Learning the conditional law: signatures and conditional GANs in filtering and prediction of diffusion processes

Fabian Germ and Marc Sabate-Vidales

Abstract—We consider the filtering and prediction problem for a diffusion process. The signal and observation are modeled by stochastic differential equations (SDEs) driven by Wiener processes. In classical estimation theory, measure-valued stochastic partial differential equations (SPDEs) are derived for the filtering and prediction measures. These equations can be hard to solve numerically. We provide an approximation algorithm using conditional generative adversarial networks (GANs) and signatures, an object from rough path theory. The signature of a sufficiently smooth path determines the path completely. In some cases, GANs based on signatures have been shown to efficiently approximate the law of a stochastic process. In this paper we extend this method to approximate the prediction measure conditional to noisy observation. We use controlled differential equations (CDEs) as universal approximators to propose an estimator for the conditional and prediction law. We show well-posedness in providing a rigorous mathematical framework. Numerical results show the efficiency of our algorithm.

I. INTRODUCTION

In many applications the state of a system is not fully observable and instead only partial or noise information is available, from which the state has to be estimated. Due to the high demand, the development of estimation theory for deterministic and stochastic dynamical systems has received enormous attention over the past decades. A very common model are SDEs, consisting of a signal and an observation model are SDEs, consisting of a signal

\[ \text{E} \left\{(X_t | F_s^t)\right\} \text{minimizes a mean square error. Sometimes it is desirable to estimate} \]

\[
\mathbb{E}(\varphi(X_t)|F_s^t)
\]

to as Kushner-Shiryaev equation [3], as well as for an unnormalized conditional distribution, referred to as Zakai equation. These are referred to as filtering equations and have been thoroughly investigated for diffusion processes. In a similar way, SPDEs for the smoothing and prediction measures, respectively \( P(X_t \in dx | \mathcal{F}_s^t) \) and \( P(X_t \in dx | \mathcal{F}_r^t) \), \( s < t < r \), can be obtained [4], [5]. Under additional regularity assumptions, it is possible to prove the existence and regularity of densities to these measures, see [6], [7], [8], [9] for early works on this and [10], [11] for a recent extension to systems with discontinuous noise.

The filtering equations are numerically challenging to solve and different approaches have been developed to approximate their solutions [2]. One of the most common, the splitting method, separates the right-handside into a deterministic and a random operator and solves for them separately [12], [13]. This either requires additional assumptions on the spaces involved [14] or relatively high regularity of the coefficients [15], [12], [13]. However, numerical solvers for (S)PDEs often underly the curse of dimensionality. Recently the splitting-up method was combined with a neural net representation to overcome this [16]. The prediction density can then be obtained using the transition probability of the process \( Z = (X, Y) \) [8], [5].

While filtering and prediction theory is mainly developed in a stochastic setting, the techniques have also proven successful in observer design for deterministic dynamical systems, where the driving disturbance is a single, though often well-behaved path [17], [18], [19].

Rough path theory is a young field, developed to treat differential equations driven by paths of low regularity that escape the scope of classical integration, see [20] and the references therein. Signatures, as sequence of iterated integrals with similarity to the Taylor expansion, are an object arising in rough path theory which encode a surprising amount of information about the path. Early works by Chen [21], [22] show that the signature map, sending a path to its signature, is injective when restricting it to a certain class of paths and later results [23], [24] establish uniqueness up to tree-like equivalence for paths with bounded variation. These results motivated the use of signatures in machine learning [25] as paths obtained by interpolation of data can be uniquely characterized by their signature [26].

Generative Adversarial Networks (GANs) were first introduced in 2014 [27] as a novel way to learn some data distribution. In this setting, two neural networks compete to generate and verify potentially new or fake data. In a time series context, there have been many recent contributions,
especially attempting to learn conditional laws, [28], [29], [30].

This paper presents a first signature-GANs based estimator for the conditional and prediction law of a diffusion process. More precisely, our model learns the conditional measure $P(X_t \in dx_i \{ Y_r : r \in [0,s] \})$, $s \leq t$ by using the universal approximation property of neural differential equations (NDEs). We prove that the estimator is well-posed and give explicit forms of the neural nets involved. Numerical results show the efficiency of our method. In a subsequent paper we will provide a proof of convergence as well as error bounds for the learned conditional distribution to the true one.

In section 2 we state conditions under which the filtering and prediction measures admit densities, required for well-posedness of our estimator. Section 3 introduces the signature and collects useful results. In section 4 we present our estimator and show well-posedness. Numerical results are shown in section 5.

**Notation.** Throughout the paper we use the following notation. We fix a $T > 0$ and consider the time interval $[0,T]$. We denote by $\mathcal{X} \subset [0,T]$ a finite set of points including 0 and $T$. We denote by $C_\mathcal{X} = C_\mathcal{X}([0,T], \mathbb{R}^d)$ the set of continuous functions that are linear between the points in $\mathcal{X}$. If $(X_t)_{t \in [0,T]}$ is a stochastic process with continuous sample paths, then we denote by $(\tilde{X})_{t \in [0,T]}$ the process constructed by interpolating the points $X_t$, where $t \in \mathcal{X}$. Moreover, for any process $(X_t)_{t \in [0,T]}$ the notation $\tilde{X}$ means the time-averaged path $(t,X_t)_{t \in [0,T]}$. For $p \geq 1$ we denote by $\mathcal{F}^p([0,T], \mathbb{R}^d)$ the space of $\mathbb{R}^d$-valued continuous paths with finite $p$-variation [20].

**II. The Filtering and Prediction Densities**

Let $(\Omega, (\mathcal{F}_t)_{t \in [0,T]}, P)$ be a complete filtered probability space. Consider the signal-observation system

$$dX_t = b(t, X_t, Y_t) \, dt + \sigma(t, X_t, Y_t) \, dW_t + \rho(t, X_t, Y_t) \, dV_t \tag{2}$$

where $(X_t)_{t \in [0,T]}$ and $(Y_t)_{t \in [0,T]}$ are $\mathbb{R}^d$ and $\mathbb{R}^d'$-valued respectively, $b$, $h$, $\sigma$ and $\rho$ are $\mathcal{B}(\mathbb{R}^{1+d+d'})$-measurable functions taking values in $\mathbb{R}^d$, $\mathbb{R}^d$, $\mathbb{R}^{d \times d'}$ and $\mathbb{R}^{d \times d'}$, respectively, and where $(W_t, V_t)_{t \in [0,T]}$ is a $d' + d'$-valued $\mathcal{F}_t$-Wiener process.

We make the following assumptions.

**Assumption 2.1:** (i) The initial condition $Z_0 = (X_0, Y_0)$ is a $\mathcal{F}_0$-measurable, independent of $(W_t, V_t)_{t \in [0,T]}$ and satisfies $\mathbb{E}[|Z_0|^2] < \infty$.

(ii) There are constants $K_0, K_1 \geq 0$ such that for all $z \in \mathbb{R}^{d+d'}$, $t \in [0, T]$ we have $|h(t, z)| \leq K_0$ and

$$|b(t, z)|^2 + |\sigma(t, z)|^2 + |\rho(t, z)|^2 \leq K_0 + K_1 |z|^2.$$ 

(iii) There exists $L \geq 0$ such that for $z_1, z_2 \in \mathbb{R}^{d+d'}$, $t \in [0, T]$,

$$|h(t, z_1) - h(t, z_2)| + |\sigma(t, z_1) - \sigma(t, z_2)| + |\rho(t, z_1) - \rho(t, z_2)| \leq L |z_1 - z_2|.$$

If Assumption 2.1 is satisfied, then by a well-known theorem by Itô we know that there exists a unique $\mathcal{F}_t$-adapted solution $Z = (Z_t)_{t \in [0,T]} = ((X_t, Y_t))_{t \in [0,T]}$ to (2) such that $Z_0 = (X_0,Y_0)$ almost surely, $Z$ has continuous sample paths almost surely and $\mathbb{E} \sup_{t \in [0,T]} |Z_t|^2 < \infty$. Let for $t \in [0,T]$

$$\mathcal{F}_t^Y := \sigma(Y_r : r \in [0,t]) \cup \mathcal{N}$$

be the filtration generated by $Y$ and completed by the zero set $\mathcal{N}$. The goal of filtering and prediction is to derive and analyze the quantities

$$\mathbb{E}(\phi(X_t)|\mathcal{F}_t^Y) \quad \text{and} \quad \mathbb{E}(\phi(X_t)|\mathcal{F}_s^Y), \quad s \leq t,$$

respectively, for $t \in [0,T]$ and $\phi \in C_0^\infty(\mathbb{R}^d)$. Fix an $s \in [0,T]$. In many applications it is desirable to obtain real valued density processes, $(\pi_t)_{t \in [0,T]}$ and $(\pi_s)_{s \in [0,T]}$, such that for each $s, t \in [0,T]$, $t \geq s$,

$$\pi_t(x) = \frac{P(X_t \in dx | \mathcal{F}_t^Y)}{dx} \quad \text{and} \quad \pi_s(x) = \frac{P(X_t \in dx | \mathcal{F}_s^Y)}{dx}$$

almost surely and hence for all $\phi \in C_0^\infty$ and $s, t \in [0,T]$,

$$\mathbb{E}(\phi(X_t)|\mathcal{F}_s^Y) = \int_{\mathbb{R}^d} \phi(x) \pi_t(x) \, dx,$$

almost surely, where $\pi_{s,t} = \pi_t$.

The following result is well-known. For a proof and more details we refer to [2], [1], [3] for classical literature, or [11] for a recent generalization to a wider class of systems.

**Theorem 2.1:** Let Assumption 2.1 hold and let $\pi_0 = P(X_0 \in dx | \mathcal{F}_0^Y) / dx \in L_2(\mathbb{R}^d)$. Then there exist an $\mathcal{F}_t^Y$-adapted measure valued process $P_t(dx) = P(X_t \in dx | \mathcal{F}_t^Y)$ such that almost surely for each $t \in [0,T]$ and $\phi \in C_0^\infty(\mathbb{R}^d)$,

$$\mathbb{E}(\phi(X_t)|\mathcal{F}_t^Y) = \int_{\mathbb{R}^d} \phi(x) P_t(dx).$$

Moreover, there is an $L_2$-valued weakly continuous process $(\pi_t)_{t \in [0,T]}$ such that for each $t \in [0,T]$ almost surely

$$\pi_t = P(X_t \in dx | \mathcal{F}_t^Y) / dx.$$

The following relates the prediction density to the filtering density, [5]. For that purpose, denote by $p(t_1, z; t_0, z_0)$ the transition probability for the process $(Z_t)_{t \in [0,T]} = ((X_t, Y_t))_{t \in [0,T]}$, that is, for $t_0, t_1 \in [0,T]$, $t_1 \geq t_0$ and $z_0 \in \mathbb{R}^{d+d'}$, for every $B \in \mathcal{B}(\mathbb{R}^{d+d'})$,

$$P(Z_t_1 \in B | Z_{t_0} = z_0) = \int_B p(t_1, z; t_0, z_0) \, dz.$$ 

**Theorem 2.2:** Let Assumption 2.1 hold and let $\pi_0 = P(X_0 \in dx | \mathcal{F}_0) / dx \in L_2(\mathbb{R}^d)$. Assume the process $Z$ has the transition density $p = p(t_1, z; t_0, z_0)$ and let $(\pi_t)_{t \in [0,T]}$ be the filtering density from Theorem 2.1 and fix $s \in [0,T]$. Then there exists a measure valued process $(P_t, s \in [s,T])$ such that (i) for each $t \in [s,T]$, $P_t$ is the regular conditional distribution of $X_t$ given $\mathcal{F}_s^Y$ and such that (ii) for each $t \in [s,T]$, $P_t$ has the Radon-Nikodym derivative

$$\pi_{s,t}(x) = \int_{\mathbb{R}^d} \int_{\mathbb{R}^d} p(t, x, y; s, x', Y_s) \pi_{s,t}(x') \, dx' \, dy.$$

For fixed $s \in [0,T]$ we call $(\pi_{s,t})_{t \in [s,T]}$ the prediction density of $(X_t)_{t \in [s,T]}$ given $\mathcal{F}_s^Y$. Indeed, an immediate calculation shows that for each $\phi \in C_0^\infty$, $t \in [s,T]$, almost surely

$$\mathbb{E}(\phi(X_t)|\mathcal{F}_s^Y) = \int_{\mathbb{R}^d} \phi(x) \pi_{s,t}(x) \, dx.$$
Henceforth we assume for the conditions of Theorem 2.2 to hold.

III. SIGNATURES AND ELEMENTS FROM ROUGH PATH THEORY

In this section we collect some objects and properties that will be used later. If not mentioned otherwise, the reader is referred to [20] and the references therein, as well as to [25], for the use of signatures in machine learning.

It is first necessary to introduce the space of formal series of tensors, which is the space signatures live in. For simplicity, we restrict ourselves to tensors over $\mathbb{R}^d$. We denote by $((\mathbb{R}^d)^\otimes n)$ the usual space of tensors over $\mathbb{R}^d$ of order $n \geq 0$.

**Definition 3.1:** (i) The space of formal series of tensors of $\mathbb{R}^d$, denoted by $T((\mathbb{R}^d))$, is defined as space of sequences,

$$T((\mathbb{R}^d)) := \{a = (a_0, a_1, a_2, \ldots) : a_n \in (\mathbb{R}^d)^\otimes n, n \in \mathbb{N}\}.$$  

For two elements $a = (a_0, a_1, a_2, \ldots)$ and $b = (b_0, b_1, \ldots)$ we can define an addition and a product by

$$a + b = (a_0 + b_0, a_1 + b_1, \ldots), \quad a \otimes b = (c_0, c_1, \ldots),$$

where for each $n \in \mathbb{N}_0$, with the usual (finite-dimensional) tensor product $\otimes$, $c_n = \sum_{k=1}^{n} a_k \otimes b_{n-k}$.

(ii) Let $N \in \mathbb{N}$ and define $B_N = \{a \in T((\mathbb{R}^d)) : a_0 = \cdots = a_{N-1} = 0\}$. Then the truncated tensor algebra of order $N$ is the quotient algebra

$$T_N(\mathbb{R}^d) = T((\mathbb{R}^d))/B_N,$$

with the canonical homomorphism $\pi_N : T((\mathbb{R}^d)) \rightarrow T_N(\mathbb{R}^d)$.

We can now identify $T_N(\mathbb{R}^d)$ with $\mathbb{R} \oplus \mathbb{R}^d \oplus \cdots \oplus ((\mathbb{R}^d)^\otimes N)$. Now we can introduce the (truncated) signature.

**Definition 3.2:** Let $X : [0, T] \rightarrow \mathbb{R}^d$ be a path of finite variation and for $s,t \in [0, T]$, $n \in \mathbb{N}$ define the iterated integral

$$X_{s,t}^{(n)} := \int_{0 \leq s_1 < \cdots < s_n \leq t} dX_{s_1} \otimes \cdots \otimes dX_{s_n}.$$  

Then the signature of $X$ over $(s,t) \subset [0,T]$ is

$$X_{s,t} = (1, X_{s,t}^{(1)}, X_{s,t}^{(2)}, \ldots) \in T((\mathbb{R}^d)).$$

Similarly, the truncated signature is

$$X_{s,t}^N = (1, X_{s,t}^{(1)}, \ldots, X_{s,t}^{(N)}) \in T_N(\mathbb{R}^d).$$

Though signature captures deep geometric properties of a path, it does not necessarily characterise the path completely. It was shown that for continuous paths of bounded variation, the signature determines the path up to tree like equivalence [23]. A sufficient result for the present case is the following, Theorem 2.29 in [20].

**Theorem 3.1:** Among all paths with bounded variation sharing the same signature, there exists a path with minimal length, which is unique up to reparametrization. For linearly interpolated data points this in particular means the following. Recall the notation introduced above.

**Corollary 1:** For $X, Y \in C^p$, $X = Y$ only if $X = Y$.

It is clear that for a basis $(e_1, \ldots, e_d)$ of $\mathbb{R}^d$ and its dual basis $(e_1, \ldots, e_d)'$ of $((\mathbb{R}^d)^\ast)$, the elements $(e_i = e_i \otimes e_i)_{i=1,\ldots,d}$ form a basis of $((\mathbb{R}^d)^\otimes 2)$, just as the elements $(e_i = e_i \otimes e_i \otimes e_i)_{i=1,\ldots,d}$ form a basis of $((\mathbb{R}^d)^\otimes 3)$. Recall that we can canonically identify $((\mathbb{R}^d)^\ast)^\otimes n$ with $((\mathbb{R}^d)^\otimes n)^\ast$. Thus we have a linear mapping $((\mathbb{R}^d)^\ast)^\otimes n \rightarrow T((\mathbb{R}^d))^\ast$ by the relation

$$e_i(a) = e_i(\pi_n(a)) = a_{i_1,\ldots,i_n},$$

which is the coefficient in front of the basis vector $e_i$ in $a$.

In this way we get a linear mapping [20]

$$T((\mathbb{R}^d)^\ast) = \bigoplus_{n=0}^{\infty} ((\mathbb{R}^d)^\ast)^\otimes n \rightarrow (T((\mathbb{R}^d))^\ast)^n.$$  

Thus also, for a path $X$ and its signature $X$, by linearity

$$e_i(X) = \int_{0 \leq s_1 < \cdots < s_n \leq t} e_i dX_s \otimes \cdots \otimes e_i dX_s.$$  

**Definition 3.3:** Let $(\mathcal{Q}, \mathcal{F}, \mathbb{P})$ be a probability space, $(X_t)_{t \in [0,T]}$ an $\mathbb{R}^d$-valued stochastic process and $X$ its signature. If $\mathbb{E}(X) < \infty$, then it is the expected signature of $X$.

The following is a very useful result [31].

**Theorem 3.2:** Let $p \geq 1$, let $K \subset S^{\ast\ast}([0,T], \mathbb{R}^d)$ be compact and let $f : K \rightarrow \mathbb{R}$ be continuous. Then for every $\varepsilon > 0$ there exists a linear functional $L \in T((\mathbb{R}^d))^\ast$ such that for all $a \in K$ we have

$$\|f(a) - La\| \leq \varepsilon.$$  

While we do not go into details on the choice of a norm $\|\cdot\|$ on $T((\mathbb{R}^d))^\ast$ (see [20] for instance), we define, for functionals $f \in T((\mathbb{R}^d))^\ast$.

$$\|f\|_{Lip, 1} := \sup_{a \neq b} \frac{|f(a) - f(b)|}{\|a - b\|}.$$  

IV. THE SIG-WASSERSTEIN-GAN PREDICTOR

In the following we provide a mathematical framework for our approximation method. First we give precise meaning and forms to the neural nets in the GAN used in our model, relying on the theory of optimal transport [32]. Then we outline the use of the Wasserstein distance on the signature space [28], [29] using expected signatures [26].

A. Well-posedness of the estimator

We build the estimator as the composition of two Neural Differential Equations (NDEs) [33]. The first NDE encodes the information carried by the filtration $(\mathcal{F}_t^Y)_{0 \leq t \leq 5}$, whilst the second NDE is carefully designed so that its vector field parametrizes the rate of change of the mean prospective transition, see Lemma 4.2 below.

**Estimator equations.** Let $\theta = (\theta_{0,0}, \theta_1, \theta_{2,0}, \theta_2) \in \Theta := \mathbb{R}^{P_1+p_1+P_2+p_2}$, for some $p_1,0, p_1, p_2, p_2 \in \mathbb{N}$ which we refer to as (learning) parameter and parameter space respectively. Fix $k \in \mathbb{N}$ and let $\mathbb{K} := \mathbb{R}^k$ and $\mathbb{Z} := \mathbb{R}^d$ be latent and sampling space respectively. Let $\gamma \sim \mathcal{N}(0, I)$ be a standard Gaussian $\mathbb{Z}$-valued random variable with law $\mu_B$ and density $k(z)$. For each $\theta \in \Theta$ let $\theta_B : \mathbb{R}^d \rightarrow \mathbb{K}$, $H_{\theta_B} : \mathbb{K} \times \mathbb{Z} \rightarrow \mathbb{R}^d$, $G_{\theta_B} : \mathbb{R} \times \mathbb{R}^d \rightarrow \mathbb{R}^d$ be continuous functions in all its variables. Let $(X, Y)_{t \in [0,T]}$ be the solution
of \(\tilde{\mathcal{F}}\). Henceforth we fix an \(s \in [0,T]\). Consider the following generator equations, which will serve as an estimator for sample paths of \(\mathbb{E}(X_t|\mathcal{F}_t^Y), \, t \in [s,T]\).

1) For \(r \in [0,s]\), let \(\tilde{X}\) be a \(\mathcal{F}_t^Y\)-adapted \(\mathbb{K}\)-valued process given by the CDE

\[
\begin{align*}
\tilde{X}_0 &= h_{\theta,0}(Y_0) \\
\tilde{X}_r &= \tilde{X}_0 + \int_0^r G_{\theta}(u,\tilde{X}_u) \, dY_u \\
(3)
\end{align*}
\]

2) For \(r \in [s,T]\), let

\[
\begin{align*}
\tilde{X}_r &= h_{\theta,0}(\tilde{X}_0, z) \\
\tilde{X}_r &= \tilde{X}_r + \int_0^r G_{\theta}(u,\tilde{X}_u) \, du \\
(4)
\end{align*}
\]

Equation (3) is solved using the Log-ODE method [34], and \(h_{\theta,0}, G_{\theta}\) are parametrized feed-forward neural networks, with \(\theta\) denoting the learning parameters. Similarly, \(h_{\theta,0}\) and \(G_{\theta}\) are feed-forward neural nets, parametrized by \(\theta\) respectively. Then, equation (4) can be solved by any ODE solver. The aim is to find \(\tilde{\theta} \in \Theta\), such that for each \(t \in [s,T]\) and \(\varphi \in C^\infty_c(\mathbb{R}^d)\) we have

\[
\mathbb{E}(\varphi(X_t)|\mathcal{F}_t^Y) \approx \frac{1}{N} \sum_{i=1}^N \varphi(\tilde{X}_t^i),
\]

where \(z^i\) is a sample from the random variable \(z\). More precisely, if the mappings \(h_{\theta,0}, H_{\theta,0}, G_{\theta}\) and \(G_{\theta}\) are such that for each \(t \in [s,T]\),

\[
\begin{align*}
\mathbb{E}(\varphi(X_t)|\mathcal{F}_t^Y) &= \int_{\mathbb{R}^d} \varphi(z) \mu_\theta(dz) \\
(5)
\end{align*}
\]

then (5) is an example of simple random sampling [35]. It is known then, by the Law of Large Numbers (LLN), the right-hand side of (5) converges to \(\mathbb{E}(\varphi(X_t)|\mathcal{F}_t^Y)\) almost surely as the sample size \(N \to \infty\). Similarly, in the remainder of this subsection we show that the model (3)-(4) is well posed. In other words, we argue that the approximation error of (5) can be made arbitrarily small by the right choice of \(\nu \in \Theta\).

For \(X \in \mathcal{F}_t^Y\) define the norm \(\|X\|_{\mathcal{F}_t^Y} = \|X\|_{BV} + \|X\|_{\infty}\), where the subscript BV stands for bounded variation. Recall the notation \(\tilde{X}\) for the time-augmented path \((t, X_t) \in [0,T]\). Let \(m, k \in \mathbb{N}\). The following result, Theorem B.7 in [36], shows that CDEs of the form (3) are universal approximators in \(\mathcal{F}_t^Y\).

**Lemma 4.1:** Let a path \(R \in \mathcal{F}_t^Y([0,T], \mathbb{R}^k)\). Then for any \(\varepsilon > 0\) there exist continuous functions \(f_0 : \mathbb{R}^d \to \mathbb{R}^m\) and \(f : \mathbb{R}^m \to \mathbb{R}^{m \times (d+1)}\), a linear map \(I : \mathbb{R}^m \to \mathbb{R}^k\) and a path \(\tilde{X} \in \mathcal{F}_t^Y([0,T], \mathbb{R}^k)\) such that the unique solution of the CDE

\[
\tilde{R}_t = \tilde{R}_0 + \int_0^t f(\tilde{R}_r) \, dX_r, \quad \tilde{R}_0 = f_0(X_0),
\]

satisfies \(\|R - I(\tilde{R})\|_{\mathcal{F}_t^Y} \leq \varepsilon\).

It is known, [5], that for some \(\mathcal{F}_t^Y\)-predictable process \(C\) we can write

\[
\mathbb{E}(X_t|\mathcal{F}_t^Y) = \mathbb{E}(X_0|\mathcal{F}_0^Y) + \int_0^t C_u \, dY_u.
\]

Consider, for \(\mathcal{F}\), the processes \(\mathbb{E}(X_t|\mathcal{F}_t^Y), \, r \in [0,s]\) and \(\tilde{Y}\). Then Lemma 4.1 ensures that \(\tilde{X}\) can be arbitrarily well approximated by (3) for the right choice of \(\nu \in \Theta\), with \(\tilde{Y}\) instead of \(Y\). A rigorous proof exceeds the scope of the present article and will be given in a follow-up paper.

The following result gives an explicit form to the mappings \(H_{\theta,0}\) and \(G_{\theta}\) in (4), where we suppress the dependence on \(\theta_{\nu,0}\), \(\theta_0\) and \(\tilde{X}\) for the reader’s convenience. In other words, we consider model (3)-(4) for a fixed \(\sigma \in \Omega\). Let \(\mu_\nu\) be a standard Gaussian \(\mathcal{Z} = \mathbb{R}^d\)-valued random variable with law \(\mu_\nu\).

**Lemma 4.2:** Assume the transition probability \(p(t,x,y,s,x',y')\) from Theorem 2.2 is continuously differentiable in time for all \(s, t \in [0,T]\) and \((x,y), (x',y') \in \mathbb{R}^{d+d'}\). Fix \(\omega \in \Omega\).

(i) There exists a diffeomorphism \(H : \mathcal{Z} \to \mathbb{R}^d\) such that \((\mu \circ H^{-1}) = \pi_\nu\). Then

\[
\mathbb{E}(X_s|\mathcal{F}_s^Y) = \int_{\mathcal{Z}} H(z) \mu_\nu(dz).
\]

(ii) Moreover, the mean prospective transition

\[
G(t,x) := \frac{\partial}{\partial t} \int_{\mathbb{R}^d} \int_{\mathbb{R}^d} p(t,x,y;x',y') \, dy \, dx
\]

satisfies

\[
\mathbb{E}(X_t|\mathcal{F}_t^Y) = \int_{\mathcal{Z}} H(z) \mu_\nu(dz) + \int_{\mathcal{Z}} \int_{\mathbb{R}^d} G(r,H(z)) \, dr \, \mu_\nu(dz).
\]

**Proof:** Let \(A\) and \(B\) denote the first and second term on the right-hand side of (3) respectively. It is known, see [32], that since \(\mu_\nu\) and \(\pi_\nu\) are absolutely continuous with respect to the Lebesgue measure, there is a diffeomorphism \(H : \mathcal{Z} \to \mathbb{R}^d\) such that \((\mu \circ H^{-1})(dx) = P(X_s \in dx|\mathcal{F}_s^Y)\), or alternatively, [32, Ch. 1]

\[
k(z) = \pi_\nu(H(z)) |\det D H(z)|.
\]

Then, a calculation using change of variables yields

\[
A = \int_{\mathcal{Z}} H(z) k(z) \, dz = \int_{\mathcal{Z}} H(z) \mu_\nu(H(z)) \, |\det D H(z)| \, dz
\]

\[
= \int_{\mathbb{R}^d} x \pi_\nu(x) \, dx = \mathbb{E}(X_0|\mathcal{F}_0^Y).
\]

This proves (6). For the second term, we compute

\[
B = \int_{\mathcal{Z}} \int_{\mathbb{R}^d} G(r,H(z)) k(z) \, dz \, dr
\]

\[
= \int_{\mathcal{Z}} \int_{\mathbb{R}^d} G(r,H(z)) \pi_\nu(H(z)) \, |\det D H(z)| \, dr \, dz
\]

\[
= \int_{\mathbb{R}^d} x \pi_\nu(x) \, dx = \int_{\mathbb{R}^d} x \pi_\nu(x) \, dx = \mathbb{E}(X_t|\mathcal{F}_t^Y) - \mathbb{E}(X_t|\mathcal{F}_t^Y)
\]

where we used the form (7). This finishes the proof. \(\blacksquare\)

In applications the data corresponds to a collection of values

\[
\mathcal{D}_{\nu,m} := \{(X_{t_1}, Y_{t_1})(\omega), \omega_j \in \Omega\} \, j = 1, \ldots, m
\]

for integers \(m, n \in \mathbb{N}\). The estimator (3)-(4) is then applied to the interpolated paths \((\tilde{X}(\omega)_j, \tilde{Y}(\omega)_j), j = 1, \ldots, m\). Depending on the context and required regularity, different
interpolation techniques can be used [36], [28]. In the context of our well-posedness results, note that (i) always \((\hat{X}, \hat{Y}) \in \mathcal{Y}\) and that (ii), we only require a finite collection of diffeomorphisms \(H(\omega_j, \cdot)\), which is sure to exist. This motivates the following.

**Claim 1:** For each \(\epsilon > 0\) and \(\delta > 0\) there exists an equidistant partition \(\mathcal{D}\) of size \(m\), a data set \(\mathbb{D}_{\mathcal{D}, m}\) and mappings \(h_0, \cdots, H_d\), \(G_0, \cdots, G_d\) such that

\[
P \left( \left| \mathbb{E}(X_t|\mathcal{F}_s) - \frac{1}{N} \sum_{i=1}^{N} X^i_t \right| \geq \delta \right) \leq \epsilon. \tag{10}\]

**Proof:** The proof of this result is quite technical and will be the subject of a subsequent paper. Here we only provide a rough sketch. For simplicity of exposition we set \(d = d' = k = 1\) and only present the case \(t = s\), corresponding to the filtering problem. First observe that as \(P \sup_{t \in [0, T]} |X_t| < \infty\) the random variable \(P \sup_{t \in [0, T]} |X_t| \) is uniformly integrable, meaning that for each \(\epsilon\) there exists a \(K_{\epsilon}\) such that \(P(\sup_{t \in [0, T]} |X_t| \geq K_{\epsilon}) \leq \epsilon\). Next we partition the set \(\Omega^t := \left\{ \sup_{t \in [0, T]} |X_t| < K_{\epsilon} \right\}\) of probability \(1 - \epsilon\). For \(r_i \in \mathcal{D} \cap [0, s]\), \(i = 1, \ldots, n\) and numbers \(k_j = L_{\Omega}^{\mathcal{D}} j, j = 0, \ldots, M\), assume without loss of generality that \(X_{t_i} \geq 0, t \in [0, s]\), and define sets of the form

\[
A^i_j := \{ \omega \in \Omega^t : \mathbb{E}(X_{t_i}|\mathcal{F}_s^t)(\omega) \in [k_j, k_{j+1}] \}, \\
B_j := \bigcap_{i=1 \ldots n \in \{0, \ldots, n\}} A^i_j.
\]

The set \(B_j\) prescribes a certain range of paths for \(\mathbb{E}(X_{t_i}|\mathcal{F}_s^t)(\omega)\), when \(\omega \in B_j\). We show that due to the integrability and continuity of \((X, Y)\) and the universal approximation property of Lemma \[4.4\] we can obtain \(\{\theta\}\) on \(B_j\). Repeating this procedure yields the result for \(t = s\). 

Recall the notation for \(\mathcal{D}\) and \(C_\mathcal{D}\). The identification \(\mathcal{D} \ni f \leftrightarrow (f_i)_{i \in \mathcal{D}} \in \mathbb{R}^{d \times n}\) induces a \(\sigma\)-algebra on \(C_\mathcal{D}\) in a natural way. Then, as for each \(\omega \in \Omega\), \(\hat{X}(\omega) \in C_\mathcal{D}\), by an abuse of notation we can equivalently regard \(\hat{X}\) as \(C_\mathcal{D}\)-valued random variable with a distribution \(\mu_0\) on \(C_\mathcal{D}\). Further, by Corollary \[3.2\] we have a bijection of the signature map

\[
S: C_\mathcal{D} \rightarrow \mathcal{P}(C_\mathcal{D})\]

enabling us to consider the push-forward measure \(\mu_0 \circ S^{-1}\) on \(S(C_\mathcal{D})\). Let \(\mathcal{P}(S(C_\mathcal{D}))\) denote the set of all such push-forward measures. The following result, Proposition 1 and Corollary 3.3 in [26], is fundamental to our methods.

**Lemma 4.3:** Consider two continuous \(\mathbb{R}^d\)-valued processes \((X_t)_{t \in [0, T]}\) and \((Y_t)_{t \in [0, T]}\) such that \(\sup_{t \in [0, T]} \mathbb{E}(|X_t| + |Y_t|) < \infty\). Denote by \(\mu^X, \mu^Y \in \mathcal{P}(C_\mathcal{D})\) the push-forward measures constructed by the construction above and denote by \(\mathbb{E}_{\mu^X}, \mathbb{E}_{\mu^Y}\) the expectation under \(\mu^X, \mu^Y\) respectively. Then

\[
\mathbb{E}_{\mu^X}(S) = \mathbb{E}_{\mu^Y}(S) \text{ iff } \mu^X = \mu^Y. \tag{11}\]

Then naturally \(\hat{X} = \hat{Y}\) in distribution.

As we want to learn the conditional law \(P(X_t \in dx|\mathcal{F}_s^t)\) for the solution \((X,Y)\) of our diffusion system \[2\] based on a finite set of data points at times in \(\mathcal{D}\), we need a metric on \(\mathcal{P}(S(C_\mathcal{D}))\) which makes use of \(\|\cdot\|_{L^2}\). Making use of Theorem \[3.2\] allows us to approximate the usual Wasserstein metric by the 1-Wasserstein metric

\[
W_1(\mu, v) = \sup_{\|f\|_{L^1} \leq 1} \mathbb{E}_{\mu}(f(S)) - \mathbb{E}_{v}(f(S)) \\
\approx \sup_{\|L\|_{L^1} \leq 1} \mathbb{E}_{\mu}(LS) - \mathbb{E}_{v}(LS) \tag{12}\]

where \(\mu, v \in \mathcal{P}(S(C_\mathcal{D}))\). In a very useful way, if \(\mu, v \in \mathcal{P}(S(C_\mathcal{D}))\) have compact support we get

\[
\text{Sig-W}_1(\mu, v) = \|\mathbb{E}_{\mu}(S) - \mathbb{E}_{v}(S)\|_2, \tag{13}\]

where the subscript \(2\) denotes the \(L^2\)-norm on the signature space. In practice the truncated signature is used, which results in the use of the Euclidian norm. For a detailed derivation see the recent work [28], where this is first introduced. This justifies the use of signatures in Conditional Generative Adversarial Networks, resulting in the Conditional Sig-Wasserstein GAN (CS-WGAN).

**B. Implementation**

**Training.** Consider again the model \[3\] \[4\] and the setup in subsection \[IV-A\]. To train the estimator we generate data \(\mathbb{D}_{\mathcal{D}, m}\) as in \[9\]. Considering \(\mathbb{E}(X_t|\mathcal{F}_s^t)\) as random variable on the space \(C_\mathcal{D}\), we obtain an approximative measure \(\mu_0\), which for each fixed time \(t > s\) approximates the prediction measure \(P(X_t \in dx|\mathcal{F}_s^t)\). Then, using the Sig-W_1 metric in \[12\], we train the neural nets in the estimator \[3\] \[4\] so that

\[
\theta^* = \arg \min_{\theta} \mathbb{E}(W_1(\mu_0, \nu_\theta)), \tag{14}\]

where \(\nu_\theta\) is the distribution of the approximated conditional expectation in \[5\], i.e. our estimator. This is outlined in Algorithm \[1\].

**V. Numerical Results**

We consider the linear SDE with \(X_t, Y_t \in \mathbb{R}\)

\[
dX_t = 0.1 (1 + t) dW_t + dV_t, \quad X_0 \sim \mathcal{N}(0, 1) \]
\[
dY_t = 0.2 X_t dW_t + dW_t, \quad Y_0 \sim \mathcal{N}(0, 1) \tag{15}\]

where \(X_0\) and \(Y_0\) are independent. The generator \[3\] \[4\] is parametrized as follows: \(h_{\theta_0}, H_{\theta_0}\) are feedforward neural networks with one hidden layer with 20 neurons and ReLU activation function. The resulting process \(\hat{X}\) from equation \[3\] takes values in \(\mathbb{R}^{10}\), and \(\hat{Y}\) takes values in \(\mathbb{R}\). The vector fields \(G_0, G_\theta\) are parametrized by feedforward neural networks with one hidden layer with 128 hidden neurons and Tanh activation function.

We use \[15\] to create a synthetic dataset \[9\] with 20 000 samples. The algorithm is trained for a total of 50
Algorithm 1 Training and evaluation of CSigWGAN

\textbf{Input:} i) Time discretisation \( \mathcal{D} := \{0 = t_0 < \ldots < t_N = T\} \) and fixed \( s < t \in \mathcal{D} \),

ii) Training dataset \( \mathbb{D}_{\mathcal{D},m} := \{(X_t,Y_t)(\omega_j),t_i \in \mathcal{D};j=1,\ldots,m\} \)

\textbf{Notation:} \( \mathbb{E}^D \) denotes the empirical expectation calculated on the dataset \( \mathbb{D} \).

\textbf{Training:}

1) Approximate the conditional expectation \( \mathbb{E}(X_{t,s}^N|\mathcal{F}_s) \)

under the data measure by the \( L_2 \)-orthogonal projection of \( X_{t,s}^N \) on the space of \( \mathcal{F}_s \)-measurable r.v.,

by leveraging Doob-Dynkin lemma and Theorem 3.2

\[ \hat{L} := \arg\min_L \mathbb{E}^D \left[ (X_{t,s}^N - L(Y_{0,s}^N))^2 \right], \]

\( \hat{L} \) is linear

\[ \mathbb{E}(X_{t,s}^N|\mathcal{F}_s)(\omega) \approx \hat{L}(Y_{0,s}^N(\omega)). \]

2) Use Stochastic Gradient Descent to minimise (13),

\[ \theta^* = \arg\min_{\theta} \mathbb{E}^D \left[ \|L(Y_{0,s}^N) - \mathbb{E}_{v_0}(X_{t,s}^N)\|_2 \right], \]

where \( \mathbb{E}_{v_0}(X_{t,s}^N) \) can be estimated using Monte Carlo by drawing samples from the generator using different values of \( z \) in the generators (3)-(4).

\textbf{return} \( \theta^* \).

epochs, where the NDEs are backpropagated using the adjoint method [38].

Fig. 1 provides an example of the numerical approximation of \( \mathbb{E}(X_t|\mathcal{F}_s),t \geq s,s = 0.5 \) compared to the existing analytical solution of \( \mathbb{E}(X_t|\mathcal{F}_s) \) given by the Kalman filter. Each red line is a sample generated with (3)-(4) for one sample of \( z \). The conditional expectation, depicted in stronger red, is then approximated using the average of the samples according to (5). For \( t = s \), our estimator matches the Kalman filter.

Prediction methods are used less frequently in the literature in comparison to filtering and are more challenging to implement. However, the Kalman filter, being the optimal estimate and using more information on the observation process \( Y \), can be used well for validation purposes.

The implementation can be found at \url{https://github.com/patrick-kidger/signatory}. The relevant modules that we use are \texttt{torchdiffeq} [36] to solve (3), \texttt{torchdiffeq} [38] to solve (4) and \texttt{signatory} [36] to calculate and backpropagate through the path signatures.
