pre-training phase, we use inputs sampled from $P_U$ to learn an encoder $\hat{f}$ which minimizes the spectral contrastive loss (Equation 5). We define the embedding matrix $\hat{F} \in \mathbb{R}^{8 \times k}$ as follows: the $i$-th row of $\hat{F}$ is the feature vector for example $i$—that is, $\hat{F}_i = \hat{f}(i)$ where $\hat{F}_i \in \mathbb{R}^k$ denotes the $i$-th row of $\hat{F}$.

In this step of the proof we will compute $\hat{F}$ analytically. $\hat{F}$ is given by the top $k$ eigenvectors and eigenvalues of the adjacency matrix $A$, following the analysis in HaoChen et al. (2021). We begin by computing these eigenvectors and eigenvalues.

Let $A$ be the adjacency matrix, where $A_{ij} = S_+(i, j)$ is the probability of sampling a positive pair $(i, j)$. Writing $A$ out explicitly,

$$A = \frac{1}{C} \begin{bmatrix} \rho & \beta & \alpha & \gamma & 0 & 0 & \alpha & \gamma \\ \beta & \rho & \gamma & \alpha & 0 & 0 & \alpha & \gamma \\ \alpha & \gamma & \rho & \beta & \alpha & \gamma & 0 & 0 \\ \gamma & \alpha & \beta & \rho & \gamma & \alpha & 0 & 0 \\ 0 & 0 & \alpha & \gamma & \rho & \beta & \alpha & \gamma \\ 0 & 0 & \gamma & \alpha & \beta & \rho & \gamma & \alpha \\ \alpha & \gamma & 0 & 0 & \alpha & \gamma & \rho & \beta \\ \gamma & \alpha & 0 & 0 & \gamma & \alpha & \beta & \rho \end{bmatrix}$$ \hfill (77)

for normalization constant $C = 8\rho + 16\alpha + 8\beta + 16\gamma$.

Let $\lambda' \in \mathbb{R}^8$ be the eigenvalues of $A$, and $U \in \mathbb{R}^{8 \times 8}$ be a matrix where the columns are corresponding unit-norm
We now write out the embedding matrix. We choose \( k > \gamma \) for the representation dimension of contrastive learning, following Theorem 1. We now show that the top 3 eigenvalues includes \( \lambda_1 \) and \( \lambda_8 \) and does not include \( \lambda_2 \) and \( \lambda_6 \).

Since \( \rho, \alpha, \beta, \gamma > 0 \), from basic algebra:

\[
\lambda_1 > \lambda_4 = \lambda_5 > \lambda_2 = \lambda_3.
\] (80)

Since \( \alpha > \gamma + \beta \) and \( \beta > 0 \), we also have \( \alpha > \gamma \), which means:

\[
\lambda_3 > \lambda_6.
\] (81)

Using these facts, we also get:

\[
\lambda_1 > \lambda_8 > \lambda_2 = \lambda_3.
\] (82)

We assumed that \( \alpha > \gamma + \beta \), which gives us:

\[
\lambda_8 > \lambda_4 = \lambda_5.
\] (83)

Finally, we note that \( \lambda_1 > \lambda_8 \) and \( \lambda_1 > \lambda_7 \) because \( \rho, \alpha, \beta, \gamma > 0 \).

Collating all these inequalities, we find that \( \lambda_1 \) is the largest eigenvalue, and that \( \lambda_8 \) is larger than \( \lambda_2, \lambda_3, \lambda_4, \lambda_5, \lambda_6 \) (all eigenvalues except possibly \( \lambda_7 \), which can be larger or smaller than \( \lambda_8 \)). This shows that the top 3 eigenvalues includes \( \lambda_1 \) and \( \lambda_8 \). Since \( \lambda_2 \) is smaller than \( \lambda_1, \lambda_8, \lambda_4, \lambda_5 \) and \( \lambda_6 \) is even smaller than \( \lambda_2 \), we also get that \( \lambda_2, \lambda_6 \) (and \( \lambda_3 \)) are not among the top 3 eigenvalues.

We now write out the embedding matrix \( F \) in terms of the top 3 eigenvectors and eigenvalues. From above, we know that the top 3 eigenvalues are \( \lambda_u, \lambda_1, \lambda_8 \), where \( a \neq 2 \) and \( a \neq 6 \). Let \( u_a, u_1, u_8 \) be the corresponding eigenvectors: the \( a \)-th, 1-st, and 8-th column of \( U \) respectively. From HaoChen et al. (2021) (specifically, Lemma 3.2 and then using Eckart–Young–Mirsky theorem), for some orthonormal (rotation) matrix \( R \in \mathbb{R}^{k \times k} \), we have:

\[
\hat{F} = [\sqrt{\lambda_u}u_8; \sqrt{\lambda_1}u_1; \sqrt{\lambda_8}u_a]R = \frac{1}{\sqrt{C}}[\sqrt{\lambda_8}u_8; \sqrt{\lambda_1}u_1; \sqrt{\lambda_a}u_a]R.
\] (84)

where each column of \( U \) is an eigenvector of \( A \), and \( D \) is a diagonal matrix that normalizes the eigenvectors to unit norm, given by:

\[
D = \text{diag} \left( \sqrt{\lambda_1}, \sqrt{\lambda_2}, \sqrt{\lambda_3}, \sqrt{\lambda_4}, \sqrt{\lambda_5}, \sqrt{\lambda_6}, \sqrt{\lambda_7}, \sqrt{\lambda_8} \right).
\] (79)
Let $\tau_8 = \sqrt{X_a} \cdot D_{88} = \sqrt{X_8} / \sqrt{8}$, $\tau_1 = \sqrt{X_1} \cdot D_{11} = \sqrt{X_1} / \sqrt{8}$, and $\tau_a = \sqrt{X_a} \cdot D_{aa}$. We can then write $\hat{F}$ as follows, where $\tau_8, \tau_1, \tau_a > 0$. Focus on the values in the first column since this will be especially important in step 2 of the proof:

$$
\hat{F} = \begin{bmatrix}
-\tau_8 & \tau_1 & \tau_a U_{1a} \\
\tau_8 & \tau_1 & \tau_a U_{2a} \\
-\tau_8 & \tau_1 & \tau_a U_{3a} \\
\tau_8 & \tau_1 & \tau_a U_{4a} \\
-\tau_8 & \tau_1 & \tau_a U_{5a} \\
\tau_8 & \tau_1 & \tau_a U_{6a} \\
-\tau_8 & \tau_1 & \tau_a U_{7a} \\
\tau_8 & \tau_1 & \tau_a U_{8a}
\end{bmatrix} R. \tag{85}
$$

Next, we show that $U_{1a} = U_{2a}$. To see this, recall that $a \notin \{1, 2, 6, 8\}$. Inspecting $U$ above in Equation 78, we see that for all other possible choices of $a$ (so $a \in \{3, 4, 5, 7\}$), $U_{1a} = U_{2a}$.

Therefore, we can write $\hat{F}$ as (we have only changed the third column on the second row, notice now that the first two rows only differ on the first coordinate):

$$
\hat{F} = \begin{bmatrix}
-\tau_8 & \tau_1 & \tau_a U_{1a} \\
\tau_8 & \tau_1 & \tau_a U_{1a} \\
-\tau_8 & \tau_1 & \tau_a U_{3a} \\
\tau_8 & \tau_1 & \tau_a U_{3a} \\
-\tau_8 & \tau_1 & \tau_a U_{5a} \\
\tau_8 & \tau_1 & \tau_a U_{5a} \\
-\tau_8 & \tau_1 & \tau_a U_{7a} \\
\tau_8 & \tau_1 & \tau_a U_{7a}
\end{bmatrix} R. \tag{86}
$$

**Step 2 (Linear probing):** We consider the target error of a classification head $\hat{b}$ composed with the encoder $\hat{f}$ learned by contrastive pre-training. The classification head minimizes the following objective (originally defined in Equation 6):

$$
\mathcal{L}(B) = \mathbb{E}_{x \sim P_x} \left[ \| \hat{f}(x)^\top B - y_x \|^2_2 + \eta \| B \|^2_2 \right] \tag{87}
$$

where $B \in \mathbb{R}^k$, the regularization is nonzero ($\eta > 0$), and predictions are made by $\text{sign}(\hat{f}(x)^\top B)$. The pre-trained encoder $\hat{f}$ is fixed and obtained from step 1 above, and so the minimization is over $B$. In our case we only have two source labeled points, so the objective is minimized over these two labeled source points $x \in \{1, 2\}$. Since the objective is rotationally symmetric, without loss of generality we can omit the rotation matrix $R$ in the pretrained representation above in Equation 86. We consider the minimizer $\hat{B}$ of the fine-tuning objective $\mathcal{L}$. Since the regularization strength $\eta$ is strictly greater than 0, the $j$-th coordinate of the minimizer $\hat{B}_j$ is 0 when the features for the labeled data $x \in \{1, 2\}$ are identical on the $j$-th coordinate: $\hat{f}(1)_j = \hat{f}(2)_j$.

Note that $y_1 = 1$ and $y_2 = -1$, and $\hat{f}(1)$ and $\hat{f}(2)$ are given above in Equation 86. Solving the optimization problem in Equation 87 analytically (e.g., by taking derivatives setting to 0), we get for some $\omega > 0$:

$$
\hat{B} = [-\omega, 0, 0]. \tag{88}
$$

Finally we show that this classifier (composed with the features learned in the previous step) predicts every target example correctly. Inspecting the feature matrix in Equation 86, we have for $x \in \{1, 3, 5, 7\}$:

$$
\hat{B}^\top \hat{f}(x) = \tau \omega > 0 \text{ and } y_x = 1, \tag{89}
$$

and for $x \in \{2, 4, 6, 8\}$,

$$
\hat{B}^\top \hat{f}(x) = -\tau \omega < 0 \text{ and } y_x = -1. \tag{90}
$$

In other words, $\text{sign}(\hat{f}(x)^\top \hat{B}) = y_x$ for all $x$, and so the target error is 0, as desired.
Conversion from augmentation to positive pair distribution. Above, we worked out the proof for contrastive pre-training in terms of the positive pair distribution $S_+(x', x)$. We showed that if $\alpha > \gamma + \beta$ then contrastive pre-training achieves 0 target error. We still need to show that such a setting exists—we started out by defining the augmentation probabilities, and we show that there is indeed some setting of $\rho', \alpha', \gamma', \beta'$ such that the condition $\alpha > \gamma + \beta$ holds.

Recall that the positive pair distribution is defined as

$$S_+(x', x) = \mathbb{E}_{x \sim P_U}[A(x \mid \bar{x})A(x' \mid \bar{x})].$$

The distribution $S_+$ induced by $A$ on $X$ is

$$S_+(x', x) = \begin{cases} 
\rho = \frac{1}{C} \left[ \rho^2 + 2\alpha'^2 + \beta'^2 + 2\gamma^2 \right] & x = x' \\
\alpha = \frac{1}{4C} \left[ \rho\alpha' + \beta'\gamma' \right] & y_x = y_{x'}, x \neq x' \\
\beta = \frac{1}{4C} \left[ \rho'\beta' + 2\alpha'\gamma' \right] & \{x', x\} \in \{(1, 2), (3, 4), (5, 6), (7, 8)\} \\
\gamma = \frac{1}{4C} \left[ \rho'\gamma' + \alpha'\beta' \right] & \{x', x\} \in \{(1, 4), (2, 3), (3, 6), (4, 5), (5, 8), \{6, 7\}, (1, 8), (2, 7)\}
\end{cases}$$

(92)

where the constant $C$ ensures that the probabilities sum to 1.

By setting $\gamma' = 0, \beta' = 0, \alpha' > 0, \rho' > 0$ such that $2\alpha' + \rho' = 1$, we get the desired condition $\alpha > \gamma + \beta$. This shows that there exists one such scenario, where the condition holds, as desired. However, we note that there are many situations where the condition $\alpha > \gamma + \beta$ holds.

B Additional Details for Section 5

B.1 Additional Experiments

Table 4 contains target test accuracies on all individual pairs of DomainNet domains (Table 2 contains only the average) with all baselines and SwA V, in addition to MoCo-V2 and MoCo-V3 (additional contrastive pre-training methods). Table 6 contains target test accuracies on BREEDS of SwA V (with source-only and target-only splits of the pre-training data), MoCo-V3 (with source and target pre-training), and Dino and Barlow Twins (both with ImageNet pre-trained weights downloaded from official Github repositories). The MoCo-V2 and MoCo-V3 hyperparameters were tuned on ImageNet, and we did not tune either; therefore, for MoCo-V2 the target test accuracies are lower than several of the baselines on DomainNet (which is more different from ImageNet than Living-17 is).

Table 4: Test accuracy (%) of baselines, MoCo-V2, MoCo-V3, SwA V, and SwA V+extra on all individual domain pairs of DomainNet. SwA V on average is comparable with the best baseline, DANN+strong-augs (44.91 vs. 45.00).
Table 5: Test accuracy (%) of SENTRY and SENTRY+strong-augs on DomainNet with model selection via early stopping on target test accuracy (as opposed to the final iterate, which is used in the main experiments). This model selection criterion significantly improves SENTRY transfer accuracy of pairs with painting or clipart as the source domain, and slightly improves accuracy of pairs with real or sketch as the source domain, but still underperforms both SwAV and MoCo.

Table 6: Test accuracy (%) of additional contrastive pre-training methods on Living-17 and Entity-30: SwAV (with source-only and target-only pre-training), MoCo-V3 (source and target pre-training), Dino+ (ImageNet pre-training), and Barlow Twins+ (ImageNet pre-training). For ease of comparison, SwAV (S+T) and SwAV+ results are repeated from Table 2. On both datasets, with source and target pre-training MoCo-V3 is comparable with SwAV and with ImageNet pre-training Dino and Barlow Twins are comparable with SwAV.

B.2 Datasets

BREEDS. BREEDS is a subpopulation shift benchmark derived from ImageNet by constructing a hierarchical tree structure of classes from WordNet. Nodes at a specified depth of the tree become the labels for the classification task, and descendant nodes are treated as subpopulations that can be randomly partitioned into source and target domains.

We use the dataset creation functions defined in the robustness Python library to generate the Living-17 and Entity-30 tasks from the original ImageNet dataset (Engstrom et al., 2019; Russakovsky et al., 2015). The Living-17 dataset is an animal classification task which consists of nodes in the subtree rooted at the “living thing” node in the WordNet hierarchy. An example of a label is “ape” with subpopulations of gibbons, orangutans, gorillas, and chimpanzees. The Entity-30 dataset is a much more general task, incorporating nodes in the “entity” subtree. Labels include “building” and “home appliance”. The trailing number in the dataset name is the total number of classes in that dataset.

DomainNet. DomainNet is a large unsupervised domain adaptation task, consisting of approximately 600,000 images and 345 classes in 6 domains. Each image belongs to one of 6 domains, including sketches, clipart, and photographs. For our experiments we utilize the same filtered version of DomainNet from Prabhu et al. (2021), which uses 40 of the 345 classes and the sketch, painting, photograph, and clipart domains. This refinement is done to eliminate much of the noise present in the original DomainNet dataset (Tan et al., 2020).

For our baseline experiments with the SENTRY algorithm (Prabhu et al., 2021), we use the authors’ official repository (https://github.com/virajprabhu/SENTRY), which filters the original DomainNet dataset automatically as described above.

STL→CIFAR. CIFAR10 consists of 32 × 32 images from the former TinyImages dataset, and STL10 is derived from ImageNet and contains images with resolution 96 × 96. Both are classical image recognition datasets and are often paired together for domain shift tasks (Shu et al., 2018; French et al., 2018). We resize the STL-10 images to 32 × 32 to match the resolution of CIFAR10, as done in French et al. (2018). The two non-overlapping classes (“monkey” in CIFAR-10 and “frog” in STL10) are removed from both datasets before training, making the task a 9-class classification problem.
B.3 Algorithms and Hyperparameter Tuning

We standardize the compute requirements of all methods as much as possible, by enforcing that all methods are run for the same number of epochs with unlabeled data. For joint-training baselines, we always use the final iterate and we select hyperparameters based on target test accuracy (i.e., OOD accuracy).

ERM.

- **DomainNet.** The SENTRY algorithm runs ERM with class balancing (starting with ImageNet-pretrained initialization) prior to beginning entropy minimization, and therefore the SENTRY repository contains an ERM implementation and hyperparameters for DomainNet. Therefore, using that ERM implementation we run ERM for 550 epochs and multiply the initial learning rate by 10x, keeping all other hyperparameters from (Prabhu et al., 2021) constant.

- **BREEDS.** We use almost the same hyperparameters as Santurkar et al. (2020). However, on Entity30, we train for 500 epochs and divide the learning rate by 10 every 500/3 = 167 epochs. On Living17, we train for 500 epochs and divide the learning rate by 10 every 167 epochs. For both datasets we use a learning rate of 0.1, a weight decay of \(10^{-4}\), and a batch size of 128.

- **STL \(\rightarrow\) CIFAR.** The STL10 training set is much smaller than those of DomainNet and BREEDS, which gives us more freedom to sweep over hyperparameters. In turn, we vary the number of training epochs amongst \(\{100, 150, 200, 250, 300\}\), the learning rate amongst \(\{0.0001, 0.001, 0.01, 0.1\}\), the softmax temperature amongst \(\{0.5, 0.75, 1.0\}\), and the weight decay parameter amongst \(\{0.0005, 0.005, 0.05, 0.5\}\). We train the ERM model for 1000 epochs.

SENTRY. We use the official implementation (**https://github.com/virajprabhu/SENTRY**).

- **DomainNet.** For each pair of domains, we conduct a hyperparameter search through learning rates \(\in \{0.01, 0.001\}\) and temperature \(\in \{0.9, 1.0\}\). As with SENTRY, we run all hyperparameter setting for 100 epochs, select the best one (based on target test accuracy), and run for an additional 300 epochs for 400 total epochs. We initialize the SENTRY model with an ERM model trained for 150 epochs.

- **BREEDS.** We keep the default hyperparameters from the SENTRY repo but search over 3 learning rates \(\{0.001, 0.01, 0.1\}\) for 100 epochs and then run the best hyperparameter setting for 300 additional epochs for 400 total epochs. We initialize the model with an ERM model trained for 100 epochs.

- **STL \(\rightarrow\) CIFAR.** We initialize SENTRY with an ERM model trained for 100 epochs and then train SENTRY for 1000 epochs, varying the learning rate between \(\{0.001, 0.01, 0.1\}\), the weight decay between \(\{0.0005, 0.005, 0.05, 0.5\}\), and the unsupervised loss weight between \(\{0.01, 0.1, 1.0\}\).

For the “strong augmentation” version of SENTRY, we replace the RandAug algorithm used for consistency regularization with the augmentations used for SwAV (in DomainNet and BREEDS) or SimCLR (for STL / CIFAR).

DANN. We use the implementation provided in the SENTRY repository (**https://github.com/virajprabhu/SENTRY**).

- **DomainNet.** For each pair of domains, we conduct a hyperparameter search through learning rates \(\in \{0.01, 0.001\}\) and temperature \(\in \{0.9, 1.0\}\). As with SENTRY, we run all hyperparameter setting for 100 epochs, select the best one (based on target test accuracy), and run for an additional 300 epochs for a total of 400 epochs. We initialize the SENTRY model with an ERM model trained for 150 epochs.

- **BREEDS.** We sweep over two learning rates of 0.001 and 0.0005 for 100 epochs and choose the learning rate that achieves the highest OOD accuracy. We then run DANN for 300 additional epochs for 400 total epochs. The model is initialized with an ERM model trained for 100 epochs.
**STL → CIFAR.** We follow an identical procedure to that of SENTRY, initializing DANN with an ERM model trained for 100 epochs and sweeping over the same hyperparameter set. DANN was run for 1000 epochs.

For the “strong augmentation” version of DANN we simply replace the input augmentations with the augmentations used by SwAV (for DomainNet and BREEDS) or SimCLR (for STL / CIFAR) and initialize DANN from an ERM checkpoint trained with SwAV augmentations.

**DIRT-T.** DIRT-T (Shu et al., 2018) is a domain adaptation method that addresses two flaws of domain adversarial neural networks (Ganin et al., 2016): 1) distribution matching is a weak constraint, and 2) in some domain adaptation settings there does not exist a good joint classifier on both source and target. The authors address the first shortcoming by adding a conditional entropy regularization term so that the model’s decision boundaries do not overlap high-density regions of data. This is inspired by the *cluster assumption*, which states that the input space is divided into well-separated clusters, one for each class in the label space. The lack of a good classifier on both source and target is then addressed via self-training on the unlabeled target data. We report the STL→CIFAR DIRT-T results from Shu et al. (2018).

**B.4 SwAV**

We use the official SwAV implementation (https://github.com/facebookresearch/swav) and keep almost all of the hyperparameters provided by the original paper for 400 epoch, 256-batch-size training on ImageNet. However, we use a batch size of 512 and tuned SwAV slightly on Living-17 using only the training curves (no labels) and following the advice from the Github README and issues answered by the original authors:

- In order to stabilize training, we do not use a queue on DomainNet and the subsampled variants of Living-17. For pre-training on the full Living-17 and Entity-30 datasets, we introduce the queue at epoch 60.
- We set the number of prototypes to be 10 times the number of classes (170, 300, and 400 for Living-17, Entity-30 and DomainNet, respectively).
- We set $\epsilon = 0.03$.
- We set the base learning rate to 0.6, following a linear scaling rule based on batch size.

We note that the joint-training baselines required extensive hyperparameter tuning for *every* transfer task. In contrast, because SwAV was tuned for ImageNet training, we selected hyperparameters once (on Living-17) and use the same hyperparameters (except for the queue) on all our datasets. For fine-tuning, we always initialize with the final iterate of SwAV pre-training (400 epochs). Additional dataset-specific details:

- **DomainNet.** For consistency, we fine-tune SwAV pre-trained models for 150 epochs with strong data augmentations using the ERM implementation in the SENTRY repository (without running any joint-training algorithm), keeping all hyperparameters other than the number of epochs constant. We report the target test accuracy of the final iterate (i.e., after 150 epochs).
- **Living-17.** We fine-tune SwAV models for 100 epochs strong data augmentations and with a cosine learning rate schedule without restarts. We use SGD with initial learning rate 0.1 for the classifier head and 0.01 for the encoder, momentum 0.9, and weight decay 0.0001. We use a batch size of 96, and once again report the target test accuracy of the final model (i.e., after 100 epochs).
- **Entity-30.** We linear probe for 100 epochs instead of fine-tune on Entity-30, due to its large size (300k examples).

**B.5 SimCLR**

We use the official SimCLR implementation (https://github.com/google-research/simclr). We use a batch size of 256, a learning rate of 0.2, and weight decay $10^{-4}$. The projection head has two layers and an output dimension of 64. We pre-train the model for 1000 epochs with square-root learning rate scaling and we train the linear probe for 100 epochs on batches of size 512 and a learning rate of 0.1.
B.6 MoCo-V2 and MoCo-V3

We use the official MoCo implementations (https://github.com/facebookresearch/moco and https://github.com/facebookresearch/moco-v3). We use a batch size of 512 and otherwise all the default hyperparameters for MoCo-V2. We use a batch size of 256 and otherwise all the default hyperparameters for MoCo-V3. We fine-tune both MoCo versions on DomainNet and Living-17 using the same protocol as SwAV fine-tuning for each dataset.

B.7 DINO and Barlow Twins

We use ImageNet pre-trained weights from the official Github repositories (https://github.com/facebookresearch/dino and https://github.com/facebookresearch/barlowtwins). We fine-tune on Living-17 and linear probe on Entity-30 using the same protocol as for SwAV. We note that while SwAV+extra is pre-trained for 400 epochs, the DINO and Barlow Twins models were pre-trained for 800 and 1000 epochs, respectively.

B.8 Model architectures.

For all BREEDS experiments, we use a standard ResNet50 from the PyTorch torchvision library. For DomainNet, we use a ResNet50 slightly modified for few-shot learning, following Prabhu et al. (2021). On STL→CIFAR for ERM, DANN, SENTRY, and SimCLR baselines we use a standard ResNet18 from torchvision, and we additionally report the DIRT-T performance from Shu et al. (2018), which uses a custom 18-layer CNN.

C Results and Protocol for Estimating conn on Benchmark Datasets

Table 9 reports the connectivity estimates for the input space and the feature spaces learned by SwAV and DANN+strong-augs for all pairs of DomainNet domains. To estimate the connectivity between two class-domain pairs \((c,d)\) and \((c',d')\), we use the following algorithm:

1. Label all training examples of class \(c\) and domain \(d\) as 0 and all training examples of class \(c'\) and domain \(d'\) as 1. Discard the remaining examples from other classes/domains.
2. Train a ResNet50 for 100 epochs using strong augmentations and a cosine learning rate. We did not exhaustively tune this training step, but we kept the procedure constant for all classes and domains. If estimating connectivity in the input space, we train the entire network; if estimating in the feature space, we train only a linear classifier with a frozen encoder.
3. Create the test set analogously to step 1, and evaluate the classifier on strongly augmented data. The test error of the classifier is interpreted as an estimate for connectivity between the two class-domain pairs.

Each domain in DomainNet has a unique label distribution (all of which are far from uniform), and therefore in computing the average connectivity we compute the weighted mean, where each pair of (class, domain) pairs is weighted by the ratio of the less to more frequent label (0 or 1).

D Additional Experiments Verifying the Theory

D.1 Target accuracy as a function of connectivity

Eq. 10 can be rewritten as

\[
\log(\text{target accuracy}) \approx \epsilon \cdot \log(\alpha/\gamma) + \delta \cdot \log(\beta/\gamma)
\]  

(93)

and for each baseline, we fit \(\epsilon\) and \(\delta\) using a linear regression model on data from the 12 source/target domain pairs of DomainNet. We then compute the coefficient of determination \(R^2\) between the observed and predicted target accuracies.
Figure 5: Target accuracies observed vs. accuracies predicted using a function of the connectivity ratios. The top left panel reports SwAV results (repeated from the left panel of Fig. 3 for ease of comparison), the top right panel reports MoCo-V2 results, and the bottom panel reports MoCo-V3 results. The line of best fit between the observed and predicted is also plotted to help visualize the relationship.

The fitted exponents $\epsilon, \delta$ and $R^2$ for SwAV, MoCo-V2, MoCo-V3, DANN+strong-augs, and SENTRY are provided in Table 7. Figures 5 and 6 plot the observed target accuracies (y-axis) against the predicted (x-axis), along with a line of best fit through them as a visual aid.

### D.2 Disentanglement of class and domain information

Table 8 contains individual results on the cosine similarity between domain and class classifiers on DomainNet.

<table>

Table 7: Values of $\epsilon$ and $\delta$ fitted to Eq. 93, along with the coefficients of determination ($R^2$) between the observed and predicted target accuracies. Accuracies of contrastive pre-training methods (SwAV, MoCo-V2, and MoCo-V3) are well-explained using the connectivity ratios ($R^2$ of 0.78, 0.79, 0.60, respectively), while accuracies of baselines are poorly-explained ($R^2$ of 0.37 and 0.15 for DANN+strong-augs and SENTRY).
Figure 6: Target accuracies observed vs. accuracies predicted using a function of the connectivity ratios. The left panel reports DANN+strong-augs results and the right panel contains SENTRY results. The connectivity ratios are a poor predictor of the observed accuracies ($R^2 = 0.37$ and 0.15 for DANN and SENTRY, respectively). The line of best fit between the observed and predicted is also plotted to help visualize the relationship.

Table 8: Cosine similarity of class and domain classifiers trained on SwAV representations (average over all classes) on DomainNet. Class classifiers trained on the source and target individually learn similar linear weights, evidenced by the average cosine similarity 0.18. However, domain classifiers learn linear weights that are nearly orthogonal to the class classifier weights, suggesting that SwAV pre-training learns features containing domain and class information in somewhat separate directions.
Table 9: Empirical estimates of the different parameters of connectivity in the input space (top) and feature spaces computed by SwAV (middle) and DANN+strong-augs (bottom). The numbers provided are the error of classifying different types of class-domain pairs.
