Abstract

The dynamic oxygen migration on the interface of carbon materials, such as graphene and carbon nanotube, has opened up a new avenue to realizing the dynamic covalent materials. However, the understanding of dynamic behaviors of oxygen groups on the non-honeycomb structure, such as the biphenylene sheet, is still limited. Using both density functional theory calculations and ab initio molecular dynamics simulations, we demonstrate that the oxygen groups on the biphenylene, which is an allotrope of graphene and composed of four-, six- and eight-membered rings with unequal C-C bonds, can exhibit locally spontaneous dynamic oxygen migration through the breaking/reforming of the C-O bond. The density of state analyses show that the \( p \)-band center of the oxygen atom is closer to the Fermi energy level on biphenylene, compared to that of the oxygen atom adsorbed on graphene. This contrast confirms the locally spontaneous dynamic activity of the oxygen atom on biphenylene. This work provides scientific guidance for the exploration of the locally/globally spontaneous dynamic covalent materials and adds a new member to the 2D dynamic covalent material family.
Introduction

Graphene, a two-dimensional (2D) material that emerged in 2004,\textsuperscript{1} has been one of the most popular and attention-grabbing 2D materials for many years due to its unique mechanical, electronic, and thermal properties.\textsuperscript{2-6} Graphene has definitely triggered a research boom in 2D materials, which has led more and more researchers to explore new 2D materials, such as borophene,\textsuperscript{7-9} silicene,\textsuperscript{10-13} germanene,\textsuperscript{14-16} tellurene,\textsuperscript{17-19} etc., to obtain good applications in electronics,\textsuperscript{19} biomedicine,\textsuperscript{20,21} photoelectric detection,\textsuperscript{18} etc. Recently, Fan et al. synthesized a novel 2D allotrope of graphene by zipping together strings of 2,5-difluoro-p-phenylene on the Au(111) surface using a dehydrofluorination reaction, named biphenylene.\textsuperscript{22} Also as a pure carbon material, unlike the semimetallic graphene with hexagon honeycomb structure, the metallic biphenylene combines four-, six- and eight-membered rings on itself resulting in more active sites on it than on graphene, showing great potential in catalytic,\textsuperscript{23-25} hydrogen evolution reaction,\textsuperscript{24} and sensors,\textsuperscript{23,26} etc.

In our previous work, the dominant epoxy on graphene oxide, assisted by water molecules or Cu substrates, can spontaneously break/reform its C-O bonds for migration and shows structural adaptivity to the adsorption of biomolecules, which demonstrates that graphene oxide may be an excellent candidate for dynamic covalent materials.\textsuperscript{27,28} As an allotrope of graphene, biphenylene is more chemically active and more easily oxidized, which inevitably makes some active sites on it occupied by oxygen functional groups.\textsuperscript{29} Therefore, the research on the oxygen atom on the surface active sites of biphenylene and whether biphenylene has the same potential as graphene in developing dynamic covalent materials is particularly important.

In this work, density functional theory (DFT) is employed to calculate the migration energy barriers of oxygen atoms on the surface of biphenylene. Compared to the migration energy barrier of 0.81 eV on graphene oxide,\textsuperscript{30} the migration energy barrier near the $C_4$ ring of biphenylene does not exceed 0.36 eV and is as low as 0.06 eV, which allows for local spontaneous dynamic oxygen migration at room temperature. However, there is still
a high energy barrier that hinders the oxygen atoms to cross the $C_6$ and $C_8$ rings and thus achieving migration between the neighboring $C_4$ rings (the globally dynamic oxygen migrations). To the best of our knowledge, this is the first report on the local dynamic properties of biphenylene, which predicts that biphenylene may be an excellent candidate for 2D dynamic covalent materials and lays the foundation for its future studies of globally dynamic properties.

**Method**

All calculations are investigated based on first-principles calculations within the framework of density functional theory (DFT), implemented by the Vienna Ab initio Simulation Package (VASP). Projector-augmented wave (PAW) method is used to describe electron-ion interaction with the plane-wave kinetic energy cutoff of 500 eV. The exchange-correlation energy is described by the generalized gradient approximation (GGA) with the Perdew-Burke-Ernzerhof (PBE) exchange functional. The convergence accuracy for energy and force in all calculations are $10^{-5}$ eV and 0.01 eV/Å, respectively. Convergence on the k-point sampling shows that the Gamma-centered $1 \times 1 \times 1$ sampling is accurate enough for structure relaxation. To avoid interaction between periodic images in the perpendicular direction, the vacuum layer in the $z$-axis direction is set to 20 Å. The periodic $5 \times 4$ supercell containing 120 carbon atoms and an oxygen atom is employed to search the minimum energy paths (MEPs) of the oxygen migrations via the climbing image-nudged elastic-band (CI-NEB) method. The Ab initio Molecular Dynamic (AIMD) simulation with the same supercell under the canonical (NVT) ensemble is performed. The temperature was controlled by the Nosé-Hoover thermostat for 10 ps with a time step of 1.0 fs. The VASPkit code is used to facilitate data processing and graphics production.
Results and discussion

Figures 1(a) and (b) illustrate the top and side views of the minimal cell structure of biphenylene. The six carbon atoms are contained in a single cell with optimized lattice constants of $a = 3.765$ Å and $b = 4.519$ Å. The energy band across the Fermi energy level in the 3D-band structure of biphenylene indicates its metallicity, unlike the semi-metallicity of graphene. Different from primitive the hexagon honeycomb structure graphene with the C-C bond length of 1.425 Å, the $C_4$, $C_6$, and $C_8$ rings on biphenylene show four different C-C bond lengths ranging from 1.408–1.463 Å (see Figure 1(d)) and a more chemically active interface.

**Figure 1:** (a,b) Top and side view of the biphenylene unit cell and its lattice constants. (c) 3D-band structure of biphenylene. (d) Top and side views of the crystal structure of biphenylene and its unequal bond lengths and angles. The unequal C-C bonds on the biphenylene are marked by dashed lines of different colors.

In previous DFT calculations, the migration energy barrier of epoxy on graphene from bridge sites to adjacent bridge sites by breaking/reforming the C-O bond was reported, and the relatively high energy barrier of 0.81 eV is difficult to overcome at room temperature. However, unlike the equivalent bridge sites on graphene, the migrations of epoxy on biphenylene are more complicated due to the presence of different carbon rings ($C_4$, $C_6$, and $C_8$ rings).
Figure 2: Reaction pathways and state configurations for oxygen migration on biphenylene. The inset on the left shows the six sites of the oxygen atom on the biphenylene. The insets on the right show top and side views of the epoxy and dangling oxygen atoms. Notations: 1-5: the epoxides at bridges; T: the dangling oxygen atom at C\textsubscript{4} ring; TS: transition states (TS).

Figure 2 shows the adsorption energy of various states along the oxygen migration paths among six different sites. Herein, the C-C bond at site 1 is the shared bond of the adjacent C\textsubscript{8} ring, while the C-C bond at site 2/5 is the shared bond of the C\textsubscript{6} and C\textsubscript{8} rings, site 3 for C\textsubscript{4} and C\textsubscript{8} rings, and site 4 for C\textsubscript{4} and C\textsubscript{6} rings. Besides, a stable dangling C-O bond, i.e. a dangling oxygen atom, is observed on the shared carbon atom of C\textsubscript{4}, C\textsubscript{6}, and C\textsubscript{8} rings, which is not presented on graphene. The adsorption energy is defined as $\Delta E_{ad} = E_{O@bip} - E_{bip} - \frac{1}{2}E_{O_2}$, where $E_{O@bip}$ and $E_{bip}$ are the total energies of biphenylene with and without the adsorbed oxygen atom, respectively. $E_{O_2}$ is the total energy of the O\textsubscript{2} molecule. The adsorption energy of the oxygen atom is a positive value at site 1 (0.82 eV), indicating that the oxygen atom is difficult to be adsorbed. On the contrary, the adsorption of an oxygen atom at other sites is more feasible, especially at site 3, where the adsorption energy is even up to -0.94 eV.

All possible migration pathways of oxygen atoms on biphenylene are shown in Figure 2. The difficult adsorption as well as the high migration energy barrier (1.38 eV, 2/5→1)
severely hinder the migration of the oxygen atom from 2/5 site to site 1. Additionally, the energy barrier which prevents oxygen from migrating between sites 2 and 5 is almost equivalent to that on graphene, and both are difficult to occur spontaneously. In contrast, the oxygen migrations are easier around the \( C_4 \) ring. The interconversion between sites 2, 3, and 4 can be achieved by the intermediate state T. The presence of the dangling oxygen atom at the T site lowers the bridge-to-bridge migration barriers, making spontaneous dynamic oxygen migrations possible.

Dynamic oxygen migration is more likely to occur on the \( C_4 \) ring of biphenylene and shows the dynamic property of locality. The epoxy at site 2 can spontaneously migrate towards T and becomes a dangling oxygen atom, with an energy barrier of only 0.09 eV, much lower than the migration towards 1/5. And then, the dangling C-O bond can spontaneously migrate to the 3/4 site under thermal fluctuations at room temperature. Obviously, the exothermic reaction (T→3) with the energy barrier of 0.05 eV is more likely to occur, while the endothermic reaction (T→4) requires overcoming the energy barrier of 0.28 eV and is relatively unlikely to occur. The migration of epoxy from 2 to 3 can be divided into two continual exothermic processes (2→T→3) by the dangling C-O bond at site T and has almost no energy barrier, which means that the oxygen atom adsorbed at site 2 will spontaneously migrate to site 3. Besides, thermal fluctuations at room temperature can make the epoxy at site 4 behave in the same way. That is, no matter where the oxygen atom is adsorbed (site 1 is not feasible), it will spontaneously migrate to site 3 for the lowest structure energy. Thus, the locally spontaneous dynamic oxygen migration is revealed.

The analysis of the O \( p \)-band center explains why the local dynamic oxygen migration occurs more readily on biphenylene than on graphene. Herein, Figure 3 presents the O \( p \)-band centers of oxygen atom adsorbed on graphene (a) and on the \( C_4 \) ring of biphenylene (b-d) with the energy window of -5 to 3 eV. The \( p \)-band center of the oxygen atom adsorbed on graphene is at -2.10 eV, while that of it on the \( C_4 \) ring of biphenylene shifts rightward to -1.77 eV (site 3), -1.56 eV (site 4), and -1.17 eV (site T). Near the Fermi level, the number
Figure 3: The $p$-band center (dash line) of the oxygen atom adsorbed on graphene and biphenylene. The charge density difference of the oxygen atoms at 3, 4, and T sites are shown in insets, respectively. Red and green colors in insets represent charge accumulation and depletion regions, respectively.

of electronic states of the oxygen atom on the $C_4$ ring of biphenylene increases significantly compared to that on graphene. The rightward shift of the O $p$-band center confirms that the oxygen atom on the $C_4$ ring of biphenylene is more active and prefers to migrate than that on graphene. Also, the charge difference density of the oxygen atoms are shown on the insets in Figures 3(b)-(d). It is evident that the oxygen atom adsorbed at sites 3, 4, and T gains 0.79e, 0.77e, and 0.93e from the bonded carbon atoms, respectively.

*Ab initio* molecular dynamics (AIMD) simulations further confirmed the spontaneously dynamic oxygen migration on the $C_4$ ring of biphenylene. Figure 4 shows the AIMD trajectory with two pathways. In the snapshots from 0.00 ps to 1.11 ps (pathway I), the C-O bond starts to break and an intermediate dangling C-O bond appears. Subsequently, the dangling oxygen was easy to transform back into epoxy at site 3 with thermal disturbance. Similarly in pathway II, epoxy at site 4 transforms to a dangling oxygen atom at 4.58 ps, and then reforms the C-O bond with the other carbon atom to an epoxy at site 3. Both of reaction dynamics present in the AIMD simulations agree with the pathways based on
Figure 4: AIMD trajectory of oxygen migration on the $C_4$ ring of biphenylene. Two reaction pathways are denoted by reactions I ($2 \rightarrow T \rightarrow 3$) and II ($3 \rightarrow T \rightarrow 4$), and the numbers indicate the time of snapshots.

DFT calculations, indicating a local spontaneously dynamic oxygen migration on $C_4$ ring of biphenylene.

**Conclusions**

In summary, based on density functional theory calculations and ab initio molecular dynamics simulations, the locally spontaneous dynamic covalent property of biphenylene is confirmed. The break/reform of the C-O bond allows the epoxy on biphenylene to achieve the local bridge-top-bridge migration, which is attributed to the change of interfacial activity due to the unequal carbocyclic structure ($C_4$, $C_6$, and $C_8$ rings) of biphenylene. The calculations of O $p$-band center further confirm the increase in the activity of the oxygen atom on the $C_4$ ring. Notably, regardless of the position of the oxygen atom adsorbed on the biphenylene, the oxygen atom spontaneously migrates toward the C-C bond connecting the two C6 rings thus achieving structural energy minimization.

Our work demonstrates the locally spontaneous dynamic covalent properties of biphenylene. As a promising 2D dynamic covalent material, the globally spontaneous dynamic covalent properties of biphenylene are worthy of further exploration in the future.
damental studies of this property, either locally or globally, will help further modulate and
develop biphenylene in the future, and more importantly, may draw attention to 2D dynamic
covalent materials and promoting the development of 2D dynamic covalent material-based
high-performance environment-adaptive sensors, actuator and biomedical devices and so on.
