Unsignalized Intersection Management Strategy for Mixed Autonomy Traffic Streams

Junjie Zhou, Zhaokun Shen, Xiaofan Wang, Lin Wang

Abstract—With the rapid development of connected and automated vehicles (CAVs) and intelligent transportation infrastructure, CAVs and connected human-driven vehicles (CHVs) will coexist on the roads in the future for a long time. This paper comprehensively considers the different traffic characteristics of CHVs and CAVs, and systemically investigates the unsignalized intersection management strategy from upper decision-making level to lower execution level. Combined with the designed vehicle planning and control algorithm, the unsignalized intersection management strategy consists of two parts: the heuristic priority queues based right of way allocation (HPQ) algorithm, and the vehicle planning and control algorithm. In the HPQ algorithm, a vehicle priority management model considering the difference between CAVs and CHVs is built to design the right of way management for CAVs and CHVs, respectively. In the lower level for vehicle planning and control algorithm, different control modes of CAVs are designed according to the upper level decision made by the HPQ algorithm. Moreover, the vehicle control execution is realized by the model predictive controller combined with the geographical environment constraints and the unsignalized intersection management strategy. The proposed strategy is evaluated by simulations, which show that the proposed intersection management strategy can effectively reduce travel time and improve traffic efficiency. The intersection management strategy captures the real-world balance between efficiency and safety for potential future intelligent traffic systems.

Index Terms—Mixed autonomy traffic streams, connected and automated vehicles (CAVs), unsignalized intersection, intelligent intersection, right of way allocation.

I. INTRODUCTION

In recent years, traffic congestion has become a critical social problem that troubles people’s lives and hinders social development [1]. With the development of autonomous driving technology and the maturity of communication technology, CAVs have gradually come into the public horizon. It is the primary direction for researchers to improve intersection efficiency through vehicle coordination under safe conditions. Traffic signal control methods have good effects on intersections with relatively large traffic volume and strong traffic capacity. But for intersections with small traffic volume and weak traffic capacity, signal control will cause unnecessary travel time loss.

Unsignalized intersections are considered as an effective solution to improve traffic efficiency in the past few years [2]. While unsignalized intersections provide effective tools to reduce energy consumption and traffic delays, it is also necessary to improve safety to reduce the number of accidents [3], [4]. Considering the traffic environment of mixed CHVs and CAVs will exist for a long period of time in the future, efficient and reasonable intersection management strategies should be developed to ensure vehicle safety and improve the traffic efficiency for mixed autonomy traffic streams.

This paper focuses on the design of unsignalized intersections management strategy for mixed autonomy traffic streams based on the vehicle-to-infrastructure (V2I) architecture, which consists of the heuristic priority queues based right of way allocation (HPQ) algorithm and vehicle planning and control algorithm for the mixed traffic flow intersections. The HPQ algorithm is used to manage the right of way of vehicles at intersections to maximize the utilization efficiency of the conflict area. Through the geographic modeling of the intersection, the trajectories and conflict table of vehicles passing through the intersection are formulated, and the traffic condition constraints are used to ensure the safety of vehicles. According to the decision made by the HPQ algorithm at the intersection, the vehicle planning and control algorithm is designed based on four control modes including car following mode, cruise mode, waiting mode and conflict-solving mode. Furthermore, the model predictive controller is applied to realize the four control modes. The main contributions of this paper are as follows:

- Unsignalized intersection management strategy is developed systematically for mixed autonomy traffic streams. Considering the differences between CAVs and CHVs in handling trajectory conflicts and the priority management conditions, an improved HPQ algorithm is designed, so that the passage of high priority vehicles will not be affected, while low priority vehicles may also obtain the right of way earlier than high priority vehicles.

- Four different vehicle control modes are proposed according to the developed HPQ algorithm, and the model predictive control law is designed to ensure the undisturbed switching between different control modes.

- A hybrid simulation process is carried based on SUMO and PreScan to verify the efficiency and safety of the proposed strategy from two aspects of both macroscopic and microcosmic. The developed unsignalized intersection management strategy outperforms the two existing state-of-the-art strategies in terms of travel time and the
number of halts benefiting from the comprehensive design of the right of way management and vehicle planning and control algorithm.

The rest of the paper is organized as follows. Section II reviews the related works. Section III introduces the preliminary and system architecture of the proposed strategy. Section IV details the design of the HPQ algorithm, including the priority management model and right of way management model. Section V details the design of vehicle planning and control algorithm, including the path planning model, speed planning model and modified model predictive control for vehicle control modes. The simulation and performance comparison are presented in Section VI. While section VII concludes the paper.

II. LITERATURE REVIEW

A. Unsignalized Autonomous Intersection Management

As summarized in [5], there are two approaches to calculate the possible conflict between two vehicles at the intersection, including the expected vehicle trajectories and the spatio-temporal occupancy map. The vehicle conflict of the expected vehicle trajectories is directly represented by the conflict points, which has the advantage of low time complexity when calculating the priority of the vehicles at the intersection. The vehicle conflict of the spatio-temporal occupancy map is represented by overlapping grids, which has the advantage of flexible path selection.

The system architecture of unsignalized intersections is divided into centralized system and distributed system. At the centralized control intersection, vehicles obtain traffic schemes from the Intersection Control Unit (ICU) through V2I communications, while at the distributed cooperative intersection, vehicles negotiate with each other through vehicle-to-vehicle (V2V) communication [6].

The autonomous intersection management (AIM) of the centralized system follows the server-client scheme, which can be divided into two types: request-based intersection management and release-based intersection management. In [7], [8], a request-based intersection management scheme is proposed. In this scheme, the intersection is divided into the queuing area and acceleration area. Only in the queuing area can vehicles send requests to the ICU. Platoon formation is also widely used in unsignalized autonomous intersection management. CAVs form platoons through V2V communication, and each platoon has a leading vehicle [9], [10]. On behalf of the entire platoon, the leading vehicle sends the expected arrival time and travel time of the platoon to the ICU to request passage. After evaluation, the ICU chooses to approve or reject the request. Release-based intersection management has also been widely studied. In [11], a demand-responsive control strategy is proposed. The ICU collects the information of all vehicles within the intersection and assigns feasible trajectories to each vehicle. Some similar release-based intersection management schemes are also provided in [12], [13]. The vehicle sends its kinematics information to the ICU when it approaches the intersection. The ICU comprehensively considers all vehicle information and assigns an appropriate passing time to each vehicle. In order to capture the effective relative motion law of vehicles and describe the dynamic platoon related to each lane at intersections, an advanced hybrid queuing model was proposed in [14]. This model designed a traffic management method based on model predictive control to minimize the travel time of vehicles at the intersection.

In addition to centralized intersection management, distributed intersection management has also received extensive attention. The advantages of the distributed intersection management include that it does not require the support of roadside infrastructure and has good scalability. Intersection management methods based on distributed architecture are studied in [15], [16]. All vehicles share their state information with each other. Once a vehicle obtained all information of other vehicles, it will become the traffic manager at the intersection and plan the right of way for all vehicles during that period of time. Besides, virtual formations are used to allow the vehicle in conflict with other vehicles to maintain sufficient headway distance at a T-shaped intersection to coordinate the conflicts [17]. After that, this method is extended to the scene of other types of intersections in [18], [19], and the trajectory conflict points of the intersection are modeled and analyzed in detail. In addition, the depth-first spanning tree is used in [19] to calculate the right of way of vehicles at the intersection.

These unsignalized autonomous intersection management strategies can regulate the movement states of CAVs on a global scale to avoid collisions. However, they seldom consider the optimization of the combination of high-level scheduling and low-level vehicle control, and have limited utilization of conflict areas at intersections, which restrain their applicability and popularization. In this paper, we benefit from the idea of priority queues to reduce the required calculation time, and further optimize the scheduling strategy to improve traffic efficiency. Moreover, based on the macro vehicle priority management at intersections, we also design four different vehicle control modes for CAVs to maximize the utilization efficiency of the intersection conflict area.

B. Mixed Autonomy Traffic Streams Management

According to the prediction, CAVs will not be fully popularized before 2045 [20]. For a long period of time in the future, the traffic environment of mixed CHVs and CAVs will always exist. Therefore, it is necessary to study AIM in the mixed autonomy traffic streams. Stone et al. first proposed AIM cooperative driving strategy for mixed traffic streams, which adopts the strategy called First Come First Served (FCFS) manner in the signalized intersection [21], [22]. FCFS strategy grants the right of way to the vehicle that arrives at the intersection first. Human-driven vehicles (HVs) obey traffic signals, while CAVs adopt the request-based method to request the right of way at the intersection. In [23], a Hybrid Autonomous Intersection Management (H-AIM) protocol was proposed to grant reservation for vehicles at intersections in FCFS order which is demonstrated to be effective even in complex traffic scenarios. The biggest difference between this intersection management method and the intersection management method proposed in [21] is that it allows CAVs
to obtain the right of way even at a red light, as long as the corresponding right of way is not occupied at this time. In [24], three different types of vehicles are considered, including HVs with only communication devices, HVs with driving assistant systems and autonomous vehicles.

Furthermore, in order to improve traffic throughput and reduce energy consumption, Ref. [25] established a connected vehicle center (CVC) to control the movement of all vehicles and detect the position and trajectory of HVs through sensors. When the HVs arrive near the stop line, the traffic lights are used to instruct the right of way for these HVs, while the CVC controls the AVs. In order to reduce energy consumption of the vehicles at signalized intersections for mixed traffic streams, Zhao et al. [26] proposed dynamic platoon splitting and merging method in terms of cooperation and combined it with model predictive control to reduce the fuel consumption of the fleet. In addition, a distributed intersection protocol for mixed traffic streams is proposed in [27], where the AVs switch to the synchronous cooperation mode and pass through the intersection without stopping for the case of no HVs entering. When the AV detects that the HV is entering the intersection, it will switch to the signalized mode and obey the traffic lights like HVs.

These existing approaches consider the AIM for mixed autonomy traffic streams and put forward effective intersection management strategies to improve the safety and efficiency of the intersection. To the best of our knowledge, few studies have considered the difference between CAVs and CHVs at unsignalized intersections. In this paper, we formally characterize the differences between CAVs and CHVs in handling trajectory conflicts and priority management conditions, and design an improved HPQ algorithm to ensure the safety and travel efficiency of vehicles at unsignalized intersections, which derive a futuristic and practical unsignalized intersection management strategy.

III. DESIGN OF SYSTEM ARCHITECTURE

In this section, a new type of unsignalized AIM system architecture is designed to enable vehicles to pass through the intersection more safely and efficiently. The Cooperative Vehicle Infrastructure System (CVIS) is used to provide hardware and communication support for the intersection. All vehicles at the intersection are assumed to be equipped with On Board Unit (OBU) and can transmit the information of ego vehicle to other vehicles and ICU at the intersection via V2V and V2I communications. Sensor equipment is installed on the roadside to ensure that all messages such as the speed and position of all vehicles can be obtained at the intersection. At the same time, it ignores the delay, packet loss and information attacks in the communication process. When CAVs and CHVs enter the intersection, they will send the estimated driving route to the ICU, and the drivers of CHVs will follow the driving route. A human-machine interface will be installed in the CHVs to display the traffic instructions of the ICU.

Fig. 1 depicts the architecture of unsignalized intersection with a mix of CAVs and CHVs. The overall architecture is mainly composed of two levels. The high level is the HPQ algorithm which is designed in detail in Section IV. It determines the priority management of vehicles and formulates corresponding right of way management methods for the two types of vehicles. The low level includes vehicle planning and control algorithm for CAVs, which is developed in detail in Section V.

Considering the feasibility and practicability of edging computing, the low-level vehicle planning and control algorithm uses the ICU to collect surrounding vehicle information, which can better ensure the safety of vehicles at the intersection and improve the traffic efficiency. Since CAVs have high
controllability and intelligence, four control modes including car following mode, cruise mode, waiting mode and conflict-solving mode are designed for CAVs, according to the decision information made from the high-level HPQ right of way allocation algorithm. Moreover, the model predictive controller is designed to realize the four control modes of the CAVs. In addition, through the geographic modeling of the intersection, the trajectories and conflict tables of vehicles passing through the intersection are provided in real time.

IV. HPQ RIGHT OF WAY ALLOCATION ALGORITHM

In this paper, we consider a two-way and single-lane intersection, as illustrated in Fig. 2. This intersection has four directions and each direction contains an entry lane and an exit lane. Let $M = \{M_j | j = 1, 2, 3, 4\}$ be the set of all directions. In unsignalized intersections, the right of way allocation algorithm plays a vital role in ensuring the safety. A typical conflict scenario is illustrated in Fig. 3, where $P$ is the point of conflict between the two vehicles. Let $T_b$ and $T_f$ be the moments when the ego vehicle and the preceding vehicle enter the intersection, respectively. The essential requirement to ensure the ego vehicle safely pass through the intersection is that:

$$T_b \geq T_f + h + t_f - t_b, \tag{1}$$

where $t_f = \frac{d_f}{v_f}$ and $t_b = \frac{d_b}{v_b}$ are the travel time of the preceding vehicle and the ego vehicle from the stop line to the conflict point $P$, respectively; $s_f^d$ and $s_b^d$ are the distance of the preceding vehicle and the ego vehicle from the stop line to the conflict point $P$, respectively; $v_f$ and $v_b$ are the speed of the preceding vehicle and the ego vehicle, respectively; $h$ is the minimum time headway, as illustrated in Table I.

For CAVs, the vehicle priority, the location of the conflict point, the position and speed of the preceding vehicle can be obtained through V2V and V2I communication, and the
conflict with the preceding vehicle can be easily handled according to constraint (1). However, for CHVs, it is difficult to deal with conflict scenarios, as shown in Fig. 3, since human beings have no accurate perception system and fast computing system like machines. Human may make wrong decisions especially in confusion and complex scenes, which will cause deadlocks or collisions. In this paper, CHVs have a human-machine interface to obtain traffic instructions of the ICU to ensure that they will not collide with other vehicles.

A. Priority Management Model

The priority of vehicles at intersections is designed by the policy of FCFS, and the vehicles entering the area of the intersection first will get lower priority value \( P(V) \). The smaller the priority value \( P(V) \) obtained by the vehicle, the higher the priority of the vehicle. The priority value \( P(V) \) of the vehicle entering the intersection area first is 1, and the following vehicles are incremented by 1 according to the order in which they enter the intersection. When a vehicle obtains the right of way, the priority value \( P(V) \) of all vehicles is reduced by 1. When the vehicle enters the entry area, the moment of the current vehicle will be recorded by the ICU. When two vehicles have trajectory conflict, the right of way of the vehicles is determined by comparing the size of the time stamp.

The length of the entry area will influence the driving comfort. In order to guarantee the vehicle can slow down and stop in front of the stop line gracefully. Here, as illustrated in Fig. 2, the length of the entry area \( A_1 \) satisfies the constraint (2) as follow:

\[
A_1 \geq \frac{v_{\text{limit}}^2}{2a_d}.
\]

where \( v_{\text{limit}} \) is the speed limit for the road and \( a_d \) is the maximum acceleration without loss of comfort.

Usually, the priority is not allowed to be changed, since changing the priority will easily cause deadlock at the intersection. The deadlock at an intersection means that multiple vehicles fall into a stalemate of cyclical waiting due to the fight for the right of way, and the vehicles can not pass normally at the intersection.

However, for abnormal situations such as breakdown at the conflict area, the priority of the vehicle can be changed in the priority management model. If the abnormal vehicle keeps occupying the right of way, it will lead to the deadlock of the vehicles whose priority is lower than it and trajectory conflicts with it. In this instance, the ICU will kick the abnormal vehicle out of the priority sorting queue and adjust the priority of the vehicles that are in the same lane with the abnormal vehicle to the lowest to ensure the normal traffic of vehicles in other lanes. Here, a vehicle will be labeled as an abnormal vehicle, if the passing time \( t_e \) of the vehicle through the conflict point is larger than:

\[
t_e > \frac{A_1}{v_{\text{limit}}} + \sigma, \tag{3}
\]

where \( \sigma \) is the time constant of abnormal judgment.

B. Right of Way Management Model

The most significant difference between an intersection with and without signal lamps is that the former allocates the right of way for each lane, while the latter allocates the right of way for each vehicle individually. Here, the factors that affect the right of way of each vehicle include vehicle priority, trajectory conflicts and vehicle type. In order to save the computing resources, the ICU divides all vehicles \( S \) within the intersection into three groups. The first group \( S_1 \) is the set of vehicles that have passed through the conflict area, which does not need intersection management; the second group \( S_2 \) is the set of vehicles that have not passed through the conflict area but have obtained the right of way; the third group \( S_3 \) is the set of vehicles that have not obtained the right of way. The right of way management only needs to determine which vehicles in \( S_3 \) can get the right of way.

In the same lane, the vehicle in the front must have priority over the vehicle in the back. Therefore, the third group \( S_3 \) can be divided into four priority queues \( (Q_1, Q_2, Q_3, Q_4) \) according to the four entry lanes, where \( Q_i \) corresponds to the \( i \)-th lane and ranks the priority of vehicles in the \( i \)-th lane from small to large according to the time stamp of the vehicle entering the intersection. Every time when the right of way is allocated, the ICU only needs to consider the vehicles at the top of the four queues \( Q_1[0], Q_2[0], Q_3[0], Q_4[0] \), which are classified as set \( Q_p \). For the four vehicles at the top of the queue, sort them according to their priorities by the policy of FCFS, and check whether the vehicles meet the following conditions for obtaining the right of way. The objective is to find one vehicle that meets the conditions to obtain the right of way. According to the differences between CHVs and CAVs, the conditions are set respectively:

1) Conditions for CHVs to obtain the right of way: There is no trajectory conflict with the vehicles in the second set \( S_2 \) and there is no trajectory conflict with the vehicles with higher priority in the third set \( S_3 \).
The trajectories in Fig. 4 can be regarded as a circle with the same color represents the existence of merging. The number in the circle in Fig. 4 represents the time location of the vehicles at the intersection. If there is a trajectory conflict between the vehicle $V$ in the priority queue $Q_p$ and the other vehicles in $S_2$, the ID of the conflict vehicle will be recorded in the trajectory conflict variable $L$ and the value of $N_1$ will increase by 1. Finally, judge whether the vehicle $V$ in the priority queue $Q_p$ is a CHV or CAV. If the vehicle $V$ in the priority queue $Q_p$ is a CHV and satisfies the conditions for CHVs to obtain the right of way, that is, there is no trajectory conflict between the vehicle $V$ in the priority queue $Q_p$ and the other vehicles in $S_3$, the vehicle $V$ in the priority queue $Q_p$ is granted the right of way. If the vehicle $V$ in the priority queue $Q_p$ is a CAV and satisfies the conditions for CAVs to obtain the right of way, that is, the number of trajectories conflict between the vehicle $V$ in the priority queue $Q_p$ and the other vehicles in the sets $S_2$ and $S_3$, the vehicle $V$ in the priority queue $Q_p$ is granted the right of way. When a vehicle is granted the right of way, the ICU will issue an instruction to allow the vehicle to pass. Finally, further conflict checks are carried out according to the real-time location of the vehicles at the intersection. If there is a trajectory conflict that requires to be dealt with, the ICU will also send the information of the trajectory conflict to the conflict vehicles. In addition, CAVs can obtain information about other vehicles through V2V communication, so as to improve the accuracy of low-level vehicle planning and control.

The time complexity of the right of way management algorithm is $O(n)$, where $n$ is the total number of vehicles at the intersection. In HPQ Algorithm 1, a vehicle information

![Vehicle trajectory conflict relationship diagram at intersections.](image)

2) Conditions for CAVs to obtain the right of way: There can be a trajectory conflict with at most one vehicle in the second set $S_2$ and there is no trajectory conflict with the vehicles with higher priority in the third set $S_3$.

For trajectory conflict in the typical intersection as shown in Fig. 2, straight-through vehicles in entry area $A_3$ have crossing conflicts with straight-through vehicles and left-turn vehicles in entry area $A_2$, and have merging conflicts with right-turn vehicles in entry area $A_2$. Here, pairwise conflicting relationships are represented by an undirected conflict graph $G = (V, E)$, which will be used to sort vehicles without conflicts that can pass the intersection at the same time. Fig. 4 shows the vehicle trajectory conflict relationship diagram at the intersection. The number in the circle in Fig. 4 represents the trajectory number, where vehicle trajectory numbers 0, 3, 6, 9 represent right-turn movements; vehicle trajectory numbers 1, 4, 7, 10 represent through movements; vehicle trajectory numbers 2, 5, 8, 11 represent left-turn movements. And the circle with the same color represents the existence of merging conflicts. The trajectories in Fig. 4 can be regarded as a set of nodes $V = \{v_0, v_1, v_2, \cdots, v_{n-1}\}$. And the crossing conflict between two trajectories can be represented by an edge, as indicated in Fig. 4. Here, $n = 12$ for the two-way and single-lane intersection, and the set of the edges is $E = \{e_0, e_1, e_2, \cdots, e_{m-1}\}$, with $m = 16$.

When a vehicle enters the intersection, it should send its own position, speed, acceleration, and other kinematics information to the ICU, including the type of vehicle $C(V)$ ($C(V) = 1$ means CHV, and $C(V) = 0$ means CAV), the time stamp of entering the intersection and the expected driving direction (going straight, turning right and turning left). After the ICU collects all the vehicles’ information, it will execute the HPQ algorithm once in each control cycle to grant at most one vehicle the right of way. Once a vehicle obtains the right of way, the algorithm will update the status of all sets of vehicles and priority queues. Here, a control cycle means
struct $(U)$, five priority queues $(Q_1, Q_2, Q_3, Q_4, Q_p)$, and four vehicle sets $(S, S_1, S_2, S_3)$ need to be updated in each control cycle. The priority queue is implemented by heap. The time complexity of building heap is $O(n)$, and the time complexity of heap insertion and deletion is $O(\log n)$. After that, to check whether a vehicle conflicts with another vehicle, it needs to query the adjacency matrix that represents the conflict relationship, and the time complexity of this operation is $O(1)$. Then it needs to query all the corresponding sets $S_2$ and $S_3$, and the time complexity is $O(n)$. Because there are only four vehicles in $Q_p$ at most, the time complexity of querying all vehicles in $Q_p$ is $O(n)$. Therefore, the overall time complexity is $O(n)$, which guarantees the efficiency of real-time control for the right of way can be achieved.

According to the designed HPQ algorithm, vehicles with low priority may get the right of way earlier than vehicles with high priority. In order to take advantage of the intersection conflict area as efficiently as possible, vehicles with low priority can obtain the right of way as long as they do not affect the vehicles with high priority and vehicles that have already obtained the right of way. This means that the vehicles from different entry areas of the intersection can pass the intersection simultaneously. For example, the vehicle with trajectory number 11 in Fig. 4 arrives at the intersection first and gets the highest priority, and then vehicles with trajectory numbers 0 and 5 also enter the intersection. Although the vehicle with trajectory number 11 has the highest priority, vehicles with trajectory numbers 0 and 5 can also obtain the right of way, and these three vehicles can pass the intersection simultaneously. Moreover, the CAVs are allowed to obtain the right of way in the case of conflicting with one vehicle that has been granted the right of way, since CAVs can solve the vehicle conflict through the designed low-level vehicle planning and control algorithm to ensure the safety of vehicles.

V. VEHICLE PLANNING AND CONTROL

ALGORITHM DESIGN

In the previous section, we have developed the HPQ algorithm which combines the differences between CAVs and CHVs to arrange corresponding right of way. In this section, we focus on vehicle planning and control for CAVs, since the ICU has high computing power, and can obtain the global information of the traffic participants near the intersection.

According to the driving situation of CAVs at the intersection, we introduce four possible decision making modes for CAVs: the first mode is to follow the preceding vehicle; the second mode is autonomous cruise; the third mode is to stop before the stop line to wait for the right of way; and the last mode is to resolve the trajectory conflicts. In the following text, the corresponding planning and control methods for the four decision making modes of CAVs will be designed in detail. The motion planning problem is divided into two subproblems including path planning and speed planning, where path planning is constrained by the layout of the road and the geographical model of the intersection, and speed planning
is to enable passing through the intersection quickly, safely, and economically. By using model predictive control, CAVs can switch undisturbedly to the corresponding decision making mode according to the current traffic environment. The whole procedure of vehicle planning and control is illustrated in Fig. 5. Based on the right of way allocation results calculated by the HPQ algorithm and the real-time traffic environment, the control modes of vehicles are calculated by switching algorithm for control modes. Then the motion planning is carried out, in which the path planning and the speed planning run in parallel to obtain the best lateral and longitudinal control scheme. All these control actions are finally output to the actuator for execution.

A. Path Planning Model

For a typical two-way single-lane unsignalized intersection as shown in Fig. 6, the intersection trajectory is modeled, and the intersection coordinate system, lane coordinate system and vehicle coordinate system are established to carry out vehicle path planning. The intersection coordinate system $\xi_i$, $i \in \{1, 2, 3, 4\}$ takes the midpoint of the starting position of each lane in the entry area as the origin, where A-axis is along the center line of the lane, and B-axis is obtained by rotating A-axis 90 degrees counterclockwise. The vehicle coordinate system $\xi_v$ takes the vehicle centroid as the origin, where M-axis is the direction of vehicle heading, and N-axis is obtained by rotating M-axis 90 degrees counterclockwise.

The trajectory tracking of CAVs can be solved by vehicle lateral control [28]–[30]. For convenience, the Cartesian coordinate system is transformed into the coordinate system for vehicle path tracking, and the corresponding descriptions for left turn trajectory, straight trajectory, right turn trajectory are formulated as follows. The coordinate of the CAVs in the lane coordinate system is denoted as $(\alpha_p, \beta_p)$. The distance traveled by the CAVs is denoted as $s$. The heading angle of the CAVs is denoted as $\theta$. The left turn trajectory is shown in Equations (4) and (5). The straight trajectory is shown in Equations (6) and (7). The right turn trajectory is shown in Equations (8) and (9).

$$s = \begin{cases} \alpha_p, & 0 \leq \alpha_p \leq l, \\ l + r \times \arctan \frac{\alpha_p - l}{r - \beta_p}, & l < \alpha_p < l + r, 0 < \beta_p < R, \\ l + \frac{\pi r}{2} - \beta_p - r, & \alpha_p = l + r, R \leq \beta_p \leq R + l. \end{cases}$$

(4)

$$\theta = \begin{cases} \alpha_p, & 0 \leq \alpha_p \leq l, \\ \arctan \frac{\alpha_p - l}{r - \beta_p} - \frac{\pi}{2}, & l < \alpha_p < l + r, 0 < \beta_p < R, \\ 90, & \alpha_p = l + r, R \leq \beta_p \leq R + l. \end{cases}$$

(5)

$$s = \begin{cases} \alpha_p, & 0 \leq \alpha_p \leq l, \\ l + r \times \arctan \frac{\alpha_p - l}{r + \beta_p}, & l < \alpha_p < l + r, -r < \beta_p < 0, \\ l + \frac{\pi r}{2} + \beta_p + r, & \alpha_p = l + r, -l - r \leq \beta_p \leq -r. \end{cases}$$

(6)

$$\theta = \begin{cases} \alpha_p, & 0 \leq \alpha_p \leq l, \\ -\arctan \frac{\alpha_p - l}{r + \beta_p} - \frac{\pi}{2}, & l < \alpha_p < l + r, -r < \beta_p < 0, \\ 90, & \alpha_p = l + r, -l - r \leq \beta_p \leq -r. \end{cases}$$

(7)

where $l$ is the length of the entry area; $l_w$ is the width of the lane; $L$ is the radius of the control range of the intersection area; $R$ and $r$ are the radius of turning left and turning right respectively, and meet the constrain $R + r = 2l_w$. 

B. Speed Planning Model

Since CAVs need to make corresponding decisions according to different environments, here four control modes are designed to ensure the safety of vehicles and improve the traffic efficiency, where each control mode includes a corresponding speed planning. The control modes of CAVs are listed as follows:

- Car following mode: Keep a safe distance from the preceding vehicle and follow it.
- Cruise mode: Keep the vehicle at a constant speed.
- Waiting mode: Slow down until the vehicle is stopped before the stop line.
- Conflict-solving mode: Resolve vehicle trajectory conflicts when passing through conflict areas.

In order to improve the conflict resolution ability of CAVs and ensure the safety of vehicles, the real-time switching of four vehicle control modes should be guaranteed. Define a bool type variable $B$ to denote whether the ego vehicle $V$ obtains the right of way at the intersection. $I_e$ represents the ID of the vehicle that has trajectory conflicts with the ego.
vehicle \( V \), and \( I_f \) represents the ID of the preceding vehicle of ego vehicle \( V \). Define \( S_V(E) \) and \( S_V(stopline) \) to denote the position of vehicle \( E \) and the position of the stop line in the vehicle coordinate system corresponding to the ego vehicle \( V \), respectively. And \( \epsilon \) is the distance constant.

We develop an undisturbed switching algorithm for the control modes by combining the real-time traffic environment around the ego vehicle \( V \). First, judge whether each vehicle has obtained the right of way according to the high-level HPQ algorithm. For vehicles without obtaining the right of way: if there is a preceding vehicle, the control mode is switched to the car following mode; if there is no vehicle ahead and vehicle \( V \) reaches near the stop line, the control mode is switched to the waiting mode; otherwise, the control mode is switched to cruise mode.

For vehicles with the right of way: if it can form a vehicle formation with the preceding vehicles to travel together without interference from other vehicles, the control mode is switched to the car following mode; if the vehicle formation may be interfered by other vehicles, the control mode is switched to conflict-solving mode; otherwise, the control mode is switched to cruise mode. Define \( \text{ind}(\min(d_1, d_2)) \) as an index when the minimum function gets the minimum value. The value of \( \text{ind}(\min(d_1, d_2)) \) is 0 when \( d_1 \leq d_2 \), otherwise it is 1. The principles of switching between the four control modes are shown in Algorithm 2.

Let \( s \) and \( v \) be the current position and velocity of vehicle \( V \) in the corresponding lane coordinate system. For the four control modes of CAVs, different reference positions \( s_{\text{ref}} \) and reference speeds \( v_{\text{ref}} \) are designed respectively, as shown in Equations (10-13).

- **Car following mode:**
  \[
  \begin{cases}
    s_{\text{ref}} = s_f - d_{\text{min}} - l_V - h V, \\
    v_{\text{ref}} = v_f,
  \end{cases}
  \]
  (10)
  where \( s_f \) and \( v_f \) are the position and speed of the preceding vehicle respectively; \( d_{\text{min}} \) is the minimum safety distance between the ego vehicle and the preceding vehicle; \( h \) is the minimum travel time from the rear of the preceding vehicle to the front of the following vehicle; and \( l_V \) is the length of vehicle \( V \).

- **Cruise mode:**
  \[
  \begin{cases}
    s_{\text{ref}} = s, \\
    v_{\text{ref}} = v_{\text{tar}},
  \end{cases}
  \]
  (11)
  where \( v_{\text{tar}} \) is target speed of vehicle \( V \).

- **Waiting mode:**
  \[
  \begin{cases}
    s_{\text{ref}} = s_{\text{stopline}} - l_{\text{tar}}, \\
    v_{\text{ref}} = 0,
  \end{cases}
  \]
  (12)
  where \( s_{\text{stopline}} \) is the position of stop line and \( l_{\text{tar}} \) is the target distance from vehicle centroid to the stop line.

- **Conflict-solving mode:**
  \[
  \begin{cases}
    s_{\text{ref}} = s_p - \bar{s}_p + \bar{s}_f - d_{\text{min}} - l_V - h V, \\
    v_{\text{ref}} = v_f,
  \end{cases}
  \]
  (13)
  where \( s_p \) is the position of the conflict point \( P \) in the lane coordinate system corresponding to vehicle \( V \); \( \bar{s}_p \) is the position of the conflict point \( P \) in the lane coordinate system corresponding to the vehicle that conflicts with vehicle \( V \); and \( \bar{s}_f \) is the position of the vehicle \( V \) in the lane coordinate system corresponding to the vehicle that conflicts with vehicle \( V \).
The conflict-solving mode uses the idea of virtual formation [18] to solve the problem of vehicle conflict, as shown in Fig. 8. To make the preceding vehicle and the ego vehicle pass through the conflict point \( P \) safely, we improve the speed planning model by introducing four control modes of undisturbed switching and virtual formation. Assuming that the distance between the ego vehicle and conflict point \( P \) is \( \Delta s_h \) and the distance between the preceding vehicle and conflict point \( P \) is \( \Delta s_f \). In order to make the time interval between the ego vehicle and the preceding vehicle reaching at conflict point \( P \) equal to \( H \) which is greater than the minimum safety time headway, the virtual formation is used for position mapping to calculate the relative position between conflicting vehicles. The position of the preceding vehicle can be mapped from the original lane to the lane the ego vehicle is in, and the relative distance between the preceding vehicle and the conflict point \( P \) remains unchanged, which meets \( \Delta s_f = \Delta s_f \), as illustrated in Fig. 8. As long as the ego vehicle and the virtual preceding vehicle maintain time headway \( H \), both the ego vehicle and the preceding vehicle can pass through the intersection safely and quickly. Different types of vehicles have different time headway \( H \) to ensure the safety of the vehicle to the greatest extent [31].

C. Vehicle Control based on Model Predictive Control

- Lateral control:

The vehicle steering model uses the Stanley method [32], as shown in Fig. 9. To obtain the steering model, it is essential to determine the closest point from the center point of the front axle to the target trajectory. The blue curve in Fig. 9 is the target trajectory obtained by the path planning model; \((\alpha_c, \beta_c)\) is the closest point; \(e_{sc} \) is the offset between the center point of the front axle and the closest point \((\alpha_c, \beta_c)\); and \( \theta_e \) is the angle between the vehicle heading and the tangent to the trajectory of the closest point. The steering angle \( \delta \) of the front wheel can be calculated as Equation (14).

\[
\delta = \theta_V - \theta_P + \arctan\left(\frac{k_f e_{sc}}{v}\right),
\]

where \( \theta_V \) is the heading angle of vehicle \( V \); \( \theta_P \) is the tangent angle at point \((\alpha_c, \beta_c)\) relative to the target trajectory; \( k_f \) is the proportional parameter; and \( v \) is the speed of vehicle \( V \).

- Longitudinal control:

For longitudinal control, the speed planning model is controlled by model predictive controller designed in [33]. Define the longitudinal position error of vehicle \( V \) as \( e_{sf} = s_{ref} - s \) and the speed error as \( e_u = v_{ref} - v \). Error state equations of CAVs in continuous time domain is shown in Equations (15-16), which is utilized in [33] to establish the state space model of longitudinal dynamics of vehicles.

\[
\dot{x}(t) = \Xi x(t) + \Psi_1 \tau(t) + \Psi_2 \omega(t),
\]

\[
\Xi = \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix}, \quad \Psi_1 = \begin{bmatrix} -\bar{h} \\ -1 \end{bmatrix}, \quad \Psi_2 = \begin{bmatrix} 0 \\ 1 \end{bmatrix},
\]

where \( x = [e_{sf}, e_u]^T \), \( \tau = a \),\( \omega = a_t \). \( a \) is the acceleration of vehicle \( V \) and \( a_t \) is the acceleration of other vehicles including preceding vehicle or the vehicle conflicts with vehicle \( V \). \( a_t = 0 \) means that there is no preceding vehicle or vehicle conflicts with vehicle \( V \). If the control mode of vehicle \( V \) is car following mode or conflict-solving mode, \( \bar{h} = h \). Otherwise, \( \bar{h} = 0 \).

Since the update of the vehicle state quantity \( x \) is discrete, the Equations (15-16) are transformed into discrete linear state equations as shown in Equations (17-18).

\[
x(k+1) = \Xi x(k) + \Psi_1 \tau(k) + \Psi_2 \omega(k),
\]

\[
\Xi = \begin{bmatrix} 1 & \varphi \\ 0 & 1 \end{bmatrix}, \quad \Psi_1 = \begin{bmatrix} -\bar{h}\varphi - \frac{1}{2}\varphi^2 \\ -\varphi \end{bmatrix}, \quad \Psi_2 = \begin{bmatrix} \frac{1}{2}\varphi^2 \\ \varphi \end{bmatrix},
\]
where $\varphi$ is the control cycle. We use the idea of rolling optimization in model predictive control to realize the longitudinal control of the CAVs. The overall objective is to minimize the total deviation between the vehicle speed $v$ and the reference speed $v_{ref}$ in a finite period of time in the future. The objective function and constraints of the proposed algorithm are shown in Equations (19-22).

$$\min_{\tau} \sum_{\eta=1}^{N_\tau} \|x(\kappa + \eta | \kappa)\|_\Theta^{2} + \sum_{\eta=0}^{N_c-1} \|\tau(\kappa + \eta | \kappa)\|_\Phi^{2},$$  

(19)

$$x_{min} \leq x(\kappa + \eta | \kappa) \leq x_{max} \quad (\eta = 1, 2, \ldots, N_p),$$  

(20)

$$\tau_{min} \leq \tau(\kappa + \eta | \kappa) \leq \tau_{max} \quad (\eta = 0, 1, \ldots, N_c - 1),$$  

(21)

$$\Delta \tau_{min} \leq \tau(\kappa + \eta | \kappa) - \tau(\kappa + \eta - 1 | \kappa) \leq \Delta \tau_{max} \quad (\eta = 0, 1, \ldots, N_c - 1),$$  

(22)

where $N_p$ is the predictive step length; $N_c$ is the control step length; $\Theta$ is the state weight matrix; $\Phi$ is the input weight matrix; $x_{min}$ and $x_{max}$ are the lower limit of the state quantity and the upper limit of the state quantity respectively; $\tau_{min}$ and $\tau_{max}$ are the lower limit of the control quantity and the upper limit of the control quantity respectively; $\Delta \tau_{min}$ and $\Delta \tau_{max}$ are the lower limit of the increment of control quantity and the upper limit of the increment of control quantity respectively.

VI. SIMULATION RESULTS

In order to verify the efficiency of HPQ algorithm systematically and comprehensively, we conduct extensive simulations using SUMO [34] to generate mixed random traffic flow. We select scenarios with traffic flows of approximately 1000 passenger car units/hour (pcu/h), 1300 pcu/h and 1600 pcu/h to simulate the algorithm and compare it with the hybrid AIM protocol proposed in [23], the delay-time actuated traffic lights algorithm proposed in [35] and the distributed conflict-free cooperation algorithm proposed in [19].

The hybrid AIM protocol [23] is a request-based right of way allocation algorithm for mixed traffic intersection management. Green trajectories and active green trajectories are defined to represent the right of way allocation of the intersection in real time. An active green trajectory is defined as a green trajectory with a HV present on it or on its incoming lane. If the trajectory of the CAV conflicts with the active green trajectory, the reservation of the CAV will be denied. Besides, the hybrid AIM protocol also investigates how to assign turning options for each lane and vehicle type and proposes turning assignment policy to improve traffic efficiency. The delay-time actuated traffic lights algorithm [35] proposes an approach to control signal lamps by capturing the delay time of vehicles and utilize them to regulate the traffic signal timing. Within the range of the minimum and maximum green time, once the accumulated delay on a lane is dissolved, the running green phase is terminated. The distributed conflict-free cooperation algorithm [19] is an iterative depth-first spanning tree algorithm. Each vehicle represents a vertex in the spanning tree. The depth of the vertices in the spanning tree is determined one by one according to the distance between the vehicle and the intersection center, and the conflict graph. According to the spanning tree, the right of way is granted to the corresponding vehicles. Further than these previous AIM algorithms, we comprehensively study the combination of the high-level HPQ algorithm and the low-level vehicle planning and control algorithm, and carry out detailed design for the vehicle control modes to improve traffic efficiency.

Although SUMO can realize efficient mixed random traffic flow simulation in complex dynamic environment, it is arduous to integrate vehicle dynamics and verify the efficiency of the vehicle planning and control algorithms. Therefore, a joint simulation platform based on Matlab and PreScan [36] is built up to simulate the scenario of unsignalised intersections to verify the proposed vehicle planning and control algorithms. In the joint simulation platform based on Matlab and PreScan, Prescan can provide the realistic 3D modelling environment for traffic and physical models of sensor, and V2V and V2I communication simulation. Matlab can embed the vehicle planning and control algorithm to better realize algorithm simulation. The unsignalized intersection management strategy is validated by these simulation tools.

A. Performance of HPQ Algorithm

We use SUMO to generate mixed random traffic flow to evaluate the performance of the proposed HPQ algorithm. To ensure the safety of vehicles at intersections, the speed limit is 13.8 m/s. The simulation scenario of the HPQ algorithm is a small traffic two-way single-lane intersection covering 200 m × 200 m, as shown in Fig. 2. We use the average number of halts, average travel time and average speed to evaluate the performance of algorithms. Vehicle stop state refers to the state when the vehicle speed is less than 1.4 m/s. In order to better evaluate the performance of the HPQ algorithm under mixed autonomy traffic streams, the simulation is carried out when the CAV penetration rates are 50%. The simulation results within 15 minutes are used for comparison.

1) Traffic fluency: The average number of halts of vehicles under different traffic flows is calculated as shown in Fig. 10. It can be seen that both HPQ algorithm and the distributed conflict-free cooperation algorithm can greatly reduce the average number of halts of vehicles when the traffic flows are 1000 pcu/h and 1300 pcu/h. However, when the traffic flow increases to 1600 pcu/h, the HPQ algorithm is significantly better than the distributed conflict-free cooperation algorithm for traffic fluency. And the HPQ algorithm is always better than the delay-time actuated traffic lights algorithm and Hybrid AIM protocol under different traffic flows. Therefore, the HPQ algorithm can effectively reduce the number of halts of vehicles and greatly improve the traffic fluency at intersections.

2) Travel time: The travel time of vehicles under different traffic flows is shown in Fig. 11. It can be seen that both HPQ algorithm and the distributed conflict-free cooperation algorithm can greatly reduce the average travel time of vehicles when the traffic flows are 1000 pcu/h and 1300 pcu/h. All vehicles can pass through the intersections efficiently in a limited time. Moreover, the HPQ algorithm reduces the average
travel time by up to 34% compared to the distributed conflict-free cooperation algorithm when the traffic flow is 1600 pcu/h. And the distributed conflict-free cooperation algorithm is more easily impacted by traffic densities. Compared with the delay-time actuated traffic lights algorithm and Hybrid AIM protocol, the HPQ algorithm can reduce the average travel time of vehicles at intersections by 22% to 65% under different traffic flows. The traffic light scheme seriously restrains traffic efficiency of intersections. In particular, the travel times of the HPQ algorithm at different periods and different traffic flows are very stable, comparing with the fluctuations of the other three algorithms. Therefore, the HPQ algorithm can effectively reduce the travel time of vehicles at intersections, so that vehicles can pass through the intersections more smoothly.

3) Average speed: To further investigate the effectiveness of the HPQ algorithm, we evaluate their performance using average vehicle speed, as shown in Fig. 12. It can be seen that vehicles under the control of the HPQ algorithm can pass through the intersection smoothly at a relatively high speed under different traffic flows. However, the speed of vehicles under the control of the other three algorithms fluctuates widely. This can be well explained since the vehicles under the control of the other three algorithms encounter a greater number of halts. The HPQ algorithm can reduce the number of halts and increase the speed of vehicles at intersections, therefore effectively improve the comfort and safety of occupants.

In general, the vehicles at the intersection under the control of the HPQ algorithm have a significant improvement in the traffic efficiency compared with the vehicles at the intersection under the control of the delay-time actuated traffic lights algorithm, the Hybrid AIM protocol and the distributed conflict-free cooperation algorithm. In addition, the performance of the HPQ algorithm is stable with different situations. Under low density traffic streams, vehicles almost do not need to slow down and stop at the intersection to avoid collision.

### B. Simulations of Vehicle Planning and Control Algorithm

Fig. 13 shows the comprehensive simulation scenario configuration. Table II illustrates the parameters used in simulation for vehicle planning and control algorithm based on intersection coordinate system. According to the HPQ algorithm and the vehicle planning and control algorithm proposed in this paper, the control modes of all vehicles are as follows:

- **Vehicle 1:** Firstly, vehicle 1 obtains the right of way and switches to the conflict-solving mode to coordinate the merging conflict with vehicle 5. After vehicle 5 passed through the conflict area, vehicle 1 switches to car following mode to follow vehicle 5.
- **Vehicle 2:** Vehicle 2 follows vehicle 1 when entering the intersection control area. When vehicle 2 gets near the stop line, vehicle 2 switches to the waiting mode because vehicle 2 cannot get the right of way. If it is not until vehicle 3 passed through the conflict area that vehicle 2 obtains the right of way and switches to the conflict-solving mode to coordinate the merging conflict with vehicle 6. After vehicle 6 passed through the conflict area, vehicle 2 switches to car following mode to follow vehicle 6.
- **Vehicle 3:** When vehicle 3 enters the intersection control area, it first switches to cruise mode. When vehicle 3 is near the stop line, it will switch to the waiting mode because it has not obtained the right of way. Vehicle 3 will not get the right of way until the vehicle 5 passes the conflict area, and then vehicle 3 switches to the conflict-solving mode to coordinate the merging conflict with the vehicle 1. After vehicle 1 passed through the conflict area, vehicle 3 switches to car following mode to follow vehicle 1.
- **Vehicle 4:** When vehicle 4 enters the intersection control area, it follows vehicle 5 first. When vehicle 4 approaches the stop line, it switches to waiting mode because it has not obtained the right of way. Vehicle 4 will obtain the right of way and switch to the conflict-solving mode to coordinate the crossing conflict with vehicle 6 when vehicle 3 passed through the conflict area. After vehicle 6 passed through the conflict area, vehicle 4 switches to cruise mode.
- **Vehicle 5:** When vehicle 5 arrives at the intersection control area, it will obtain the right of way, and the driver will drive at a constant speed.
- **Vehicle 6:** The driver first drives at a constant speed to the stop line and waits. Until vehicle 3 passes through

the conflict area, vehicle 6 will obtain the right of way and continue to drive at a constant speed through the intersection.

During the whole simulation, the allocation of the right of way at the intersection is shown in Fig. 14. The blue bars represent the time when the vehicle is granted the right of way. We can see that vehicle 1 and vehicle 5 obtain the right of way first. The control modes switching of CAVs are shown
in Fig. 15. Different colors represent different control modes of CAVs. When the color of the bar is blue, it means that the vehicle is in car following mode. We can see that vehicle 2 and vehicle 4 are in car following mode at the beginning of the simulation.

The speed profiles of all vehicles in the comprehensive simulation scenario are illustrated in Fig. 16. It can be seen that the speed profiles of the CAVs are smooth enough, which not only ensures the safety of the vehicles, but also improves the comfort of the occupants.

Relative distance and speed of vehicle 1 and vehicle 3 are shown in Fig. 17. Fig. 17(a) shows the relative distance of vehicle 1 and vehicle 3 to the surrounding reference vehicles, and Fig. 17(b) shows the speed of vehicle 1 and vehicle 3 in different control modes. It can be seen from the figure that vehicle 1 and vehicle 3 can quickly and accurately switch to the corresponding control mode designed under different traffic situations. And vehicle 1 and vehicle 3 can maintain a safe distance from surrounding vehicles at a relatively stable speed. Undisturbed switching of four control modes not only guarantees vehicle safety, but also improves the utilization rate of the conflict area of the intersection.

To better verify the effectiveness and robustness of the proposed unsignalized intersection management strategy, we conduct a larger-scale simulation considering the intersection at Shanghai Intelligent and Connected Vehicle Test Zone. The scenario layout of the intersection is shown in Fig. 18, where Fig. 18(a) is the actual photo of the simulated intersection, and Fig. 18(b) is the simulation environment built in PreScan according to the real scene. The vehicles arrive at the intersection entrances randomly with the initial speed of 9 m/s. The right of way of the vehicles is calculated by the high-level HPQ algorithm. Then, the high-level calculation results are transmitted to the low-level vehicle terminal for vehicle planning and control. There are a total of 30 vehicles participated in the simulation.

Fig. 19 presents the arrival time of different types of vehicles approaching the intersection in different traffic movements. The circular contours indicate the different levels of arrival time, and their values are displayed in the color bar of the figure. Besides, the arrows indicate different vehicle movements. It can be seen from Fig. 18 that there are
three entry areas at the intersection, and each entry area is connected to two exit areas. The solid dots and hollow dots in Fig. 19 represent the time when the CAVs and the CHVs arrive at the intersection, respectively. The points on the same circle correspond to vehicles passing through the intersection at the same time. It can be seen from the figure that there is no conflict between vehicles passing through the intersection at the same time and all vehicles can pass through the intersection within 60 s, which proves that the unsignalized intersection management strategy can coordinate the vehicles passing the intersection safely and efficiently. In addition, the computation load required by the unsignalized intersection management strategy is small enough, so it is highly feasible to be applied to actual traffic control scenarios. The videos of comprehensive simulation experiments under different scenarios are uploaded online. Please visit the website to view them (https://1drv.ms/u/s!AmxETTOkRGd6gZhrrG5WDUBkrBHQQ?e=mqGGko).

VII. CONCLUSION

This paper proposes an intelligent intersection management system for mixed autonomy traffic streams, which comprehensively consists of algorithms for upper-level decision making and low-level vehicle planning and control. In the upper-level right of way allocation, the HPQ algorithm is designed according to the difference between CAVs and CHVs. Since CAVs can deal with intersection trajectory conflicts with the help of intelligent equipment, they are easier to obtain the right of way than CHVs. In the low-level vehicle planning and control for CAVs, four different control modes are designed, and the control execution is carried out through the model predictive controller. The application of the model predictive controller to the CAVs can realize the undisturbed switching of the control modes and satisfy the safety requirements of collision avoidance. Then the SUMO is used to verify the efficiency and superiority of the proposed HPQ algorithm which shows that HPQ algorithm outperforms the delay-time actuated traffic lights algorithm and the Hybrid AIM protocol by decreasing the average travel time by 5% to 65% for different traffic flows. Moreover, the PreScan is used to conduct a microscopic simulation at the intersection, which verifies the safety and effectiveness of the proposed vehicle planning and control algorithm. The proposed unsignalized intersection management strategy is practical to be applied in the near future.

For future practical application deployment, challenges such as communication delay, packet loss, and pedestrian intervention need to be further considered. The problem will be more complicated when other traffic participants such as pedestrians are considered, because the interaction behaviors at the intersections are very diverse. We will further study the intelligent intersection management strategy in the presence of pedestrians and cyclists, so that the strategy can be applied to various types of public intersections.
