Key Points:

- Key metrics of global ocean circulation (ACC transport, AMOC strength, OHC anomaly) acutely sensitive to eddy energy dissipation time-scale.
- Modest variations in the dissipation time-scale has a comparable effect to significant variations in the Southern Ocean wind forcing.
- Constraints on the dissipation time-scale critical to long-time integrations of ocean climate models such as paleoclimate scenarios.

Abstract
The global ocean overturning circulation, critically dependent on the global density stratification, plays a central role in regulating climate evolution. While it is well-known that the global stratification profile exhibits a strong dependence to Southern Ocean dynamics and in particular to wind and buoyancy forcing, we demonstrate here that the stratification is also acutely sensitive to the mesoscale eddy energy dissipation time-scale. Within the context of a global ocean circulation model with an energy constrained mesoscale eddy parameterization, it is shown that modest variations in the eddy energy dissipation time-scale lead to significant variations in key metrics relating to ocean circulation, namely the Antarctic Circumpolar Current transport, Atlantic Meridional Overturning Circulation strength, and global ocean heat content, over long time-scales. The results highlight a need to constrain uncertainties associated with eddy energy dissipation for climate model projections over centennial time-scales, but also for paleoclimate simulations over millennial time-scales.

Plain Language Summary
Modest uncertainties in mesoscale eddy energy dissipation time-scale translate to significant variations in the global ocean circulation and heat content on long time-scales. A 50% change in the eddy energy dissipation time-scale has a similar effect to halving and doubling of Southern Ocean wind stress in quasi-equilibrium calculations, leading to a global ocean heat content change that is an order of magnitude larger than those typically found in modern day era reconstructions and projections. The results highlight a need to combine theoretical, modeling, and observational efforts to constrain the uncertainties in eddy energy dissipation for climate projections and paleoclimate reconstructions.

1 Overview and key findings
Evolution of the ocean stratification plays a fundamental role in climate evolution, through the associated consequences for the global meridional overturning circulation. Reconstructions of past climate together with the use of numerical models have highlighted how shoaling and weakening of the Atlantic Meridional Overturning Circulation (AMOC), associated with changes in the deep/abyssal stratification, have important consequences for the global energy, oxygen and carbon cycles (e.g., Zhang & Vallis, 2013; Adkins, 2013; Ferrari et al., 2014; Burke et al., 2015; Bopp et al., 2017; Jansen, 2017; Takano et al., 2018; Galbraith & de Lavergne, 2019). In particular, the Southern Ocean is "disproportionately important" (Newman et al., 2019) for the global stratification profiles because of the connection in the stratification profiles, with the implication that Southern Ocean processes can exert a control on the global overturning circulation.

It is known that the Southern Ocean stratification is primarily dependent on wind forcing (Toggweiler & Samuels, 1995; Toggweiler et al., 2006), buoyancy forcing (Hogg, 2010; Morrison et al., 2011; Jansen, 2017), and to eddy dynamics (Munday et al., 2013; Farneti et al., 2015; Bishop et al., 2016). Focusing on mesoscale eddies, an extra complication arises since there are notable divergences in model response depending on how mesoscale eddies are represented, between whether they are represented explicitly or parameterized (Munday et al., 2013; Farneti et al., 2015; Bishop et al., 2016), and the form of the parameterization (Hofman & Morales Maqueda, 2011; Viebahn & Eden, 2012; Meredith et al., 2012; Munday et al., 2013; Farneti et al., 2015; Bishop et al., 2016). While the issue of mesoscale eddy representation “frequently have a larger effect on ocean climate sensitivity than the total effect of other classes of parameterizations” (Fox-Kemper et al., 2019), there have been advances on the eddy parameterization aspect, where the role of eddy energy in mesoscale eddy parameterizations is increas-
ingly being studied (Eden & Greatbatch, 2008; Marshall & Adcroft, 2010; Marshall et al., 2012; Eden et al., 2014). Models with parameterized eddies employing eddy energy constrained eddy diffusivities or transport coefficients display improved model responses that are closer to the responses displayed in analogous high resolution models (Jansen & Held, 2014; Jansen, Held, et al., 2015; Jansen, Adcroft, et al., 2015; Mak et al., 2017, 2018; Klöwer et al., 2018; Bachman, 2017). In particular, the GEOMETRIC parameterization (Marshall et al., 2012; Mak et al., 2017; Marshall et al., 2017; Mak et al., 2018) — effectively rescaling the standard Gent–McWilliams (Gent & McWilliams, 1990; Gent et al., 1995) eddy transport coefficient by the total eddy energy according to rigorous mathematical identities (Marshall et al., 2012; Maddison & Marshall, 2013) and supported in diagnoses of eddy resolving calculations (Bachman et al., 2017) — imparts an Antarctic Circumpolar Current and Atlantic Meridional Overturning Circulation sensitivity to changes in the Southern Ocean wind forcing to idealized ocean climate models that are closer to the analogous high resolution models (Mak et al., 2018).

A natural question to ask is how strong is the influence of mesoscale eddy dynamics on the Southern Ocean as well as global ocean circulation. Since there is a link between eddy energy and the degree of feedback arising from the eddies, the mesoscale eddy energy dissipation time-scale should therefore play an important role: if more energy is drained from the mesoscale eddy field, the associated eddy form stress weakens, thereby reducing vertical momentum transport, in turn modifying the momentum balance. Following this line of argument, it was argued in Marshall et al. (2017) that the overall circumpolar transport in the Southern Ocean should increase with increasing eddy energy dissipation, and so, by thermal wind shear relation, lead to steeply tilting isopycnals in the Southern and ocean and a deepening of the global pycnocline depth over long time-scales.

The extent of the influence of eddy energy dissipation on the global circulation is the primary focus of the present work. A key finding here is that a 50% variation around a control time-scale has a similar effect to halving and doubling of the present day Southern Ocean wind stress on the modeled Antarctic Circumpolar Current transport, Atlantic Meridional Overturning Circulation strength, and the global integrated ocean heat content anomaly (Fig. 1 and Fig. 3), attributed primarily to changes in the global pycnocline depth. While the Southern Ocean wind forcing is not expected to vary so dramatically, the extent of plausible mesoscale eddy energy dissipation time-scale is not known, due to a lack of theoretical and observation constraints currently available. The results here thus highlight a crucial need to combine theoretical, modeling, and observational efforts to constrain the uncertainties in eddy energy dissipation, not only from a theoretical point of view for understanding, but also for practical purposes in constraining uncertain model parameters for numerical models used in climate projections and paleoclimate reconstructions.

2 Method and model description

The principal focus here is on quasi-equilibrium sensitivities of the global overturning circulation to the eddy energy dissipation time-scale. While one might consider employing an eddy resolving ocean model for such a study, the associated computational costs are prohibitive. Thus we employ a model with parameterized eddies, and utilize the Nucleus for European Modelling of the Ocean (NEMO, v3.7dev r8666) (Madec, 2008) in the global configuration (ORCA) with realistic bathymetry, employing the tri-polar ORCA grid (Madec & Imbard, 1996) and the LIM3 ice model (Rousset et al., 2015). The present ORCA1 model has a nominal horizontal resolution of 1°, employs 46 uneven vertical levels, and is initialized with WOA13 climatology (Locarnini et al., 2013; Zweng et al., 2013). The model employs the TEOS-10 equation of state (Roquet et al., 2015), with the atmospheric forcing modeled by the NCAR
bulk formulae with normal year forcing (Large & Yeager, 2009). Sea surface salinity but not temperature restoration is included to reduce model drift.

An energetically constrained mesoscale eddy parameterization scheme is required, and for our investigation the GEOMETRIC parameterization for mesoscale eddies (Marshall et al., 2012; Mak et al., 2018) was chosen and implemented in NEMO (see Supplementary Information for implementation details). Briefly, GEOMETRIC computes a horizontally and temporally varying coefficient for eddy induced advection (Gent & McWilliams, 1990; Gent et al., 1995) according to (cf. Eq. 4 of Mak et al., 2018)

\[ \kappa_{gm} = \alpha \frac{\int E \, dz}{\int (M^2/N) \, dz}, \]

where \( M \) and \( N \) are the horizontal and vertical buoyancy frequencies, \( \alpha \) is a non-dimensional tuning parameter (bounded in magnitude by 1), and \( E \) is the total (potential and kinetic) eddy energy. The depth-integrated eddy energy \( \int E \, dz \) is provided by a parameterized eddy energy budget given by (cf. Eq. 2 of Mak et al., 2018)

\[ \frac{d}{dt} \int E \, dz + \nabla_H \cdot \left( \bar{\mathbf{u}}^z - |c| \mathbf{e}_x \right) \int E \, dz = \int \kappa_{gm} \frac{M^4}{N^2} \, dz - \lambda \int (E - E_0) \, dz + \eta_E \nabla_H^2 \int E \, dz. \]

The depth-integrated eddy energy is advected by the depth average flow \( \bar{\mathbf{u}}^z \) and propagated westward at the long Rossby wave phase speed \( |c| \) (Chelton et al., 2011; Klocker & Marshall, 2014), has growth arising from slumping of mean density surfaces, and diffused in the horizontal (Grooms, 2015; Ni, Zhai, Wang, & Marshall, 2020; Ni, Zhai, Wang, & Hughes, 2020), with \( \nabla_H \) denoting the horizontal gradient operator and the \( \eta_E \) the associated eddy energy diffusivity. A linear dissipation of eddy energy at rate \( \lambda \) (but maintaining a minimum eddy energy level \( E_0 \)) is utilized, so \( \lambda^{-1} \) is the eddy energy dissipation time-scale. For this work, \( \alpha = 0.04 \) is prescribed, partially informed by the results of Poulsen et al. (2019), and \( \eta_E = 500 \, \text{m}^2 \, \text{s}^{-1} \) was chosen. While the Gent–McWilliams coefficient follows the prescription given in Eq. 1, the isoneutral diffusion coefficient (Griffies, 1998) is kept constant at 1000 \( \text{m}^2 \, \text{s}^{-1} \). Values of the isopycnal slopes used to compute the parameterized eddy energy, eddy induced advection and isoneutral diffusion are limited to 1/100 in the interior, and linearly decreased from the base of the model mixed layer to zero at the surface to maintain no flux conditions. For more details of the GEOMETRIC parameterization and its implementation in NEMO, please see the Supporting Information.

Given the lack of constraints on the values and uncertainties associated with the eddy energy dissipation time-scale, for simplicity we take the eddy energy dissipation time-scale \( \lambda^{-1} \) to be a constant in space and time, with a control value of \( \lambda^{-1} = 100 \, \text{days} \) (e.g., Melet et al., 2015, Marshall & Zhai, pers. comm.), and consider a range of values spanning approximately 50% about the control value (in this case six experiments with \( \lambda^{-1} \) ranging 60 to 160 days in increments of 20 days). A control model utilizing \( \lambda^{-1} = 100 \, \text{days} \) was first spun up for 1500 years, after which the perturbation experiments were integrated for a further 1600 years; see Supplementary Information Fig. S1-4 for some of the resulting climatology. All metrics presented in this work were diagnosed from data averaged over the last 100 model years.

3 Results
3.1 Sensitivity to eddy energy dissipation time-scale

The key metrics of interest here are the total Antarctic Circumpolar Current (ACC) transport, Atlantic Meridional Overturning Circulation (AMOC) strength, and the globally integrated Ocean Heat Content (OHC) anomaly relative to the control
Figure 1. Diagnostics from the varying eddy energy dissipation time-scale experiments. Diagnostics are: (a) ACC transport (total in solid lines, thermal wind component in dashed lines); (b) AMOC strength; (c) domain-integrated ocean heat content anomalies as solid lines, where the anomalies are relative to the control calculation (one times wind amplification and dissipation time-scale of 100 days) with the value of 21,300 ZJ.

Figure 2. Depth-integrated ocean heat content anomaly (relative to the control calculation with dissipation time-scale of 100 days and one times wind amplification) for varying dissipation experiments (a, b, at $\lambda^{-1} = 160$ and 60 days respectively).

calculation, respectively given as the transport through the model Drake passage, the transport over the top 1000 m at the model 26° N on the Western side of the Atlantic, and the global integrated conservative temperature multiplied accordingly by the density and heat capacity. Fig. 1 compares these metrics diagnosed from experiments varying the eddy energy dissipation time-scale. Increasing the dissipation time-scale (i.e., decreased damping of the eddies) leads to a substantial decrease in the ACC transport, AMOC strength, and total ocean heat content anomaly, which can be attributed to the deepening of the global pycnocline, consistent with theoretical arguments (Marshall et al., 2017). In particular, we note that the changes in the OHC anomalies found in post-industrial period reconstructions (Levitus et al., 2012; Cheng et al., 2017, 2019; Zanna et al., 2019) are typically on the order of $10^{23}$ J (100 ZJ), while the changes to total OHC associated with the uncertainties in eddy energy dissipation time-scale here can be an order of magnitude larger ($10^{24}$ J).

The distribution of the lateral depth-integrated ocean heat content for varying eddy energy dissipation time-scale is shown in Fig. 2. Varying the eddy energy dissipation time-scale leads to a significant global change in the OHC anomalies, attributed mainly to the changes in pycnocline depth (Supporting Information, Fig. S6-9). Note also that the changes appear to be most significant over the Southern Ocean and in the Atlantic basin, attributed to significant changes in the AMOC as well as the overturning within the Southern Ocean (Supporting Information, Fig. S3-4).
Here, changing the eddy energy dissipation time-scale $\lambda^{-1}$ affects the total eddy energy $E$, which in turn impacts the Gent–McWilliams coefficient $\kappa_{gm}$. While the significant changes to global OHC and circulation arising from changing $\kappa_{gm}$ has been noted before (e.g. Zhang & Vallis, 2013), the fundamental difference here is that the sensitivities are arising through uncertainties in the eddy energy dissipation that happens to impact the Gent–McWilliams parameter, and the eddy energy dissipation is a process that in principle is perhaps more amenable to be constrained by theoretical, numerical or observational means.

### 3.2 Sensitivity to Southern Ocean wind forcing

For completeness, experiments varying Southern Ocean wind forcing were also performed. The zonal wind stress over the Southern Ocean region within the model is amplified instead of the imposed zonal wind speed, so that any modifications to the ocean surface evaporation and turbulent fluxes as calculated through the bulk formulae occurs through changes to the ocean state rather than the imposed wind forcing. Two sets of perturbation experiments were performed: (a) a $\kappa_{gm}$ that is varying in the horizontal and in time as given by Eq. 1, with no further re-tuning (denoted GEOM), and (b) a prescribed $\kappa_{gm}$ diagnosed from the last 100 years of the control spin-up (denoted GM), but one that is now time-independent although still spatially varying.

Fig. 3 shows the sensitivities of the same global ocean climatological metrics to changes in the imposed Southern Ocean wind forcing. In Fig. 3(a), while the total ACC transport (solid lines) increases with wind forcing, the ACC thermal wind transport (dashed lines) in the GEOM calculations (orange lines, cross markers) is relatively insensitive to changes in the wind forcing, demonstrating the eddy saturation phenomenon (Hallberg & Gnanadesikan, 2006; Meredith & Hogg, 2006; Munday et al., 2013; Farneti et al., 2015; Bishop et al., 2016). On the other hand, the corresponding AMOC strength shown in Fig. 3(b) in the GEOM calculations display a reduced sensitivity to changes in the Southern Ocean wind forcing relative to the GM case, and is related to the phenomenon of eddy compensation (Gent & Danabasoglu, 2011; Hofman & Morales Maqueda, 2011; Viebahn & Eden, 2012; Meredith et al., 2012; Munday et al., 2013; Farneti et al., 2015; Bishop et al., 2016). The aforementioned sensitivities coincide with a weaker sensitivity of the global pycnocline depth to changes in Southern Ocean wind forcing (Marshall et al., 2017; Mak et al., 2018). Comparing Fig. 3 with Fig. 1, a 50% change about a chosen eddy energy dissipation time-scale has a comparable effect to halving or doubling the Southern Ocean wind forcing in the diagnosed metrics. As with the varying eddy energy dissipation experiments, the OHC anomalies are particularly significant over the Southern Ocean and the Atlantic basin (Supporting Information, Fig. S5). In the present case of varying wind stress, however, the notable variations in the OHC anomalies are attributed to significant changes in the abyssal watermass properties (Supporting Information, Fig. S6-9). The observed changes in the watermass properties may perhaps be attributed to a modified sea ice extent (Supporting Information, Fig. S10) via changes in the sea ice export by the wind, leading to changes in deep water formation and abyssal watermass properties, analogous to the mechanism proposed in Ferrari et al. (2014) and Burke et al. (2015).

### 4 Summary and outlooks

The present work demonstrates that, within the context of a global configuration ocean model with an energetically constrained mesoscale eddy parameterization, modest and perhaps not implausible variations in the mesoscale eddy energy dissipation time-scale translate to significant sensitivities of the diagnosed Antarctic Circumpolar Current transport, Atlantic Meridional Overturning Circulation strength, and the global Ocean Heat Content over long time-scales in the modeled ocean. The physi-
Figure 3. Diagnostics from the varying Southern Ocean wind stress experiments (with GEOM and GM calculations in orange and blue respectively), showing: (a) ACC transport (total in solid lines, thermal wind component in dashed lines); (b) AMOC strength; (c) domain-integrated ocean heat content anomaly, where the anomalies are relative to the respective control calculations (one times wind amplification and dissipation time-scale of 100 days) with the value of 21,300 ZJ.

Theoretical reasons for the sensitivity is that modifying the eddy energy dissipation leads to changes in the mesoscale eddy dynamics in the Southern Ocean, that in turn lead to significant changes to the global ocean stratification over long time-scales. The sensitivity of the aforementioned key ocean climatological metrics to eddy energy dissipation time-scale is found to be comparable to those found for varying Southern Ocean wind forcing, where a 50% change about a chosen eddy energy dissipation time-scale has a comparable effect to halving or doubling the Southern Ocean wind forcing in the diagnosed ocean circulation metrics. In particular, changes to the globally integrated Ocean Heat Content anomalies can vary by up to an order of magnitude larger than for reconstructions for total ocean heat content for the anthropogenic period (Levitus et al., 2012; Cheng et al., 2017, 2019; Zanna et al., 2019), and comparable to the end of 21st projections under the Representative Concentration Pathways scenarios (see figure in Cheng et al., 2019). While the changes in the Southern Ocean wind forcing are not expected to vary to the extent considered in this work (e.g., Lin et al., 2018), there are no strong theoretical, numerical or observational constraints on the eddy energy dissipation time-scale and its distribution (but see next paragraph on works towards constraining the energy fluxes of the contributing processes). There is thus a need to combine and dedicate theoretical, modeling and observational efforts to constrain the uncertainties in the eddy energy dissipation time-scale, given the impact the associated uncertainties can have.

In the present work the eddy energy dissipation is linear (cf., Klymak, 2018) with a time-scale that is a prescribed constant in space and time. One particular consequence of a prescribed spatially constant eddy energy dissipation time-scale may be seen in Fig. 4, which shows the total (kinetic and potential) eddy energy diagnosed from a high-resolution global configuration model and from the control experiment here. While the eddy energy signature displays some similarities in terms of spatial patterns in the Southern Ocean and Western Boundary Current regions, there is clearly room for improvement for the parameterized case. For example, the eddy energy signature in the parameterized case is too weak in the Western Boundary Currents and in the equatorial region, attributed to the fact that the spatially constant eddy energy dissipation time-scale was chosen somewhat with the Southern Ocean in mind, and is probably too short for the ocean basin regions (Marshall & Zhai, pers. comm.). The mesoscale eddy energy dissipation time-scale is expected to be a more complicated function than the choice taken here and, fundamentally, should depend on a wide
variety of dynamical processes such as bottom drag (e.g. Sen et al., 2008; Ruan et al., 2021), non-propagating form drag (Klymak, 2018; Klymak et al., 2021), return to mean-flow (e.g. Bachman, 2017; Jansen et al., 2019) scattering into internal waves (e.g. Nikurashin et al., 2013; Melet et al., 2015; MacKinnon et al., 2017; Yang et al., 2018; Sutherland et al., 2019), loss of balance (e.g. Molemaker et al., 2005; Barkan et al., 2017; Rocha et al., 2018), and eddy killing by the wind (e.g. Xu et al., 2016; Rai et al., 2021). Though the challenges in constraining the uncertainties in the eddy energy dissipation time-scale are formidable, the observed/diagnosed eddy energy signature can perhaps act as a target towards efforts to constrain the aforementioned unknowns, highlighting the potential for further research relating to ocean energetic pathways and its consequences for climate evolution (see for example Ruan et al. (2021) for a recent review of research relating to ocean eddy energy pathways).

While the present results are based on the choice of utilizing the GEOMETRIC parameterization for mesoscale eddies (Mak et al., 2018), given the link of the eddy energy dissipation time-scale and the resulting eddy induced circulation through the eddy energy (in this work through the Gent–McWilliams coefficient for eddy induced advection), the sensitivities of key ocean climatological metrics to the eddy energy dissipation is expected to carry over if other eddy energy based parameterization schemes for mesoscale eddies (e.g. Jansen, Adcroft, et al., 2015; Bachman, 2017) are utilized, or if analogous experiments are carried out in global eddy resolving models varying possible mechanisms of mesoscale eddy energy dissipation (e.g. bottom drag, cf. Marshall et al., 2017), although the magnitude of the sensitivities may differ. While the present work focused on quasi-equilibrium calculations, similar conclusions but with reduced magnitudes of the sensitivities are expected for centennial time-scale calculations. What is clear, however, is that the present work has significant consequences for paleoclimate simulations involving the ocean, such as Paleoclimate Modelling Inter-comparison Project calculations (PMIP, Kageyama et al., 2018), given the long time-scales inherently required for the related simulations. Potential impact assessment for climate projections and paleoclimate simulations in light of the present work will be investigated and reported in due course.
