Abstract

Many proposals for the identification of causal effects in the presence of unmeasured confounding require an instrumental variable or negative control that satisfies strong, untestable assumptions. In this paper, we will instead show how one can identify causal effects for a point exposure by using a measured confounder as a ‘bespoke instrumental variable’. This strategy requires an external reference population that does not have access to the exposure, and a stability condition on the confounder-outcome association between reference and target populations. Building on recent identification results of Richardson and Tchetgen Tchetgen (2021), we develop the semiparametric efficiency theory for a general bespoke instrumental variable model, and obtain a multiply robust locally efficient estimator of the average treatment effect in the treated.

1 Introduction

In drawing causal inferences from observational data, strong assumptions are typically made regarding the absence of unmeasured confounding. For example, in a point exposure study one often assumes that the measured covariates are sufficient to account for systematic differences between treatment groups at baseline. This assumption cannot be empirically verified, and may not be plausible in many contexts. Hence there is now a long tradition in causal inference of developing identification strategies that do not rely
Arguably the most popular of these is the ‘instrumental variable’ (IV) approach, long used in economics and recently gaining attention in epidemiology in the context of Mendelian Randomisation studies (Davey Smith and Ebrahim, 2003). For validity, IV-based causal inference relies on having access to a variable that satisfies the three core IV conditions: IV.1) it is associated with the exposure (relevance); IV.2) it affects the outcome only via the exposure (exclusion restriction); and IV.3) it shares no unmeasured common causes with the outcome (unconfoundedness) (Hernán and Robins, 2006). Outside of a double-blinded randomised trial, these conditions are not usually guaranteed to hold by design. It is known that even under small violations of one or more of these conditions, IV estimators can exhibit large biases. A separate strand of work attempts to draw causal inferences based on within-subject comparisons, when one has access to repeated measurements of an outcome. Fixed effect models and the difference-in-difference (DiD) strategy are examples of this approach (Angrist and Pischke, 2008), with the latter basing identification on the ‘parallel-trends’ assumption. Synthetic control approaches allow one to relax this condition to some extent (Abadie et al., 2010), if one has access to appropriate ‘donor’ controls which can be used to approximate a treated unit had it been left untreated. In recent work, increasing attention has been given to leveraging negative control exposures and outcomes not just to detect bias, but also to remove it from confounded estimates (Lipsitch et al., 2010; Sofer et al., 2016). Negative controls can be viewed as specific examples of ‘proxy variables’ (Miao et al., 2018; Tchetgen Tchetgen et al., 2020) propose a general nonparametric identification strategy for leveraging proxies to recover causal effects when conditional exchangeability fails.

In much of this work, investigators are required to have access to additional variables beyond the measured confounders, which obey certain untestable assumptions. However, Richardson and Tchetgen Tchetgen (2021) take a different tack, and use a standard confounder to derive a ‘bespoke’ instrumental variable. For example, in a study attempting to ascertain the effect of prompt radiation exposure from the atomic bombings of Hiroshima and Nagasaki on mortality, certain individuals in the database were not present in these cities at the time of the bombings. The authors show that the association between a confounder and mortality in this reference population can be used to predict what would have occurred had exposed individuals in the target population (those who remained in the cities) been unexposed. The authors show that the association between a confounder and mortality in this reference population can be used to mean center that confounder among the individuals in the target population (those who remained in the cities). In turn, this can be used for identification of the average treatment effect on the treated (ATT) in a
‘bespoke’ IV analysis. The validity of the approach relies on having access to a reference population for whom treatment was not available, as well as the association between the chosen confounder and outcome transporting from the reference to the target population. Importantly however, the bespoke instrument does not have to satisfy the IV conditions IV.2 and IV.3, besides being predictive of the exposure, therefore satisfying IV.1.

In this paper, we first review the conditions under which a confounder can be used as a bespoke instrument to identify causal effects. We draw the links between this strategy and the IV, DiD and negative control designs and extend the results of Richardson and Tchetgen Tchetgen (2021) for identification of the ATT. We then develop a rigorous theory of estimation and inference for these causal estimands, working under a semiparametric model for the observed data distribution. This yields several novel classes of estimators, which are distinct from those proposed in Richardson and Tchetgen Tchetgen (2021). Our estimators turn out to be quadruply robust; unbiased if one out of four sets of constraints on the observed data distribution hold. We also characterize the semiparametric efficiency bound for the parameter indexing the ATT, and describe a corresponding locally semiparametric efficient estimator in the special case of a binary treatment and bespoke IV. Finally, we show how the proposed estimators simplify considerably in the case where a baseline outcome measurement is used to construct the reference population, in which case BSIV provides an alternative to standard DiD approach, without imposing the parallel trend assumption typically invoked to justify DiD.

2 Identification

2.1 Set-up

Similar to Richardson and Tchetgen Tchetgen (2021) we will first consider a setting where we have a point-treatment exposure $A$ and covariate $Z$, which are measured in a target population ($S = 1$) and for the moment both assumed to be binary. Let $Y$ denote the end-of-study outcome. Suppose furthermore that data is also available on a reference population ($S = 0$), who did not have the chance to receive the exposure, but for which $Y$ and $Z$ are observed. This may include pharmacoepidemiologic studies where a reference population may be sourced from time periods when a new treatment was not yet available. Alternatively, in environmental health studies, a natural reference population may be determined based on physical/spatial considerations that would have prevented access to the exposure.

Let $Y^a$ define the potential outcome that would have been observed, had an individ-
ual been assigned to intervention level $A = a$. Then for the moment, we will consider identification of the conditional ATT in the target population:

$$E(Y^1 - Y^0|A = 1, Z = z, S = 1).$$

We will now attempt to link the above expression to the observed data. It follows from Tchetgen Tchetgen and Vansteelandt (2013) that one can parametrise the outcome conditional mean function $E(Y|A = a, Z = z, S = 1)$ as

$$E(Y|A = a, Z = z, S = 1) = E(Y^a - Y^0|A = a, Z = z, S = 1) + E(Y^0|A = a, Z = z, S = 1) - E(Y^0|A = 0, Z = z, S = 1)$$

$$- \sum_{a'} \{E(Y^0|A = a', Z = z, S = 1) - E(Y^0|A = 0, Z = z, S = 1)\} Pr(A = a'|Z = z, S = 1)$$

$$+ E(Y^0|Z = z, S = 1)$$

$$= \beta(a, z) + \gamma(z)\{a - f(A = 1|Z = z, S = 1)\} + t(z) + c$$

where

$$\beta(a, z) = E(Y^a - Y^0|A = a, Z = z, S = 1)$$

$$\gamma(z) = E(Y^0|A = 1, Z = z, S = 1) - E(Y^0|A = 0, Z = z, S = 1)$$

$$t(z) = E(Y^0|Z = z, S = 1) - E(Y^0|Z = 0, S = 1)$$

$$c = E(Y^0|Z = 0, S = 1)$$

where we assume consistency to hold. A quick verification reveals that $E(Y|A = a, Z = z, S = 1)$ has four degrees of freedom: $E(Y|A = 1, Z = 1, S = 1)$, $E(Y|A = 0, Z = 1, S = 1)$, $E(Y|A = 1, Z = 0, S = 1)$ and $E(Y|A = 0, Z = 0, S = 1)$. However, the expression $\beta(a, z) + \gamma(z)\{a - \pi(z)\} + t(z) + c$ has 6 degrees of freedom; note that $Pr(A = 1|Z = z, S = 1)$ can be identified separately based on the association between $A$ and $Z$ in target population. Thus the identification task is to reduce this expression by two degrees of freedom.

There are several ways that this can be done; the first is to assume (partial) conditional exchangeability given $Z$: $A \perp Y^0|Z = z, S = 1$, such that $\gamma(z) = 0$ for each $z$. Unfortunately, in many studies, this assumption may not be plausible, and key confounders may either be missing or measured with error. Suppose instead that $Z$ satisfies the instrumental variable conditions IV.1-IV.3. In that case, it follows that $t(z) + c = E(Y^0)$ (a constant). However, a further assumption is required to lose an extra degree of freedom. One option is to restrict the treatment effect, such that $\beta(a, z) = \beta(a)$; in other words, the effect
of \( A \) should not be modified by the instrument (Hernán and Robins, 2006). It may not be palatable to place such a restriction on the target of interest, unless there is existing scientific knowledge to support it. Therefore, Tchetgen Tchetgen and Vansteelandt (2013) instead restrict the selection bias term, such that \( \gamma(Z) \) does not depend on \( Z \). This leads to alternative results for identification and inference. However, even if such a restriction is plausible, this strategy requires having access to a valid instrumental variable, which may not be possible in many observational studies.

We close this section by describing one last method for identification that is relevant for developments in later sections. One might lose two degrees of freedom under an assumption that \( \gamma(z) \) can be learnt using the association between treatment and an additional variable. For example, if one has access to a negative control outcome \( W \), then if

\[
E(W|A = 1, z, S = 1) - E(W|A = 0, z, S = 1) \\
= E(Y^0|A = 1, z, S = 1) - E(Y^0|A = 0, z, S = 1)
\]

then \( W \) can be harnessed to learn the selection bias. This assumption is know as additive equi-confounding and essentially requires that \( W \) and \( Y \) are measured on the same scale (Sofer et al., 2016). A special case arises when \( W \) is a baseline measurement of the outcome, in that case, the above assumption is equivalent to the parallel-trends assumption, and this identification strategy boils down to the DiD approach.

### 2.2 Bespoke instrumental variables

Suppose that the measured covariates can be decomposed as \((Z, C^T)^T\), where (for the moment) \( Z \) is binary. In what follows, we will convert \( Z \), which may be a confounder that fails to satisfy the three instrumental variable conditions, into a ‘bespoke’ instrument by leveraging information on the reference population. The key assumptions underpinning our approach are now given below:

**Assumption 1.** *Consistency:* if \( A = a \) and \( S = 1 \), then \( Y^a = Y \).

**Assumption 2.** *Degenerate reference population:* we have

\[
E(Y|z, S = 0, c) = E(Y^0|z, S = 0, c)
\]

**Assumption 3.** *Partial population exchangeability:*

\[
E(Y^0|z, S = 1, c) - E(Y^0|Z = 0, S = 1, c) \\
= E(Y^0|z, S = 0, c) - E(Y^0|Z = 0, S = 0, c) \neq 0
\]
Assumption 4. Bespoke IV relevance:

\[ E(A|z, S = 1, c) - E(A|Z = 0, S = 1, c) \neq 0 \]

We will discuss each of these assumptions in turn, noting first that Assumption 1 is standard. Assumption 2 states that in the reference population, the observed outcome (conditional on C) is equal to the potential outcome under no treatment. Such a condition can be made plausible if the reference population is sensibly chosen, such that by an exogenous intervention which may be a physical or temporal restriction, they were unable to receive treatment. Note that in those with \( S = 0 \), the usual positivity assumption is expected to fail, in the sense that \( P(A = 1|z, S = 0, c) = 0 \); hence the Bespoke IV design allows one to leverage subgroups of the patient populations for which positivity is violated.

Assumption 3 requires that the (conditional) association between the potential outcome \( Y_0 \) and \( Z \) is constant between the reference and target populations. This is not a testable assumption, and facilitates the borrowing of information from the reference population in order to obtain identification. Note that full population exchangeability would require that \( E(Y_0|z, S = 1, c) = E(Y_0|z, S = 0, c) \), such that this is a strictly weaker condition. Finally, Assumption 4 demands that \( Z \) is predictive of the exposure, and would be satisfied if \( Z \) is a confounder (and ideally a strong one). This assumption is similar to IV.1; note however, that \( Z \) is not required to satisfy either IV.2 or IV.3.

Similar to the IV set-up, Assumptions 5 and 6 will be sufficient to test the causal null hypothesis that \( E(Y_1 - Y_0|A = 1, z, S = 1, c) = 0 \) but are insufficient to identify the causal effect of interest. Therefore, we will posit two additional assumptions, of which only one is required to hold to yield identification:

Assumption 5. No effect modification (NEM):

\[ E(Y_1 - Y_0|A = 1, Z = 1, S = 1, c) = E(Y_1 - Y_0|A = 1, Z = 0, S = 1, c) = \beta(1, c) \]

Assumption 6. No selection modification (NSM):

\[ E(Y_0|A = 1, z, S = 1, c) - E(Y_0|A = 0, z, S = 1, c) = \gamma(c) \]

The first of these requires that the conditional ATT does not depend on \( Z \), whereas the second assumption requires that the selection bias is not a function of the bespoke IV.

Then we are in a position to give the main theorem for identification of the conditional ATT.
Theorem 2.1. Suppose that Assumptions 1-3 hold. Then we have that
\[ t(z, c) = E(Y|Z = z, S = 0, c) - E(Y|Z = 0, S = 0, c) \]

Further, under Assumptions 1-5,
\[ E(Y_1 - Y_0|A = 1, Z = z, S = 1, C = c) \]
\[ = \frac{E\{Y - t(Z, c)|Z = 1, S = 1, c\} - E\{Y - t(Z, c)|Z = 0, S = 1, c\}}{E(A|Z = 1, S = 1, c) - E(A|Z = 0, S = 1, c)} \]

and alternatively, under Assumptions 1-4 and 6,
\[ E(Y_1 - Y_0|A = 1, Z = z, S = 1, C = c) \]
\[ =\frac{E\{Y - t(Z, c)|A = 1, Z = 1, S = 1, c\} - E\{Y - t(Z, c)|A = 0, Z = 0, S = 1, c\}}{E(A|Z = 1, S = 1, c) - E(A|Z = 0, S = 1, c)} \]

The first two results here follow directly from Result 1 in the Appendix of Richardson and Tchetgen Tchetgen (2021). The final result can be shown along the same lines, using the previous parameterisation of the outcome conditional mean function. To give some intuition for Theorem 2.1 (using this parametrisation), for a fixed \(c\) we have:
\[ E(Y|A = a, z, S = 1, c) = \beta(a, z, c) + \gamma(z, c)\{a - f(A = 1|z, S = 1, c)\} \]
\[ + t(z, c) + E(Y_0|Z = 0, S = 1, c) \]

As before, the right hand side must be reduced by two parameters. The bespoke IV strategy does this by replacing \(t(z, c)\) by a quantity that can be calculated using a reference population, and then removing one extra parameter by restricting either the treatment effect or selection bias. A further implication from Theorem 2.1 is that the marginal ATT \(E(Y_1 - Y_0|A = 1, S = 1)\) can also be identified, by averaging conditional treatment effects over the distribution of \(Z\) and \(C\) in those with \(A = 1\) and \(S = 1\). We return to this in Section 3.4.

One can also harness baseline measurements of the outcome in order to generate a reference population; for reasons that will become clear, we label this approach ‘bespoke IV-DiD’. To be specific, let \(Y(1)\) now denote the end-of-study outcome, and \(Y(0)\) denote a baseline measurement. Then if we replace Assumptions 2 and 3 with the conditions that
\[ E\{Y(0)|z, c\} = E\{Y^0(0)|z, c\} \]
and
\[ E\{Y^0(1)|z, c\} - E\{Y^0(1)|Z = 0, c\} = E\{Y^0(0)|z, c\} - E\{Y^0(0)|Z = 0, c\} \neq 0 \quad (3) \]
then it follows from Theorem 2.1 that one can identify the effect \( E\{Y^1(1) - Y^0(1)|A = 1, Z = z, C = c\} \) by leveraging the (conditional) association between the baseline outcome \( Y(0) \) and \( Z \). Specifically, if we assume that the causal effect does not depend on \( Z \),
\[
E\{Y^1(1) - Y^0(1)|A = 1, Z = z, C = c\} = \frac{E\{Y(1) - Y(0)|Z = 1, c\} - E\{Y(1) - Y(0)|Z = 0, c\}}{E(A|Z = 1, c) - E(A|Z = 0, c)} \tag{4}
\]
and if we alternatively assume
\[
E\{Y^0(1)|A = 1, z, c\} - E\{Y^0(1)|A = 0, z, c\} = \gamma(c) \tag{5}
\]
e.g. the selection bias does not depend on \( Z \) after conditioning on covariates, then we have
\[
E\{Y^1(1) - Y^0(1)|A = 1, Z = z, C = c\} = E\{Y(1)|A = 1, z, c\} - E\{Y(1)|A = 0, z, c\} + \frac{E\{Y(1)|A = 0, Z = 1, c\} - E\{Y(1)|A = 0, Z = 0, c\}}{E(A|Z = 1, c) - E(A|Z = 0, c)} - \frac{E\{Y(0)|Z = 1, c\} - E\{Y(0)|Z = 0, c\}}{E(A|Z = 1, c) - E(A|Z = 0, c)}
\]
Ye et al. (2020) arrive at an expression similar to (4), although they consider a setting where two measurements of the exposure (in addition to the outcome) are available. In the denominator of their expression, the contrast involves the difference in the exposure measurements. In addition, Ye et al. (2020) target a different causal estimand and their identification results are separate from ours, as they require that \( Z \) satisfies the first instrumental condition (unconfoundedness). Their identification functional also appears in the econometrics literature on ‘fuzzy’ DiD designs (De Chaisemartin and d’Haultfoeuille, 2018), where it is usually interpreted (under separate assumptions) as a local average treatment effect.

The condition (2) are arguably more plausible (in general) than the corresponding Assumption 2 in the bespoke IV design, from the point of view that the best reference population is the original sample itself. As we will see, inference under the bespoke IV-DiD design will turn out to have additional advantages in terms of robustness and efficiency.
Remark. Instead of \( (5) \), one may make the assumption

\[
E\{Y^0(1) - Y^0(0) | A = 1, z, c\} - E\{Y^0(1) - Y^0(0) | A = 0, z, c\} = \gamma(c) \quad (6)
\]
e.g. the selection bias in a DiD analysis (rather than the comparison of end-of-study outcomes) does not depend on \( Z \) after conditioning on covariates. This assumption leads to an alternative identification result

\[
E\{Y^1(1) - Y^0(1) | A = 1, Z = z, C = c\} = E\{Y^1(1) - Y^0(1) | A = 0, z, c\} = 0
\]

which suggests an interesting way of combining the IV and DiD strategies. For example, assumption \( (6) \) weakens the usual parallel trends assumption

\[
E\{Y^0(1) - Y^0(0) | A = 1, z, c\} - E\{Y^0(1) - Y^0(0) | A = 0, z, c\} = 0
\]
such that the left hand side of the above is no longer required to equal zero (although it cannot depend on \( Z \)). A parallel trend-type assumption \( (3) \) is required with respect to the conditional association between \( Y(0) \) and \( Z \), although if many covariates are collected, one has at least the freedom to choose the \( Z \) for which \( (3) \) is most plausible.

The two NSM conditions \( (5) \) and \( (6) \) are distinct and one does not imply the other. We focus on analyses under \( (5) \) since it is closer in spirit to the original NSM Assumption \( 6 \) where the condition was placed on the selection bias in the target population. Nevertheless, \( (6) \) holds appeal as an alternative to the standard parallel trends assumption in DiD.

2.3 Comparison with existing approaches

2.3.1 IV analyses with potentially invalid instruments

As discussed above, \( Z \) does not need to satisfy the three IV conditions, since we can allow for violations of both unconfoundedness and the exclusion restriction. In the DiD set-up, the partial population exchangeability assumption \( (3) \) can be interpreted as a (conditional) exclusion restriction for the difference \( Y^0(1) - Y^0(0) \) rather than \( Y^0(1) \); note that this does not imply the standard exclusion restriction (and vice versa). Hence the methods described in this paper can be viewed as part of the growing literature on IV analyses with invalid...
instruments (Kang et al., 2016; Tchetgen Tchetgen et al., 2021), where there is a focus on robustness to violations of the exclusion restriction in Mendelian Randomisation studies. The assumption (3) may in particular be applicable in studies when repeated measurements of the outcome are collected, and the gene-outcome association (in the absence of treatment) may be non-null but approximately constant over time. If \( Z \) is in truth a valid instrument (in addition to satisfying Assumptions 1-4), then the proposed estimators in the following section will continue to target the causal effects, but may suffer from a loss of efficiency relative to standard IV estimators by not harnessing the exclusion restriction.

### 2.3.2 Triple differences

There is also a link with the so-called Difference-in-Difference-in-Differences or Triple Difference identification strategy (Gruber, 1994). This approach typically targets a contrast e.g. \( E\{Y^1(1) - Y^0(1) | Z = z, c \} \), and allows for violation of the parallel trend assumption at \( Z = z \) so long as the resulting bias in the naïve DiD analysis is equal to the DiD analysis in those with \( Z = z' \) for some \( z' \neq z \). This essentially requires that the selection bias operates in the same way at the difference levels of \( Z \), similar to (6), but also that the treatment has no effect at \( Z = z' \) e.g. \( E\{Y^1(1) - Y^0(1) | Z = z', c \} = 0 \). This key difference leads to alternative identification results, as this strategy therefore relies on a null causal effect rather than stability in the trend \( Y^0(1) - Y^0(0) \) between levels of \( Z \).

### 3 Estimation and inference

#### 3.1 Semiparametric Theory

In this section, we will first develop a semiparametric efficiency theory for the conditional treatment effect \( E(Y^a - Y^0 | A = a, Z = z, S = 1, C = c) = \beta(a, z, c) \) based on a bespoke IV strategy. We allow for \( A, Z \) and \( C \) to be continuous or discrete and potentially vector-valued; the previous NEM and NSM assumptions can be generalised as

**Assumption 7.** No effect modification (NEM):

\[
\beta(a, z, c) = \beta(a, c)
\]

**Assumption 8.** No selection modification (NSM):

The generalised selection bias function

\[
q(a, Z, C) = E(Y^0 | A = a, Z = z, S = 1, C) - E(Y^0 | A = 0, Z = z, S = 1, C)
\]
satisfies the restriction \( q(a, z, c) = q(a, c) \)

Generalised versions of Assumptions 1-4 are given in the Appendix. Also, we will use the notation
\[
\epsilon = Y - \beta(A, Z, C)S - [q(A, Z, C) - E\{q(A, Z, C)\mid Z, S = 1, C\}]S - t(Z, C) - b_1(C)S - b_0(C)
\]
\[
\epsilon^* = \epsilon + [q(A, Z, C) - E\{q(A, Z, C)\mid Z, S = 1, C\}]S
\]

where
\[
t(z, C) = E(Y_0\mid Z = z, S = 1, C) - E(Y_0\mid Z = 0, S = 1, C)
\]
\[
b_1(C) = E(Y_0\mid Z = 0, S = 1, C) - E(Y_0\mid Z = 0, S = 0, C)
\]
\[
b_0(C) = E(Y_0\mid Z = 0, S = 0, C).
\]

We postulate a semiparametric model
\[
\beta(a, z, c) = \beta(a, z, c; \psi^\dagger), \tag{7}
\]
where \( \psi^\dagger \) is an unknown finite-dimensional parameter vector. We will let \( \mathcal{M}_{NEM} \) denote the model defined by restriction (7) along with Assumptions 7 and 9-12 (in the Appendix); \( \mathcal{M}_{NSM} \) alternatively denotes a model defined by (7), and Assumptions 8 and 9-12.

**Theorem 3.1.** (Part a - NEM) under the semiparametric model \( \mathcal{M}_{NEM} \), the orthocomplement to the nuisance tangent space is given as
\[
\left\{ \phi(Z, S, C)\epsilon^*(\psi^\dagger) : \phi(Z, S, C) \in \Omega \right\} \cap L_2^0
\]
where
\[
\Omega = \{ \phi(Z, S, C) : E\{\phi(Z, S, C)\mid Z, C\} = E\{\phi(Z, S, C)\mid S, C = 0 \} \}.
\]

(Part b - NSM) The orthocomplement to the nuisance tangent space under model \( \mathcal{M}_{NSM} \) is given by
\[
\left\{ \{S\kappa(A, Z, C) + \phi(Z, S, C)\} \epsilon(\psi^\dagger) + S\phi(Z, S, C)[q(A, C) - E\{q(A, C)\mid Z, S = 1, C\}] : \kappa(A, Z, C) \in \Gamma, \phi(Z, S, C) \in \Omega \right\} \cap L_2^0
\]
where
\[
\Gamma = \{ \kappa(A, Z, C) : E\{\kappa(A, Z, C)\mid Z, S = 1, C\} = E\{\kappa(A, Z, C)\mid A, S = 1, C = 0 \} \}.
As reviewed e.g. in Bickel et al. (1993), by deriving the orthocomplement of the nuisance tangent space, we obtain the class of influence functions of all regular and asymptotically linear (RAL) estimators of $\psi^\dagger$. In turn, knowing this class motivates the construction of RAL estimators e.g. by solving estimating equations based on a chosen influence function. Specifically, under Assumption 5 we can estimate $\psi^\dagger$ as the solution to the equations

$$0 = \sum_{i=1}^{n} \phi(Z_i, S_i, C_i) \epsilon_i^*(\psi^\dagger)$$

for a chosen $\phi(Z, S, C)$ that satisfies the above restrictions; likewise, under (8) we solve

$$0 = \left( \sum_{i=1}^{n} \phi(Z_i, S_i, C_i) \epsilon_i^*(\psi^\dagger) \right) / \sum_{i=1}^{n} S_i \kappa(A_i, Z_i, C_i) \epsilon_i(\psi^\dagger)$$

for a chosen $\phi(Z, S, C)$ and $\kappa(A, Z, C)$.

Converting the above result into an estimation strategy requires a choice of $\phi(Z, S, C)$ and $\kappa(A, Z, C)$. In order to provide guidance, we first define a further definition.

**Definition 1. Admissible Independence Density (Tchetgen Tchetgen et al., 2010).** Consider three potentially vector-valued random variables $X_1, X_2$ and $X_3$. Let $f^\dagger(X_1, X_2|X_3) = f^\dagger(X_1|X_3)f^\dagger(X_2|X_3)$ denote a fixed density that makes $X_1$ and $X_2$ conditionally independent given $X_3$. Then $f^\dagger(X_1, X_2|X_3)$ is an admissible independence density if it is absolutely continuous w.r.t. the true joint law $f(X_1, X_2|X_3)$ with probability one.

It follows furthermore from Tchetgen Tchetgen et al. (2010) that, for admissible independence densities $f^\dagger(Z, S|C)$ and $f^\dagger(A, Z|S = 1, C)$ we have

$$\Omega = \left\{ \frac{f^\dagger(Z, S|C)}{f(Z, S|C)} [r_0(Z, S, C) - E^\dagger\{r_0(Z, S, C)\}|Z, C] 
- E^\dagger\{r_0(Z, S, C)|S, C\} + E^\dagger\{r_0(Z, S, C)|C]\} : r_0(Z, S, C) \text{ unrestricted} \right\}$$

(8)

$$\Gamma = \left\{ \frac{f^\dagger(A, Z|S = 1, C)}{f(A, Z|S = 1, C)} [r_1(A, Z, C) - E^\dagger\{r_1(A, Z, C)\}|Z, S = 1, C] 
- E^\dagger\{r_1(A, Z, C)|A, S = 1, C\} + E^\dagger\{r_1(A, Z, C)|S = 1, C]\} : r_1(A, Z, C) \text{ unrestricted} \right\}$$

(9)
conditionally independent given $C$.

Example 1. Let $A$ and $Z$ both be binary. Suppose one sets $f^\dagger(Z = 1|C) = f^\dagger(S = 1|C) = f^\dagger(A = 1|S = 1, C) = f^\dagger(Z = 1|S = 1, C) = 0.5$ (pretending $A$, $Z$, and $S$ are randomly assigned). Then $\Omega$ and $\Gamma$ are equivalently characterised respectively as

$$\Omega = \left\{ \frac{m(C)(-1)^{Z+S}}{f(Z, S|C)} : m(C) \text{ unrestricted} \right\}$$

$$\Gamma = \left\{ \frac{h(C)(-1)^{A+S}}{f(A, Z|S = 1, C)} : h(C) \text{ unrestricted} \right\}$$

if we further choose $r_0(Z, C, S) = 16(A - 0.5)(Z - 0.5)m(C)$ and $r_1(A, Z, C) = 16(A - 0.5)(Z - 0.5)h(C)$. Then e.g. under NEM, one can estimate $\psi$ via the unbiased equating function

$$\frac{m(C)(-1)^{Z+S}}{f(Z, S|C)} \epsilon^*(\psi^\dagger)$$

(10)

An alternative strategy to compute $\phi(Z, S, C)$ and $\kappa(A, Z, C)$ is through the alternating conditional expectations (ACE) algorithm [Bickel et al., 1993]. From an initial choice $\phi^{(1)}(Z_i, S_i, C_i)$, one then computes

$$\phi^{(2j)}(Z_i, S_i, C_i) = \phi^{(2j-1)}(Z_i, S_i, C_i) - E\{\phi^{(2j-1)}(Z_i, S_i, C_i)|Z_i, C_i\}$$

$$\phi^{(2j+1)}(Z_i, S_i, C_i) = \phi^{(2j)}(Z_i, S_i, C_i) - E\{\phi^{(2j)}(Z_i, S_i, C_i)|S_i, C_i\}$$

for $j = 1, 2, \ldots$ until convergence is reached at $\lim_{j \to \infty} \phi^{(2j+1)}(Z_i, S_i, C_i)$; this can then be repeated for $\kappa(A, Z, C)$. This may not lead to closed-form representations of functions of interest, since there is no closed form expression for $\kappa(A, Z, C)$ when $A$ and $Z$ include continuous components [Vansteelandt et al., 2008]. It may nevertheless lead to estimators with improved finite sample performance since this approach does not involve inverse weighting by a density.
We end this section by extending the previous results to the bespoke IV-DiD design; for the remainder of this section, let us temporarily define (or redefine)

\[ q(a, Z, C) = E(Y_0(1)|A = a, Z, C) - E(Y_0(1)|A = 0, Z, C) \]
\[ t(z, C) = E(Y_0(1)|Z = z, C) - E(Y_0(1)|Z = 0, C) \]
\[ b_1^*(C) = E(Y_0(1)|Z = 0, C) \]
\[ b_0(C) = E(Y_0(0)|Z = 0, C). \]

Under slightly altered versions of Assumptions 10 and 11, \( t(z, C) \) is identified as

\[ t(z, C) = E(Y(0)|Z = z, C) - E(Y(0)|Z = 0, C) \]

The following result is a corollary of Theorem 3.1.

**Corollary 3.1.1.** In the bespoke IV-DiD design, the (conditional) density of \( S \) is degenerate and \( f(Z|S = 1, C) = f(Z|S = 0, C) = f(Z|C) \) and the nuisance tangent space is smaller. Under the semiparametric model implied by restriction (7) and the NEM Assumption 7, the estimating function for \( \psi^\dagger \) implied by Theorem 3.1 simplifies to

\[ [\phi(Z, C) - E\{\phi(Z, C)|C\}][Y(1) - Y(0) - \beta(A, C; \psi^\dagger) - \{b_1^*(C) - b_0(C)\}] \]  

(11)

where \( \phi(Z, C) \) is arbitrary. Also, if \( q(a, z, c) = q(a, c) \), then the estimating function(s) for \( \psi^\dagger \) derived under the NSM Assumption 8 reduce to

\[ \left( \frac{[\phi(Z, C) - E\{\phi(Z, C)|C\}][Y(1) - Y(0) - \beta(A, Z, C; \psi^\dagger) - \{b_1^*(C) - b_0(C)\}]}{\kappa(A, Z, C) (Y(1) - \beta(A, Z, C; \psi^\dagger) - [q(A, C) - E\{q(A, C)|Z, C\}] - t(Z, C) - b_1^*(C))} \right) \]  

(12)

where \( \phi(Z, C) \) is arbitrary and \( \kappa(A, Z, C) \) satisfies \( E\{\kappa(A, Z, C)|A, C\} = E\{\kappa(A, Z, C)|Z, C = 0 \).

### 3.2 De-biased machine learning and multiply robust estimation

The estimation strategies previously described are not generally feasible, because the estimating equations for \( \psi^\dagger \) involve nuisance parameters that are typically unknown. One approach to deal with this is to plug-in estimates obtained from nonparametric estimators or flexible statistical learning methods. It follows from more general results in semiparametric theory, that if all nuisance parameter estimators converge at a rate faster than \( n^{1/4} \).
and sample-splitting/cross-fitting are used, then the resulting estimators of $\psi^\dagger$ are RAL, with variance equal to the variance of its influence function; see e.g. [Chernozhukov et al. (2013)] for a review. In the Appendix, we therefore use Theorem 3.1 to construct cross-fit de-biased machine learning-based estimators of $\psi^\dagger$.

The aforementioned $n^{1/4}$-rate condition is sufficient for the bias of influence function-based estimators to be second order (assuming cross-fitting is used). However, the actual structure of the bias is context dependent; characterising this structure gives a more nuanced understanding about the conditions under which the bias disappears. In certain problems, estimators with a doubly or multiply robust property may be available. As discussed in [Rotnitzky et al. (2021)], understanding whether double or multiple robustness is attainable is important because it allows one to trade off assumptions on nuisance parameter estimation (e.g. one can be poorly estimated, if another is estimated well) and potentially allows one to leverage knowledge on components of the data-generating mechanism to obtain additional robustness and efficiency.

Hence to develop a deeper understanding of the bias properties of the estimators, we will instead consider a scenario where parametric working models are used for the conditional expectations/densities that arise in estimating the causal effect of interest. Let us define the following parametric models $t(Z, C; \nu^\dagger)$ for $b_0(C)$ and $b_1(C; \theta^\dagger_1)$ for $b_1(C)$ that are required to model the conditional outcome mean for both the reference and the target population. Here, $t(Z, C; \nu^\dagger)$, $b_0(C; \theta^\dagger_0)$ and $b_1(C; \theta^\dagger_1)$ are known functions, which are smooth in $\nu^\dagger$, $\theta^\dagger_0$ and $\theta^\dagger_1$ respectively. We will sometimes use the notation $\theta^\dagger = (\theta^\dagger_0^T, \theta^\dagger_1^T)^T$. For modelling the joint conditional density $f(Z, S|C)$, we will make use of the following parametrisation based on the generalised odds ratio function

$$OR(Z, S, C) = \frac{f(Z|S, C)f(Z = z|S = s, C)}{f(Z = z|S, C)f(Z|S = s, C)}$$

(Tchetgen Tchetgen et al., 2010); one can generate $f(Z, S|C)$, $f(Z|S, C)$ and $f(S|Z, C)$ based on specification of $f(Z|S = s, C)$, $f(S|Z = z, C)$ and $OR(Z, S, C)$ (Chen, 2007). The values of $z$ and $s$ are user-specified; in what follows, we will use $z = 0$ and $s = 0$ as a generic notation. We will postulate smooth parametric models $f(Z|S = 0, C; \tau^\dagger)$, $f(S|Z = 0, C; \alpha^\dagger)$ and $OR(Z, S, C; \rho)$ for $f(Z|S = 0, C)$, $f(S|Z = 0, C)$ and $OR(Z, S, C)$ respectively. We note that $\nu^\dagger$, $\theta^\dagger_0$, $\tau^\dagger_1$ and $\alpha^\dagger$ and $\rho^\dagger$ are all finite dimensional parameters.

If we first assume the NEM restriction holds, then consider the following sets of restrictions on the observed data distribution:

- $M_1$: $t(Z, C) = t(Z, C; \nu^\dagger)$, $b_0(C) = b_0(C; \theta^\dagger_0)$ and $b_1(C) = b_1(C; \theta^\dagger_1)$. 

15
We propose the following strategy:

- \( M_2: f(Z|S = 0, C) = f(Z|S = 0, C; \tau^\dagger), \) \( OR(Z, S; C) = OR(Z, S, C; \rho^\dagger) \)
  and \( t(Z, C) = t(Z, C; \nu^\dagger) \).

- \( M_3: f(S|Z = 0, C) = f(S|Z = 0, C; \alpha^\dagger), \) \( OR(Z, S, C) = OR(Z, S, C; \rho^\dagger) \), and
  \( b_1(C) = b_1(C; \theta_1^\dagger) \).

- \( M_4: f(Z|S = 0, C) = f(Z|S = 0, C; \tau^\dagger), \) \( f(S|Z = 0, C) = f(S|Z = 0, C; \alpha^\dagger) \) and
  \( OR(Z, S, C) = OR(Z, S, C; \rho^\dagger) \).

Our goal is to construct an estimator that is quadruply robust, that is, unbiased if one of
these four restrictions on the observed data (in addition to model \( M_{NEM} \)) holds. In order
to achieve this, care needs to be taken regarding the estimation of nuisance parameters.

We propose the following strategy:

1. Estimate \( \tau^\dagger \) and \( \alpha^\dagger \) as \( \hat{\tau} \) and \( \hat{\alpha} \) using maximum likelihood or \( m \)-estimation.

2. Estimate \( \rho^\dagger \) as \( \hat{\rho} \) by solving the equations

\[
0 = \sum_{i=1}^{n} \left[ e_1(Z_i, C_i) - \frac{E\{e_1(Z_i, C_i)f(S_i = 1|Z_i, C_i; \hat{\alpha}, \rho^\dagger)f(S_i = 0|Z_i, C_i; \hat{\alpha}, \rho^\dagger)|C_i; \hat{\alpha}, \hat{\tau}, \rho^\dagger\}}{E\{f(S_i = 1|Z_i, C_i; \hat{\alpha}, \rho^\dagger)f(S_i = 0|Z_i, C_i; \hat{\alpha}, \rho^\dagger)|C_i; \hat{\alpha}, \hat{\tau}, \rho^\dagger}\}} \right] \times \{S_i - f(S_i = 1|Z_i, C_i; \hat{\alpha}, \rho^\dagger)\}
\]

for \( \rho^\dagger \) (Tchetgen et al., 2010), where \( e_1(C) \) is an arbitrary function of the
same dimension of \( \rho^\dagger \).

3. Estimate \( \nu^\dagger \) and \( \theta_0^\dagger \) as \( \hat{\nu} \) and \( \hat{\theta}_0 \) by solving the equations

\[
0 = \sum_{i=1}^{n} (1 - S_i) \left( \frac{e_2(Z_i, C_i)}{e_3(C_i)} \right) \epsilon_i^*(\psi^\dagger, \nu^\dagger, \theta^\dagger)
\]

for \( \nu^\dagger \) and \( \theta_0^\dagger \), where \( e_2(Z, C) \) and \( e_3(C) \) are of the same dimension as \( \nu^\dagger \) and \( \theta_0^\dagger \)
respectively. Re-estimate \( \nu^\dagger \) as \( \hat{\nu} \) by solving the equations

\[
0 = \sum_{i=1}^{n} (1 - S_i)[e_2(Z_i, C_i) - E\{e_2(Z_i, C_i)|S_i = 0, C_i; \hat{\tau}\}]\epsilon_i^*(\psi^\dagger, \nu^\dagger, \hat{\theta}_0, \theta_0^\dagger)
\]

for \( \nu^\dagger \) (Robins et al., 1992).
4. Estimate $\theta_1^\dagger$ and $\psi^\dagger$ as $\hat{\theta}_1$ and $\tilde{\psi}$ respectively, by solving the equations

$$0 = \sum_{i=1}^n \left( e_4(C_i) \{ S_i - E\{S_i|Z_i, C_i; \hat{\alpha}, \hat{\rho}\} \right) e_5(Z_i, C_i) S_i \epsilon_i^*(\psi, \hat{\nu}, \hat{\theta})$$

for $\theta_1^\dagger$ and $\psi^\dagger$, where $e_4(C_i)$ and $e_5(Z_i, C_i)$ are of the same dimension as $\theta_1^\dagger$ and $\psi^\dagger$ respectively.

5. Re-estimate $\psi^\dagger$ as $\hat{\psi}_{MR-NEM}$ by solving the equations

$$0 = \sum_{i=1}^n \phi(Z_i, S_i; \hat{\tau}, \hat{\alpha}, \hat{\rho}) e^*(\psi, \hat{\nu}, \hat{\theta})$$

for $\psi^\dagger$.

What is crucial here is that $\hat{\rho}$, $\hat{\nu}$, $\hat{\theta}_1$ are themselves doubly robust estimators (see the proof of the following theorem for details); we can obtain an unbiased estimator of $t(Z, C)$ even when $b_1(C; \theta_1^\dagger)$ is misspecified (and vice versa). Likewise, we can obtain an unbiased estimate of $f(Z|S, C)$ even when $f(S|Z, C)$ is poorly modelled.

**Theorem 3.2.** Under the union model $\mathcal{M}_{NEM} \cap (\mathcal{M}_1 \cup \mathcal{M}_2 \cup \mathcal{M}_3 \cup \mathcal{M}_4)$ and assuming standard regularity conditions hold, $\hat{\psi}_{MR-NEM}$ is a consistent and asymptotically normal (CAN) estimator of $\psi^\dagger$.

A nonparametric estimator of the standard error for $\hat{\psi}_{MR-NEM}$ can be obtained either using a sandwich estimator or the nonparametric bootstrap. Quadruple rather than triple robustness here hinges on the chosen parametrisation of $f(Z, S|C)$. If one were instead to use the factorisation e.g. $f(Z, S|C) = f(Z|S, C)f(S|C)$ and posit separate models for $f(Z|S, C)$ and $f(S|C)$, then the resulting estimator would be triply robust, as it would not generally be unbiased under correct models for $f(S|C)$, $b_0(C)$ and $b_1(C)$ alone. Additional benefits in terms of robustness (and precision) may be obtained when one has additional knowledge on $f(Z, S|C)$ e.g. in Mendelian Randomisation studies where it is sometimes plausible that the joint density factorises as $f(Z)f(S|C)$.

Under NSM, we will utilise an additional parametric model $q(A, C; \omega^\dagger)$ for the selection bias function $q(A, C)$, where $q(A, C; \omega^\dagger)$ is a known function smooth in a finite dimensional parameter $\omega^\dagger$. A smooth model $f(A|Z, S = 1, C; \tau^\dagger)f(Z|C, S = 1, C; \tau^\dagger, \rho^\dagger)$ is postulated for $f(A, Z|S = 1, C)$; the event that model $f(A|Z, S; \pi^\dagger)$ is correctly specified is denoted by $\mathcal{M}_a$. We will also consider alternative versions of the previous restrictions $\mathcal{M}_{1q}$ and $\mathcal{M}_{3q}$ on the data:
• $\mathcal{M}_{1q}$: $t(Z, C) = t(Z, C; \nu \dagger)$, $b_0(C) = b_0(C; \theta_0)$, $b_1(C) = b_1(C; \theta_1)$ and $q(A, C) = q(A, C; \omega \dagger)$.

• $\mathcal{M}_{3q}$: $f(S|Z = 0, C) = f(S|Z = 0, C; \alpha \dagger)$, $OR(Z, S, C) = OR(Z, S, C; \rho \dagger)$, $b_1(C) = b_1(C; \theta_1)$, and $q(A, C) = q(A, C; \omega \dagger)$.

In order to estimate nuisance parameters under NSM, one can straightforwardly update the previous strategy. For example, $\pi \dagger$ can be estimated as $\hat{\pi}$ via maximum likelihood; one can also obtain an estimator $\hat{\omega}$ by solving the equations

$$0 = \sum_{i=1}^{n} e_i(A_i, C_i) \epsilon_i(\psi \dagger, \nu \dagger, \theta \dagger, \omega \dagger, \hat{\pi})$$

for $\omega \dagger$. Finally, $\hat{\psi}_{MR-NSM}$ is obtained by solving the equations

$$0 = \sum_{i=1}^{n} \left( \phi(Z_i, S_i, C_i; \tau, \alpha, \rho) \epsilon_i(\psi \dagger, \nu, \theta, \hat{\pi}) \right)$$

for $\psi \dagger$.

**Theorem 3.3.** Under the union $\mathcal{M}_{NSM} \cap \mathcal{M}_a \cap (\mathcal{M}_{1q} \cup \mathcal{M}_2 \cup \mathcal{M}_{3q} \cup \mathcal{M}_4)$ and standard regularity conditions, $\hat{\psi}_{MR-NSM}$ is a CAN estimator of $\psi \dagger$.

Hence, we can obtain a similar quadruple robustness result under the NSM assumption, although we now require a correctly specified propensity score model. Note that a similar parametrisation of the joint density $f(A, Z|S = 1, C)$ based on the generalised odds ratio function could be used here. Nevertheless, since one needs to model $f(A|Z, S = 1, C)$ correctly in order to obtain an unbiased estimator, adopting such a parametrisation will not generally lead to greater robustness. Finally, since estimation under NSM requires consistent estimation of the propensity score, one approach would be to use flexible non-parametric/machine learning methods of $f(A|Z, S = 1, C)$ combined with cross-fitting (see the general algorithm described in the Appendix), even if one were to then use parametric models for the other nuisance parameters.

**Remark.** In the bespoke IV-DiD design, note that estimators of $\psi \dagger$ based on the estimating functions given in Corollary 3.1.1 are doubly robust. Specifically, an estimator based on equation (1) is unbiased if either i) $f(Z|C)$ or ii) $b_1(C)$ and $b_0(C)$ (or their difference) are consistently estimated. Similarly, an estimator based on equation (2) is unbiased if, in addition to $f(A|Z, C)$, either i) $f(Z|C)$ or ii) $q(A, C)$, $t(Z, C)$ $b_1(C)$ and $b_0(C)$ are consistently modelled. Hence, estimators in the bespoke IV-DiD model are expected to be additionally robust and efficient relative to estimators in the general bespoke IV setting.
3.3 Local semiparametric efficiency

Once we have obtained the class of regular and asymptotically linear estimators of \( \psi^\dagger \) under a semiparametric model, it remains to identify the optimal estimator within a given class. Under NEM, we are able to compute a closed form representation of the efficient score. Before doing this, we will define some additional notation. Let

\[
\mu(Z, S, C) = \mathbb{E} \left\{ \frac{\partial \beta(A, Z, C; \psi^\dagger)}{\partial \psi} \bigg| Z, S, C \right\}
\]

and

\[
\tilde{S} = S - \frac{E\{S\sigma^{-2}(Z, S, C)|Z, C\}}{E\{\sigma^{-2}(Z, S, C)|Z, C\}}
\]

where \( \sigma^2(Z, S, C) = E(\epsilon^2(\psi^\dagger)|Z, S, C) \).

**Theorem 3.4.** Under the semiparametric model \( \mathcal{M}_{NEM} \), the efficient score for \( \psi^\dagger \) is equal to

\[
\begin{align*}
\mu(Z, S, C) & - \frac{E\{\mu(Z, S, C)\sigma^{-2}(Z, S, C)|Z, C\}}{E\{\sigma^{-2}(Z, S, C)|Z, C\}} \times \sigma^{-2}(Z, S, C)e^*(\psi^\dagger) \\
\times & \frac{E\{\mu(Z, S, C)\sigma^{-2}(Z, S, C)\tilde{S}|C\}}{E\{\sigma^{-2}(Z, S, C)\tilde{S}^2|Z, C\}} \tilde{S}
\end{align*}
\]

Furthermore, the efficient score is an unbiased estimating function in the union model \( \mathcal{M}_{NEM} \cap (\mathcal{M}_1 \cup \mathcal{M}_2 \cup \mathcal{M}_3 \cup \mathcal{M}_4) \) that is locally efficient at the intersection submodel.

Similar to the standard IV set-up, efficient estimation generally requires modelling the conditional mean of \( A \) given \( Z, S \) and \( C \). However, even if this model is misspecified, the resulting estimating of \( \psi^\dagger \) will remain unbiased (although it will no longer generally be efficient). In order to further simplify the above result, we revisit Example 1.

**Corollary 3.4.1.** If \( Z \) is binary, then the optimal choice \( m_{opt}(C) \) of \( m(C) \) in the estimating function (10) is

\[
m_{opt}(C) = E \left\{ \{(-1)^Z + S\}^2 \sigma^2(Z, S, C) \bigg| C \right\}^{-1} \{\mu(Z = 1, S = 1, C) - \mu(Z = 0, S = 1, C)\}.
\]

If \( \sigma^2(Z, S, C) = \sigma^2 \), then \( m_{opt}(C) \) reduces to \( w_0(C)^{-1} \sigma^{-2}\{\mu(Z = 1, S = 1, C) - \mu(Z = 0, S = 1, C)\} \), where

\[
w_0(C) = \left\{ \frac{1}{f(Z = 1, S = 1|C)} + \frac{1}{f(Z = 1, S = 0|C)} + \frac{1}{f(Z = 0, S = 1|C)} + \frac{1}{f(Z = 0, S = 0|C)} \right\}
\]

19
Note that the weight function $w_0(C)^{-1}$ will automatically give high weight given in the estimating equations to strata of the data where there is most overlap in terms of the distribution $f(Z, S|C)$. In studies where the inverse weights $1/f(Z, S|C)$ are extreme, we might expect an efficient estimator to thus perform considerably better than other multiply robust estimators both in terms of precision as well as stability and finite sample bias.

Under NSM, there exists no closed-form expression for the efficient score for arbitrary $A$ and $Z$. Below, we obtain a result for binary exposure and instrument.

**Theorem 3.5.** Suppose that $A$ and $Z$ are binary, and let

$$
Q_1 = \frac{S(-1)^{A+Z}}{f(A, Z|S = 1, C)} \epsilon(\psi^\dagger)
$$

$$
Q_2 = \frac{(-1)^{Z+S}}{f(Z, S|C)} \epsilon^*(\psi^\dagger)
$$

$$
Q_3 = Q_2 - \frac{E(Q_1Q_2|C)}{E(Q_1^2|C)} Q_1
$$

where $U_{\psi^\dagger}$ is the score for $\psi^\dagger$. Then under the model $M_{NSM}$,

$$
m_{opt}(C) = \frac{E(U_{\psi^\dagger}Q_3|C)}{E(Q_3^2|C)}
$$

$$
h_{opt}(C) = \frac{E(U_{\psi^\dagger}Q_1|C)}{E(Q_1^2|C)} - \frac{E(U_{\psi^\dagger}Q_3|C)}{E(Q_3^2|C)} \frac{E(Q_1Q_2|C)}{E(Q_1^2|C)}
$$

Furthermore, if $\sigma^2(Z, S, C) = \sigma^2$ and $E(\epsilon^2|A, Z, S, C) = \bar{\sigma}^2$, then

$$
m_{opt}(C) = w_0(C)^{-1}\sigma^2\{\mu(Z = 1, S = 1, C) - \mu(Z = 0, S = 1, C)\}
$$

$$
h_{opt}(C) = w_1(C)^{-1}\bar{\sigma}^2 E \left\{ \frac{(-1)^{A+Z}}{f(A, Z|S = 1, C)} \frac{\partial \beta(A, Z, C; \psi^\dagger)}{\partial \psi} \bigg|_{\psi = \psi^\dagger} | S = 1, C \right\}
$$

where

$$
w_1(C) = \left\{ \begin{array}{c}
\frac{1}{f(A = 1, Z = 1|S = 1, C)} + \frac{1}{f(A = 0, Z = 1|S = 1, C)} \\
\frac{1}{f(A = 1, Z = 0|S = 1, C)} + \frac{1}{f(A = 0, Z = 0|S = 1, C)}
\end{array} \right\}
$$
Estimators in a model defined by restriction (6) require a consistently estimated propensity score model, as opposed to working under the restriction (5). Along the lines of Tchetgen Tchetgen and Vansteelandt (2013), if one is willing to entertain that a parametric model for the propensity is correctly specified, then this can be exploited in order to make additional efficiency gains. Below, we will derive the efficient score in the submodel for the propensity is correctly specified, then this can be exploited in order to make additional efficiency gains. Below, we will derive the efficient score in the submodel $M_{NSM} \cap M_a \cap (M_{1q} \cup M_2 \cup M_{3q} \cup M_4)$ under the assumption that a parametric model $f(A|Z, S = 1, C; \pi^\dagger)$ for $f(A|Z, S = 1, C)$ is correctly specified and one of the three sets of restrictions in the second part of Theorem (3.2) holds.

**Theorem 3.6.** The set of influence functions of $\psi^\dagger, \pi^\dagger$ in the semiparametric model $M_{NSM} \cap M_a$ consists of elements proportional to

$$S \{ \kappa(A, Z, C) + \phi(Z, S, C) \} \epsilon_1(\psi^\dagger) + S \phi(Z, S, C) [g(A, C) - E\{g(A, C)|Z, S = 1\}]$$

$$+ S[g(A, Z, C) - E\{g(A, Z, C)|Z, S = 1, C\}] :$$

$$\kappa(A, Z, C) \in \Gamma, \phi(Z, S, C) \in \Omega, g(A, Z) \text{ unrestricted} \} \cap L^0_2$$

If $A$ is binary, then functions $S[g(A, Z, C) - E\{g(A, Z, C)|Z, S = 1, C\}]$ can be equivalently expressed as $Sg(Z, C)\{A - E(A|Z, S = 1, C)\}$. Further, if $A$ and $Z$ are binary and we redefine $Q_1$ as

$$Q_1 = \frac{S(-1)^{A+Z}}{f(A, Z|S = 1, C; \pi^\dagger)} \epsilon_1(\psi^\dagger)$$

and define $Q_1 = (Q_1, Q_2)^T$, then the efficient choices $h_{opt}(C), m_{opt}(C), g_{opt}(Z, C)$ of $h(C), m(C), g(Z, C)$ are given by

$$(h_{opt}(C), m_{opt}(C))^T = E(U_{\psi^\dagger, \pi^\dagger} Q_4|C) E^{-1}(Q_4 Q_4^T|C) Q_4$$

$$g_{opt}(Z, C) = \frac{E[U_{\psi^\dagger, \pi^\dagger} \{A - f(A = 1|Z, S = 1, C; \pi^\dagger)\}|Z, S = 1, C]}{E[\{A - f(A = 1|Z, S = 1, C; \pi^\dagger)\}^2|Z, S = 1, C]}$$

where $U_{\psi^\dagger, \pi^\dagger} = (U_{\psi^\dagger}^T, U_{\pi^\dagger}^T)^T$ is the score for $(\psi^\dagger, \pi^\dagger)$. Therefore efficient estimators can be constructed by inputting $h_{opt}(C), m_{opt}(C)$ and $g_{opt}(Z, C)$ in the scores given above.

### 3.4 Nonparametric inference for the marginal ATT

It may that interest is in the marginal rather than the conditional ATT. Suppose that $A$ and $Z$ are binary; then in the case that $\beta(Z) = \beta$, previous methods can be used due to the
collapsibility of the linear link function, but one may not wish to invoke this restriction. It follows from the identification results in Section 2 that under the NEM Assumption 5,

$$\psi^* = E(Y^1 - Y^0|A = 1, S = 1) = E\{E(Y^1 - Y^0|A = 1, Z = z, S = 1)|A = 1, S = 1\}$$

is identified as

$$\psi^* = \int \beta(c)dF(c|A = 1, S = 1)$$

where

$$\beta(C) = \frac{\delta^Y(C) - t(1, C)}{\delta^A(C)}$$

$$\delta^Y(C) = E(Y|Z = 1, S = 1, C) - E(Y|Z = 0, S = 1, C)$$

$$\delta^A(C) = f(A = 1|Z = 1, S = 1, C) - f(A = 1|Z = 0, S = 1, C)$$

and alternatively, under the NSM Assumption 6 we have

$$\psi^* = E(Y|A = 1, S = 1) - \int E(Y|A = 0, z, S = 1, C)dF(z, c|A = 1, S = 1)$$

$$- \int \gamma(c)dF(c|A = 1, S = 1)$$

where

$$\gamma(C) = -\frac{\delta^Y_0(C) - t(1, C)}{\delta^A(C)}$$

$$\delta^Y_0(C) = E(Y|A = 0, Z = 1, S = 1, C) - E(Y|A = 0, Z = 0, S = 1, C)$$

In either case, we have a closed form representation of $\psi^*$ as a functional of the observed data distribution. Since $\psi^*$ is a pathwise differentiable parameter, we can then obtain nonparametric inference on $\psi$, by obtaining the efficient influence function under a nonparametric model. The following results may be of independent interest with respect to the literature of nonparametric inference in the IV model (Wang and Tchetgen Tchetgen, 2018).

22
Theorem 3.7. (Part a) In the nonparametric model defined by Assumptions 1-5, the efficient influence function is equal to:

$$EIF_1 (\psi^*) = \frac{f(A = 1, S = 1|C)(-1)^{Z+S}}{f(A = 1, S = 1)\delta^A(C)f(Z, S|C)} \times \{Y - \beta(C)\{A - f(A = 1|Z = 0, S = 1, C)\}S - t(1, C)Z - E(Y|Z = 0, S, C)\}$$

$$+ \frac{1}{f(A = 1, S = 1)}AS\{\beta(C) - \psi^*\}$$

(Part b) In the nonparametric model defined by Assumptions 1-4 and 6, the efficient influence function is given by:

$$EIF_2 (\psi^*) = \frac{f(A = 1, S = 1|C)(2Z - 1)}{f(A = 1, S = 1)\delta^A(C)f(Z, S|C)} \times \left[\frac{(1 - A)S}{f(A = 0|Z, S = 1, C)}\{Y + \gamma(C)\delta^A(C)Z - t(1, C)Z - E(Y|A = 0, Z = 0, S = 1, C)\}\right]$$

$$- S\{A - f(A = 1|Z, S = 1, C)\}\gamma(C) - (1 - S)\{Y - t(1, C)Z - E(Y|Z = 0, S = 0, C)\}\right]$$

$$- \frac{(1 - A)Sf(A = 1|Z, S = 1, C)}{f(A = 1, S = 1)f(A = 0|Z, S = 1, C)}\{Y + \gamma(C)\delta^A(C)Z - t(1, C)Z - E(Y|A = 0, Z = 0, S = 1, C)\}$$

$$+ \frac{AS}{f(A = 1, S = 1)}\{Y + \gamma(C)\delta^A(C)Z - t(1, C)Z - E(Y|A = 0, Z = 0, S = 1, C) - \gamma(C) - \psi^*\}$$

4 Simulations

We conducted a series of simulation studies to first evaluate the robustness properties of the proposed estimators from Section 3.2. Specifically, we generated covariates $C_1$ and $C_2$ from a Bernoulli distribution with expectation 0.5 and a uniform distribution on an open $(-1, 1)$ interval respectively; let $C = (C_1, C_2)$. An unmeasured confounder $U$ was also a random binary variable. Then the sample selection probability was $f(S = 1|C) = \expit(-0.5 + C_1 + 0.6C_2 + 0.5C_1C_2)$, and the bespoke instrument $Z$ was generated from a Bernoulli distribution where $f(Z = 1|C) = \expit(0.25C_1 - 0.25C_2 + 0.5C_1C_2)$. Generating $S$ in this manner led to around 60% of individuals in a simulated data set being members of the target population ($S=1$). The exposure was simulated from a Bernoulli distribution
with \( f(A = 1|Z, S = 1, C, U) = \text{expit}(1 - 1.5Z - 0.75C_1 - 0.3C_2 - 0.5C_1C_2 + U) \) for individuals in the population \( S = 1 \) and was fixed at zero for all others. Finally, we generated the outcome from the distribution

\[
\mathcal{N}(1 + A + U + 0.5C_1 + 0.5C_2 - 0.5C_1C_2 + Z(1 - 0.4C_1 - 0.4C_2 + 0.5C_1C_2) + S(0.5C_1 + 0.5C_2 + 0.5C_1C_2), 1).
\]

This data generating mechanism is compatible with the identification Assumptions \[1\]-\[5\] but not with conditional exchangeability if one does not have access to \( U \). Nor would it be compatible with the IV conditions, since \( Z \) has a direct effect on \( Y \). Note that \( Z \) is the only valid bespoke IV out of the three generated covariates, since the effects of the others in \( C \) on the outcome depend on \( S \), which violates Assumption \[3\].

In our simulations, we considered a suite of estimators of the ATT in the target population. Specifically, we looked at

- \( \hat{\psi}_{\text{TSLS}} \): a two-stage least squares estimator described in \cite{Richardson2021} that is unbiased under the model \( \mathcal{M}_{\text{NEM}} \cap \mathcal{M}_1 \).

- \( \hat{\psi}_{g-Z} \): a \( g \)-estimator described in \cite{Richardson2021} that is unbiased under the model \( \mathcal{M}_{\text{NEM}} \cap \mathcal{M}_2 \).

- \( \hat{\psi}_{g-S} \): an alternative \( g \)-estimator that is unbiased under the model \( \mathcal{M}_{\text{NEM}} \cap \mathcal{M}_3 \).

- \( \hat{\psi}_{\text{IPW}} \): an inverse probability weighted estimator that is unbiased under the model \( \mathcal{M}_{\text{NEM}} \cap \mathcal{M}_4 \).

- \( \hat{\psi}_{\text{MR}} \): the multiply-robust estimator described in Section \[3.2\] with \( h(C) = m(C) = 1 \), which is unbiased under the model \( \mathcal{M}_{\text{NEM}} \cap (\mathcal{M}_1 \cup \mathcal{M}_2 \cup \mathcal{M}_3 \cup \mathcal{M}_4) \).

- \( \hat{\psi}_{\text{MR-eff}} \): the multiply-robust estimator with \( h(C) \) and \( m(C) \) set to the optimal choices described in Section \[3.3\] which is unbiased under the model \( \mathcal{M}_{\text{NEM}} \cap (\mathcal{M}_1 \cup \mathcal{M}_2 \cup \mathcal{M}_3 \cup \mathcal{M}_4) \).

Details of the first four estimators are given in the Appendix. Nuisance parameters were estimated using maximum likelihood, and a sandwich estimator was obtained for each of the estimators given above. For comparison, we also considered a doubly robust \( g \)-estimator that is valid under a conditional exchangeability assumption \cite{Robins1992}, where a linear model was fitted for the outcome, and a logistic model for the exposure; both models were adjusted for \( Z, C_1, C_2 \) and a \( C_1C_2 \) interaction term.

We considered five settings:
1. All nuisance models are correctly specified: the intersection model $\mathcal{M}_{NEM} \cap \mathcal{M}_1 \cap \mathcal{M}_2 \cap \mathcal{M}_3 \cap \mathcal{M}_4$ holds.

2. $f(Z|S = 0, C; \tau^\dagger)$ and $f(S|Z = 0, C; \alpha^\dagger)$ were misspecified: $\mathcal{M}_{NEM} \cap \mathcal{M}_1$ holds.

3. $f(S|Z = 0, C; \alpha^\dagger)$, $b_0(C; \theta_0^\dagger)$ and $b_1(C; \theta_1^\dagger)$, were misspecified: $\mathcal{M}_{NEM} \cap \mathcal{M}_2$ holds.

4. $f(Z|S = 0, C; \tau^\dagger)$, $b_0(C; \theta_0^\dagger)$ and $t(Z, C; \nu^\dagger)$, were misspecified: $\mathcal{M}_{NEM} \cap \mathcal{M}_3$ holds.

5. $t(Z, C; \nu^\dagger)$, $b_0(C; \theta_0^\dagger)$ and $t(Z, C; \nu^\dagger)$, were misspecified: $\mathcal{M}_{NEM} \cap \mathcal{M}_4$ holds.

Misspecification was induced via omission of interaction terms. For each setting, we simulated 2,000 data sets, with a sample size of 5,000.

The results of the experiments can be seen in Table 1. As a comparison, the benchmark doubly robust $g$-estimator has a bias in all experiments of 0.24, with coverage probability <0.01. We see that the bias and coverage properties of the estimators reflect the theory; the multiply robust estimators are the only estimators that maintain good coverage properties across all experiments. The $g$-estimator $\hat{\psi}_{g-Z}$ exhibited wide confidence intervals across settings and sometimes large bias when the models were misspecified; improvements could potentially be made via modelling $b_0(C)$ and making the estimator doubly robust e.g. unbiased under model $\mathcal{M}_{NEM} \cap (\mathcal{M}_1 \cup \mathcal{M}_2)$, as described in Richardson and Tchetgen Tchetgen (2021). The efficient multiply robust estimator outperformed the two-stage least squares estimator both in terms of bias in the presence of misspecification, but also precision when models were correct. The latter aspect is perhaps not totally surprising, given that two-stage least squares estimators are not necessarily efficient even when the conditional outcome mean is correctly specified (Vansteelandt and Didelez, 2018).

5 Discussion

In this article we have proposed strategies for identifying causal effects in studies prone to unmeasured confounding by leveraging bespoke instruments. These strategies are applicable to point-treatment studies where there is access to a reference population as well as longitudinal studies with repeated measurements of the outcome. The proposed estimators are unbiased so long as one out of four restrictions on the observed data hold, and hence have two additional layers of robustness than the doubly robust estimators described in Richardson and Tchetgen Tchetgen (2021). Potential areas for future work include extending the proposal for static regimes in longitudinal data to handle dynamic treatment
Table 1: Empirical bias (Bias), empirical standard error (SE), mean estimated standard errors (ESE) and coverage probability (Cov)

</table>
regimes. One could also develop the proposal for binary, count and survival outcomes, by postulating a multiplicative model for the causal effect and (in the binary case) harnessing the nuisance model parametrisation of Richardson et al. (2017). However, results in Vansteelandt et al. (2008) suggest that only triple rather than quadruple robustness may be attainable in the multiplicative model.

In this identification strategy, one must restrict either the conditional ATT or the selection bias not to depend on the bespoke IV. Which restriction one chooses will depend to some extent on a priori information on the bespoke IV(s) of choice, but will also be a matter of taste. Restrictions on the treatment effect are perhaps less appealing than in the standard IV set-up, where the IV-outcome relationship is already constrained via the exclusion restriction. On the other hand, under NEM, the semiparametric model $M_{NEM}$ is at least guaranteed to be correctly specified under the null hypothesis.

Finally, one may wish to supplement our proposals with a sensitivity analysis. Attention may be given in particular to the crucial assumption of partial population exchangeability; one could then proceed by parametrising deviations from this condition. With multiple plausible bespoke IVs, the ATT may become over identified, and specification tests (like the Sargen-Hansen test) can then be employed to assess the validity of the identifying assumptions described here. How to optimally combine or synthesise evidence from multiple bespoke IVs is an important area for future work.

References

A Additional information

A.1 Assumptions for general bespoke IV model

Assumption 10. Degenerate reference population:

$$E(Y|Z, S = 0, C) = E(Y^0|Z, S = 0, C)$$

Assumption 11. Partial population exchangeability:

$$E(Y^0|Z = z, S = 1, C) - E(Y^0|Z = 0, S = 1, C)$$

$$= E(Y^0|Z = z, S = 0, C) - E(Y^0|Z = 0, S = 0, C) \neq 0$$

A.2 Algorithm for constructing cross-fit de-biased machine learning estimators

In what follows, let $O = (Y, A, Z, S, C)$ and $\eta(O)$ refer to the nuisance parameters (at the truth).

1. Split the sample into parts $I_k$ (that are each are of size $n_k = n/K$). Here, $K$ is an integer (we shall assume $n$ is a multiple of $K$). For each $I_k$, $I^C_k$ denotes the indices that are not in $I_k$.

2. For each $k = 1, ..., k$, using $I^C_k$ only, estimate $\eta$ as $\hat{\eta}_k = \hat{\eta}((O_i)_{i \in I^C_k})$.

3. Construct $K$ estimators $\hat{\psi}_k, k = 1, ..., k$ of $\psi^\dagger$: under NEM, solve the equations

$$0 = \sum_{i \in I_k} \phi(Z_i, S_i, C_i; \hat{\eta}_k) \epsilon_i^*(\psi^\dagger, \hat{\eta}_k)$$

for $\psi^\dagger$, for each $k = 1, ..., k$. Under NSM, solve the equations

$$0 = \left( \frac{\sum_{i \in I_k} \phi(Z_i, S_i; \hat{\eta}_k) \epsilon_i^*(\psi^\dagger, \hat{\eta}_k)}{\sum_{i \in I_k} S_i \kappa(A_i, Z_i, C_i; \hat{\eta}_k) \epsilon_i(\psi^\dagger, \hat{\eta}_k)} \right)$$

for $\psi^\dagger$, for each $k = 1, ..., K$. 

31
4. Take the average of the $K$ estimators of $\psi^\dagger$ to obtain $\hat{\psi}_{CF}$.

5. Estimate the standard error for the cross-fit estimator of $\hat{\psi}_{CF}$ using a sandwich estimator, ignoring the data-splitting; e.g. under NEM, estimate the standard error as $
abla \sqrt{\frac{1}{n} \sum_{i=1}^{n} \left\{ \phi(Z_i, S_i, C_i; \hat{\eta}^c_i) \epsilon_i^*(\hat{\psi}_{CF}; \hat{\eta}^c_i) \right\}^2}$

where $k(i) = \{k = 1, \ldots, K : i \in I_k\}$.

This follows the ‘DML1’ proposal described in Chernozhukov et al. (2018), along with the proposal for estimating standard errors described in Chernozhukov et al. (2017). Justification can be found in those papers.

As in other semiparametric regression problems, a complication is how to perform machine-learning based estimation of the nuisance parameters, given that they are not all conditional mean functions that can be estimated directly; see Section 4.2 of Chernozhukov et al. (2018) for further discussion. One option is to restrict to estimation methods that can more easily respect the structure of the semiparametric model (generalised additive models, Lasso, deep neural networks etc); the other is to adopt the ‘localised de-biased machine learning’ procedure described in Kallus et al. (2019), where e.g. an initial (biased) estimator of $\psi^\dagger$ could be used to construct estimators of other nuisance parameters.

B Proofs

B.1 Proof of Theorem 3.1

B.1.1 Proof of part (a)

Proof. We introduce some additional notation:

$\epsilon_1 = Y - \beta(A, Z, C) - [q(A, Z, C) - E\{q(A, Z, C)|Z, S = 1, C\}] - b_1^*(C) - t(Z, C)$

$\epsilon_1^* = \epsilon_1 + [q(A, Z, C) - E\{q(A, Z, C)|Z, S = 1, C\}]$

$\epsilon_0 = Y - b_0(C) - t(Z, C)$

where $b_1^*(C) = b_1(C) + b_0(C)$. Note that in order to obtain identification, we enforce that $\beta(A, Z, C) = \beta(A, C)$. 

32
The likelihood for a given observation can be written as

\[ f(O) = f(\epsilon_0 | Z, S = 0, C)^{(1-S)} \{ f(\epsilon_1 | A, Z, S = 1, C) f(A | Z, S = 1, C) \}^S \ f(Z, S | C) f(C) \]

Then we will consider the parametric submodel:

\[ f_r(O) = f_r(\epsilon_0 | Z, S = 0, C)^{(1-S)} \{ f_r(\epsilon_1 | A, Z, S = 1, C) f_r(A | Z, S = 1) \}^S \ f_r(Z, S | C) f_r(S, C) \]

which varies in the direction of \( q_r(A, Z), b_{0r}(C), b_{1r}(C), t_r(Z), f_r(A | Z, S = 1, C), f_r(Z, S | C) \) and \( f_r(C) \). Here,

\[
\begin{align*}
\epsilon_1 &= Y - \beta(A, Z, C) - [q_r(A, Z, C) - E_r\{q_r(A, Z, C) | Z, S = 1, C\}] - b_{1r}^*(C) - t_r(Z, C) \\
\epsilon_0 &= Y - b_{0r}(C) - t_r(Z, C)
\end{align*}
\]

The nuisance tangent space \( \lambda_{nuis} \) under \( \mathcal{M}_{NEM} \) can be characterised as

\[ \lambda_{nuis} = \lambda_{nuis_1} \oplus \lambda_{nuis_2} \oplus \lambda_{nuis_3} \oplus \lambda_{nuis_4} \oplus \lambda_{nuis_5} \oplus \lambda_{nuis_6} \oplus \lambda_{nuis_7} \oplus \lambda_{nuis_8} \oplus \lambda_{nuis_9} \]
where

\[ \Lambda_{nui1} = \left\{ Sd_1(\epsilon_1, A, Z, C) : \right. \\
E\{d_1(\epsilon_1, A, Z, C)|A, Z, S = 1, C\} = E\{\epsilon_1d_1(\epsilon_1, A, Z, C)|A, Z, S = 1, C\} = 0 \left\} \cap L_2^0 \]

\[ \Lambda_{nui2} = \left\{ (1 - S)d_2(\epsilon_0, Z, C) : E\{d_2(\epsilon_0, Z, C)|Z, S = 0, C\} = E\{\epsilon_0d_2(\epsilon_1, Z)|Z, S = 0, C\} = 0 \right\} \cap L_2^0 \]

\[ \Lambda_{nui3} = \left\{ d_3(Z, S, C) : E\{d_3(Z, S, C)|C\} = 0 \right\} \cap L_2^0 \]

\[ \Lambda_{nui4} = \left\{ d_4(C) : E\{d_4(C)\} = 0 \right\} \cap L_2^0 \]

\[ \Lambda_{nui5} = \left\{ S[d_5(A, Z, C) - E\{d_5(A, Z, C)|Z, S = 1, C\}]f_{\epsilon_1}' : d_5(A, Z, C) \right\} \cap L_2^0 \]

\[ \Lambda_{nui6} = \left\{ Sd_6(A, Z, C) + Sf_{\epsilon_1}' \int d_6(A^*, Z, C)q(A^*, Z, C)dF(A^*|Z, S = 1, C) : \\
E\{d_6(A, Z, C)|Z, S = 1, C\} = 0 \right\} \cap L_2^0 \]

\[ \Lambda_{nui7} = \left\{ Sd_7(C)f_{\epsilon_1}' : d_7(C) \right\} \cap L_2^0 \]

\[ \Lambda_{nui8} = \left\{ (1 - S)d_8(C)f_{\epsilon_0}' : d_8(C) \right\} \cap L_2^0 \]

\[ \Lambda_{nui9} = \left\{ Sd_9(Z, C)f_{\epsilon_1}' + (1 - S)d_9(Z, C)f_{\epsilon_0}' : d_9(C) \right\} \cap L_2^0 \]

where \( f_{\epsilon_1}' \) is the derivative of \( f(\epsilon_1|A, Z, S = 1, C) \) w.r.t. \( \epsilon_1 \) and likewise \( f_{\epsilon_0}' \) is the derivative of \( f(\epsilon_0|Z, S = 0, C) \) w.r.t. \( \epsilon_0 \).

Using standard results on the restricted mean model e.g. Tsiatis (2007), we have that

\[ \Lambda_{nui1}^\perp \cap \Lambda_{nui3}^\perp \cap \Lambda_{nui4}^\perp = \left\{ S\epsilon_1c_1(A, Z, C) + c_2(A, Z, S, C) : \\
c_1(A, Z, C) \ \text{unrestricted}, \ E\{c_2(A, Z, S, C)|Z, S, C\} = 0 \right\} \cap L_2^0 \]

Then to find elements in this space that are orthogonal to \( \Lambda_{nui5} \), we must find the elements
in \( \Lambda_{nuis_1} \cap \Lambda_{nuis_3} \cap \Lambda_{nuis_4} \) that satisfy:

\[
0 = E \left( \{ S_{\epsilon_1}c_1(A, Z, C) + c_2(A, Z, S, C) \} [d_5(A, Z, C) - E \{ d_5(A, Z, C)|Z, S = 1, C \}] \right) \\
= E (Sc_1(A, Z, C)[d_5(A, Z, C) - E \{ d_5(A, Z, C)|Z, S = 1, C \}])
\]

It follows that elements of \( Sc_1(A, Z, C) \) that will satisfy the equality are of the form \( S\phi_1(Z, C) \), where \( \phi_1(Z, C) \) are unrestricted. One can also show that the elements

\[
S\epsilon_1[\phi_1(Z, C) - E\{\phi_1(Z, C)|S = 1, C\} + c_2(A, Z, S, C)]
\]

are orthogonal to \( \lambda_{nuis_7} \).

Next, in considering \( \Lambda_{nuis_6} \), we need elements that satisfy:

\[
0 = E \left\{ S\epsilon_1[\phi_1(Z, C) - E\{\phi_1(Z, C)|S = 1, C\}] + c_2(A, Z, S, C) \right\} \\
\times [d_6(A, Z, C) - E\{Sd_6(A, Z, C)q(A, Z, C)|Z, S = 1, C\}] f'_{\epsilon_1}
\]

Then note that

\[
E \left\{ S\epsilon_1[\phi_1(Z, C) - E\{\phi_1(Z, C)|S = 1, C\}] d_6(A, Z, C) \right\} = 0
\]

\[
E \left\{ -c_2(A, Z, S, C)SE\{d_6(A, Z, C)q(A, Z, C)|Z, S = 1\} f'_{\epsilon_1} \right\} = 0
\]

We are left with the restriction that

\[
0 = E \left( Sc_2(A, Z, S, C)d_6(A, Z, C) \\
- S\epsilon_1[\phi_1(Z, C) - E\{\phi_1(Z, C)|S = 1, C\}] E\{Sd_6(A, Z, C)q(A, Z, C)|Z, S = 1, C\} f'_{\epsilon_1} \right)
\]

\[
= E \left( Sd_6(A, Z, C) \\
\times (c_2(A, Z, S, C) - [\phi_1(Z, C) - E\{\phi_1(Z, C)|S = 1, C\}][q(A, Z, C) - E\{q(A, Z, C)|Z, S = 1, C\}]) \right)
\]

and so

\[
c_2(A, Z, S, C) = S[\phi_1(Z, C) - E\{\phi_1(Z, C)|S = 1, C\}][q(A, Z, C) - E\{q(A, Z, C)|Z, S = 1, C\}]
\]

35
Hence, so far we have shown that

$$\Lambda_{nouis_1}^\perp \cap \Lambda_{nouis_3}^\perp \cap \Lambda_{nouis_4}^\perp \cap \Lambda_{nouis_5}^\perp \cap \Lambda_{nouis_6}^\perp \cap \Lambda_{nouis_7}^\perp$$

$$\{S\epsilon_1^*[\phi_1(Z, C) - E\{\phi_1(Z, C)|S = 1, C\}] : \phi_1(Z, C) \text{ unrestricted}\} \cap L_0^9$$

Considering elements in $\Lambda_{nouis_2}^\perp \cap \Lambda_{nouis_8}^\perp$, then using previous reasoning, we have that

$$\Lambda_{nouis_1}^\perp \cap \Lambda_{nouis_7}^\perp = \{(1 - S)\epsilon_0[\phi_2(Z, C) - E\{\phi_2(Z, C)|C, S = 0\}] : \phi_2(Z, C) \text{ unrestricted}\}$$

It is also straightforward to show that elements in the space $\Lambda_{nouis_2}^\perp \cap \Lambda_{nouis_8}^\perp$ are orthogonal to those in the space $\Lambda_{nouis_1}^\perp \cap \Lambda_{nouis_3}^\perp \cap \Lambda_{nouis_4}^\perp \cap \Lambda_{nouis_5}^\perp \cap \Lambda_{nouis_6}^\perp \cap \Lambda_{nouis_7}^\perp$, and therefore

$$\Lambda_{nouis_1}^\perp \cap \Lambda_{nouis_2}^\perp \cap \Lambda_{nouis_3}^\perp \cap \Lambda_{nouis_4}^\perp \cap \Lambda_{nouis_5}^\perp \cap \Lambda_{nouis_6}^\perp \cap \Lambda_{nouis_7}^\perp \cap \Lambda_{nouis_8}^\perp$$

$$\{S\epsilon_1^*[\phi_1(Z, C) - E\{\phi_1(Z, C)|S = 1, C\}]$$

$$+ (1 - S)\epsilon_0[\phi_2(Z, C) - E\{\phi_2(Z, C)|C, S = 0\}] : \phi_1(Z, C), \phi_2(Z, C) \text{ unrestricted}\}$$

It remains to find elements in this space that are orthogonal to $\Lambda_{nouis_9}^\perp$; these must satisfy

$$0 = E\left\{ \left( S\epsilon_1^*[\phi_1(Z, C) - E\{\phi_1(Z, C)|S = 1, C\}] + (1 - S)\epsilon_0[\phi_2(Z, C) - E\{\phi_2(Z, C)|S = 0, C\}] \right) \right.$$}

$$\times \left\{ Sd_9(Z, C)f_{\epsilon_1} + (1 - S)d_9(Z, C)f_{\epsilon_0} \right\}$$

$$= E\left\{ \left( S[\phi_1(Z, C) - E\{\phi_1(Z, C)|S = 1, C\}] + (1 - S)[\phi_2(Z, C) - E\{\phi_2(Z, C)|S = 0, C\}] \right) d_9(Z, C) \right\}$$

It follows from Tchetgen Tchetgen et al. (2010) that the space of elements

$$S[\phi_1(Z, C) - E\{\phi_1(Z, C)|S = 1, C\}] + (1 - S)[\phi_2(Z, C) - E\{\phi_2(Z, C)|C, S = 0\}]$$

that satisfy this equality can be represented as

$$\Omega = \{\phi(Z, S, C) : E\{\phi(Z, S, C)|Z, C\} = E\{\phi(Z, S, C)|S, C\} = 0\}.$$

Then the main result follows.
B.1.2 Proof of part (b)

Proof. Many of the steps in this proof follow along the lines of the proof of part (a) and can therefore be omitted for brevity. We note however that NSM Assumption (S) imposes different restrictions on the nuisance tangent space, such that we redefine \( \Lambda_{\text{nuis}}^{5} \) as

\[
\Lambda_{\text{nuis}}^{5} = \left\{ S[d_5(A, C) - E\{d_5(A, C)|Z, S = 1, C\}]f'_{\epsilon_1} : d_5(A, C) \text{ unrestricted} \right\} \cap L_{2}^{0}.
\]

Along the lines of the proof of Theorem 4 in Tchetgen Tchetgen and Vansteelandt (2013), one can show that

\[
\Lambda_{\text{nuis}}^{\perp 1} \cap \Lambda_{\text{nuis}}^{\perp 3} \cap \Lambda_{\text{nuis}}^{\perp 4} \cap \Lambda_{\text{nuis}}^{\perp 5} \cap \Lambda_{\text{nuis}}^{\perp 6} \cap \Lambda_{\text{nuis}}^{\perp 7} \cap \Lambda_{\text{nuis}}^{\perp 8} \cap \Lambda_{\text{nuis}}^{\perp 9} = \left\{ \{1 - S\}e_0[\phi_2(Z, C) - E\{\phi_2(Z, C)|C, S = 0\}] : \phi_2(Z, C) \text{ unrestricted} \right\}
\]

and as in the previous proof,

\[
\Lambda_{\text{nuis}}^{\perp 2} \cap \Lambda_{\text{nuis}}^{\perp 9} = \left\{ \kappa(A, Z, C) \in \Gamma, \phi_1(Z, C) \text{ unrestricted} \right\} \cap L_{2}^{0}
\]

Then one can find the elements

\[
S_{\epsilon_1}[\kappa(A, Z, C) + \phi_1(Z, C) - E\{\phi_1(Z, C)|S = 1, C\}] + S[q(A, Z, C) - E\{q(A, Z, C)|Z, S = 1, C\}][\phi_1(Z, C) - E\{\phi_1(Z, C)|S = 1, C\}] + (1 - S)e_0[\phi_2(Z, C) - E\{\phi_2(Z, C)|C, S = 0\}]
\]

that are orthogonal to \( \lambda_{\text{nuis}}^{5} \) as in the previous proof, and the main result follows.

\[\square\]

B.2 Proof of Theorems 3.2

Proof. We will first show that

\[
E\{\phi(Z, S; \tau^{\dagger}, \alpha^{\dagger}, \rho^{\dagger})e^{*}(\psi^{\dagger}, \nu^{\dagger}, \theta^{\dagger})\}
\]

37
evaluated at the limiting (rather than estimated) values is an unbiased estimating function under the union model. Under model $\mathcal{M}_{NEM} \cap \mathcal{M}_1$, by the law of iterated expectation,

$$E\{\phi(Z, S, C; \tau^\dagger, \alpha^\dagger, \rho^\dagger)\epsilon^*(\psi^\dagger, \nu^\dagger, \theta^\dagger)\}$$

$$= E\left(\phi(Z, S, C; \tau^\dagger, \alpha^\dagger, \rho^\dagger)[b_0(C) + b_1(C)S + t(Z, C) - b_0(C; \theta_0^\dagger) - b_1(C; \theta_1^\dagger)S - t(Z, C; \nu^\dagger)\right.$$

$$+ q(A, Z, C) - E\{q(A, Z, C)|Z, S = 1, C]\left]\right)\right)$$

$$= E\left[\phi(Z, S, C; \tau^\dagger, \alpha^\dagger, \rho^\dagger)\{b_0(C) + b_1(C)S + t(Z, C) - b_0(C; \theta_0^\dagger) - b_1(C; \theta_1^\dagger)S - t(Z, C; \nu^\dagger)\}\right] = 0$$

Under model $\mathcal{M}_{NEM} \cap \mathcal{M}_2$, looking back to the final line of the previous expression,

$$E\left[\phi(Z, S, C; \tau^\dagger, \alpha^\dagger, \rho^\dagger)\{b_0(C) + b_1(C)S + t(Z, C) - b_0(C; \theta_0^\dagger) - b_1(C; \theta_1^\dagger)S - t(Z, C; \nu^\dagger)\}\right]$$

$$= E\left[\phi(Z, S, C; \tau^\dagger, \alpha^\dagger, \rho^\dagger)\{b_0(C) + b_1(C)S - b_0(C; \theta_0^\dagger) - b_1(C; \theta_1^\dagger)S\}\right]$$

$$= E\left[E\{\phi(Z, S, C; \tau^\dagger, \alpha^\dagger, \rho^\dagger)\epsilon^*(\psi^\dagger, \nu^\dagger)\}|S, C\}\{b_0(C) + b_1(C)S - b_0(C; \theta_0^\dagger) - b_1(C; \theta_1^\dagger)S\}\right] = 0$$

where the final equality follows since $f(Z|S, C) = f(Z|S, C; \nu^\dagger, \rho^\dagger)$.

Under model $\mathcal{M}_{NEM} \cap \mathcal{M}_3$,

$$E\left[\phi(Z, S, C; \tau^\dagger, \alpha^\dagger, \rho^\dagger)\{b_0(C) + b_1(C)S + t(Z, C) - b_0(C; \theta_0^\dagger) - b_1(C; \theta_1^\dagger)S - t(Z, C; \nu^\dagger)\}\right]$$

$$= E\left[E\{\phi(Z, S, C; \tau^\dagger, \alpha^\dagger, \rho^\dagger)\epsilon^*(\psi^\dagger, \nu^\dagger)\}|Z, C\}\{b_0(C) + t(Z, C) - b_0(C; \theta_0^\dagger) - t(Z, C; \nu^\dagger)\}\right] = 0$$

where the final equality follows since $f(S|Z, C) = f(S|Z, C; \alpha^\dagger, \rho^\dagger)$.

Finally, under model $\mathcal{M}_{NEM} \cap \mathcal{M}_4$,

$$E\left[\phi(Z, S, C; \tau^\dagger, \alpha^\dagger, \rho^\dagger)\{b_0(C) + b_1(C)S + t(Z, C) - b_0(C; \theta_0^\dagger) - b_1(C; \theta_1^\dagger)S - t(Z, C; \nu^\dagger)\}\right]$$

$$= E\left[E\{\phi(Z, S, C; \tau^\dagger, \alpha^\dagger, \rho^\dagger)\epsilon^*(\psi^\dagger, \nu^\dagger)\}|S, C\}\{b_1(C)S - b_1(C; \theta_1^\dagger)S\}\right]$$

$$+ E\left[E\{\phi(Z, S, C; \tau^\dagger, \alpha^\dagger, \rho^\dagger)\epsilon^*(\psi^\dagger, \nu^\dagger)\}|Z, C\}\{t(Z, C) - t(Z, C; \nu^\dagger)\}\right]$$

$$+ E\left\{\phi(Z, S, C; \tau^\dagger, \alpha^\dagger, \rho^\dagger)\{b_0(C) - b_0(C; \theta_0^\dagger)\}\right\} = 0$$

Note furthermore that
• \( f(Z|S, C; \hat{\tau}, \hat{\rho}) \) is a CAN estimator of \( f(Z|S, C) \) in model \( M_2 \cup M_4 \).

• \( f(S|Z, C; \hat{\alpha}, \hat{\rho}) \) is a CAN estimator of \( f(S|Z, C) \) in model \( M_3 \cup M_4 \).

• \( t(Z, C; \hat{\nu}) \) is a CAN estimator of \( t(Z, C) \) in model \( M_{NEM} \cap (M_1 \cup M_2) \).

• \( b_1(C; \hat{\theta}_1) \) is a CAN estimator of \( b_1(C) \) in model \( M_{NEM} \cap (M_1 \cup M_3) \).

• \( b_0(C; \hat{\theta}_0) \) is a CAN estimator of \( b_0(C) \) in model \( M_{NEM} \cap (M_1 \cup M_2 \cup M_3) \).

These results follow from Robins et al. (1992) and Tchetgen Tchetgen et al. (2010). This completes the proof.

B.3 Proof of Theorem 3.3

Proof. If we consider the estimating function

\[
S_{K}(A, Z, C; \pi^\dagger, \tau^\dagger, \rho^\dagger)\epsilon(\psi^\dagger, \nu^\dagger, \theta^\dagger, \omega^\dagger, \pi^\dagger) + \phi(Z, S, C; \tau^\dagger, \alpha^\dagger, \rho^\dagger)\epsilon^*(\psi^\dagger, \nu^\dagger, \theta^\dagger)
\]

then it follows from the previous proof that

\[
E\{\phi(Z, S, C; \tau^\dagger, \alpha^\dagger, \rho^\dagger)\epsilon^*(\psi^\dagger, \nu^\dagger, \theta^\dagger)\} = 0
\]

under the union model.

Under model \( M_{NSM} \cap M_a \cap M_1q \),

\[
E\{S_{K}(A, Z, C; \pi^\dagger, \tau^\dagger, \rho^\dagger)\epsilon(\psi^\dagger, \nu^\dagger, \theta^\dagger, \omega^\dagger, \pi^\dagger)\}
\]

\[
= E\left(S_{K}(A, Z, C; \pi^\dagger, \tau^\dagger, \rho^\dagger)[b_0(C) + b_1(C)S + t(Z, C) - b_0(C; \theta_0^\dagger) - b_1(C; \theta_1^\dagger)] - q(A, C) - E\{q(A, C)|Z, S = 1, C\} - q(A, C; \omega^\dagger) + E\{q(A, C; \omega^\dagger)|Z, S = 1, C; \pi^\dagger\}\right) = 0
\]
Under model $\mathcal{M}_{NSM} \cap \mathcal{M}_a \cap \mathcal{M}_2$,

$$E \left( S_k(A, Z, C; \pi^\dagger, \tau^\dagger, \rho^\dagger) [b_0(C) + b_1(C)S + t(Z, C) - b_0(C; \theta_0^\dagger) - b_1(C; \theta_1^\dagger)S - t(Z, C; \nu^\dagger) \\
+ q(A, C) - E\{q(A, C)|Z, S = 1, C\} - q(A, C; \omega^\dagger) + E\{q(A, C; \omega^\dagger)|Z, S = 1, C; \pi^\dagger\} \right) \right)$$

$$= E \left( S_k(A, Z, C; \pi^\dagger, \tau^\dagger, \rho^\dagger) [b_0(C) + b_1(C)S - b_0(C; \theta_0^\dagger) - b_1(C; \theta_1^\dagger)S - t(Z, C; \nu^\dagger) \\
+ q(A, C) - E\{q(A, C)|Z, S = 1, C\} - q(A, C; \omega^\dagger) + E\{q(A, C; \omega^\dagger)|Z, S = 1, C; \pi^\dagger\} \right) \right)$$

$$= E \left[ SE\{k(A, Z, C; \pi^\dagger, \tau^\dagger, \rho^\dagger)|S = 1, C\} [b_0(C) + b_1(C)S - b_0(C; \theta_0^\dagger) - b_1(C; \theta_1^\dagger)S] \\
+ E \left[ SE\{k(A, Z, C; \pi^\dagger, \tau^\dagger, \rho^\dagger)|A, S = 1, C\} [q(A, C) - q(A, C; \omega^\dagger)] \right] \\
- E \left( SE\{k(A, Z, C; \pi^\dagger, \tau^\dagger, \rho^\dagger)|Z, S = 1, C\} [E\{q(A, C)|Z, S = 1, C\} - E\{q(A, C; \omega^\dagger)|Z, S = 1, C; \pi^\dagger\}] \right) \right)$$

$$= 0$$

where the final equality follows since $f(A, Z|S = 1, C) = f(A, Z|S = 1, C; \pi^\dagger, \tau^\dagger, \rho^\dagger)$.

Under model $\mathcal{M}_{NSM} \cap \mathcal{M}_a \cap \mathcal{M}_{3q}$,

$$E \left( S_k(A, Z, C; \pi^\dagger, \tau^\dagger, \rho^\dagger) [b_0(C) + b_1(C)S + t(Z, C) - b_0(C; \theta_0^\dagger) - b_1(C; \theta_1^\dagger)S - t(Z, C; \nu^\dagger) \\
+ q(A, C) - E\{q(A, C)|Z, S = 1, C\} - q(A, C; \omega^\dagger) + E\{q(A, C; \omega^\dagger)|Z, S = 1, C; \pi^\dagger\} \right) \right)$$

$$= E \left( S_k(A, Z, C; \pi^\dagger, \tau^\dagger, \rho^\dagger) [b_0(C) + t(Z, C) - b_0(C; \theta_0^\dagger) - b_1(C; \theta_1^\dagger)S - t(Z, C; \nu^\dagger)] \right)$$

$$= E \left[ SE\{k(A, Z, C; \pi^\dagger, \tau^\dagger, \rho^\dagger)|Z, S = 1, C\} [b_0(C) + t(Z, C) - b_0(C; \theta_0^\dagger) - b_1(C; \theta_1^\dagger)S - t(Z, C; \nu^\dagger)] \right]$$

$$= 0$$

where the final equality follows since $f(A|Z, S = 1, C) = f(A|Z, S = 1, C; \pi^\dagger)$.

40
Under model $\mathcal{M}_{NEM} \cap \mathcal{M}_a \cap \mathcal{M}_4$, it follows from previous arguments that

$$E\left( S_{\mathcal{K}}(A, Z, C; \pi^\dagger, \tau^\dagger, \rho^\dagger) [b_0(C) + b_1(C)S + t(Z, C) - b_0(C; \theta_0^\dagger) - b_1(C; \theta_1^\dagger)S - t(Z, C; \nu^\dagger) \\
+ q(A, C) - E\{q(A, C)|Z, S = 1, C\} - q(A, C; \omega^\dagger) + E\{q(A, C; \omega^\dagger)|Z, S = 1, C; \pi^\dagger\} \right) = 0$$

since $f(A, Z|S = 1, C) = f(A, Z|S = 1, C; \pi^\dagger, \tau^\dagger)$.

\[ \square \]

### B.4 Proof of Theorem 3.4

**Proof.** Under a restricted moment model where $t(Z, C)$, $b_0(C)$ and $b_1(C)$ are known, it follows e.g. from Robins (1994) that the efficient score for $\psi^\dagger$ is equal to

$$U_{RM-eff} = \mu(Z, S, C)\sigma^{-2}(Z, S, C)e^*(\psi^\dagger)$$

It also follows from the proofs of Theorem 1 and 4 in Vansteelandt et al. (2008) that the nuisance tangent space under $\mathcal{M}_{NEM}$ obtained in Theorem 3.1 can be equivalently represented as

$$\left\{ e_0(C) + e_1(S, C) + e_2(Z, C) \right\}\sigma^{-2}(Z, S, C)e^*(\psi^\dagger) : e_0 \in \mathcal{C}_0, e_1 \in \mathcal{C}_1, e_2 \in \mathcal{C}_2 \right\} \cap L^0_2$$

where $\mathcal{C}_0 = \{e_0(C)\} \cap \mathcal{H}$, $\mathcal{C}_1 = \{e_1(S, C)\} \cap \mathcal{H}$, $\mathcal{C}_2 = \{e_2(Z, C)\} \cap \mathcal{H}$ and $\mathcal{H}$ is the Hilbert space of functions of $Z, S, C$ with inner product given by $E\{\sigma^{-2}(Z, S, C)e_1(Z, S, C)e_2(Z, S, C)\}$ for all $e_1, e_2$.

Then the efficient score under model $\mathcal{M}_{NEM}$ is equal to the following projection

$$\Pi_{L^2_2}\left[U_{RM-eff}\left[\{e_0(C) + e_1(S, C) + e_2(Z, C)\}\sigma^{-2}(Z, S, C)e^*(\psi^\dagger)\right] \right] : e_0 \in \mathcal{C}_0, e_1 \in \mathcal{C}_1, e_2 \in \mathcal{C}_2$$

$$\Pi_{\mathcal{H}}\left(\mu(Z, S, C)\left\{e_0(C) + e_1(S, C) + e_2(Z, C)\right\} \right) : e_0 \in \mathcal{C}_0, e_1 \in \mathcal{C}_1, e_2 \in \mathcal{C}_2 \sigma^{-2}(Z, S, C)e^*(\psi^\dagger)$$

where $\Pi_{L^0_2}(\cdot)$ is the orthogonal projection operator in $L^0_2$, and $\Pi_{\mathcal{H}}(\cdot)$ is similarly defined w.r.t. $\mathcal{H}$. Vansteelandt et al. (2008) obtain a closed form representation of the projection in $\mathcal{H}$ of any function $D \in \mathcal{H}$ onto $(\mathcal{C}_1 \cup \mathcal{C}_2 \cup \mathcal{C}_2)^\perp$ as

$$J(D) = \frac{E\{D\sigma^{-2}(Z, S, C)\tilde{S}|C\}}{E\{\sigma^{-2}(Z, S, C)\tilde{S}^2|C\}} \tilde{S} - J \left( \frac{E\{D\sigma^{-2}(Z, S, C)|S, C\}}{E\{\sigma^{-2}(Z, S, C)|S, C\}} \right)$$
where we define the $J(\cdot)$ operator on function $D^*$ as

$$J(D^*) = D^* - \frac{E\{D^*\sigma^{-2}(Z, S, C)|C\}}{E\{\sigma^{-2}(Z, S, C)|C\}}$$

Applying this result, we obtain the efficient score as

$$\left[ J(\mu(Z, S, C)) - \frac{E\{\mu(Z, S, C)\sigma^{-2}(Z, S, C)|C\}}{E\{\sigma^{-2}(Z, S, C)|C\}} \right] \tilde{S} - J\left( \frac{E\{\mu(Z, S, C)\sigma^{-2}(Z, S, C)|S, C\}}{E\{\sigma^{-2}(Z, S, C)|S, C\}} \right)$$

This simplifies to the expression given in the main text upon noting that

$$E\{\sigma^{-2}(Z, S, C)|C\}^{-1} E \left[ \sigma^{-2}(Z, S, C) \frac{E\{\mu(Z, S, C)\sigma^{-2}(Z, S, C)|S, C\}}{E\{\sigma^{-2}(Z, S, C)|S, C\}} | C \right]$$

One can show the unbiasedness of the efficient score under the union model along the lines of the proof of Theorem 3.2 noting that

$$E\{\sigma^{-2}(Z, S, C)|C\}^{-1} E \left[ \frac{E\{\mu(Z, S, C)\sigma^{-2}(Z, S, C)|S, C\}}{E\{\sigma^{-2}(Z, S, C)|S, C\}} | C \right]$$

is an element in $\Omega$. Efficiency at the intersection submodel follows from general results in Robins and Rotnitzky (2001).

**B.5 Proof of Corollary 3.4.1**

**Proof.** If $Z$ is binary, then one can obtain the efficient score by obtaining the optimal choice $m_{opt}(C)$ of $m(C)$ in

$$m(C)(-1)^{Z+S} \frac{f(Z, S|C)}{f(Z|C)} e^*(\psi^t)$$
which can be done via a population least squares projection of the score \( U_{\psi^1} \) for \( \psi \) onto the above. Thus,

\[
m_{\text{opt}}(C) = E \left[ \frac{(-1)^Z}{f(Z, S|C)} \right]^2 \sigma^2(Z, S, C) \left| C \right. \left. \right]^{-1} E \left\{ \frac{(-1)^Z}{f(Z, S|C)} \epsilon_{\uparrow} \left| C \right. \right\} \\
= E \left[ \frac{(-1)^Z}{f(Z, S|C)} \right]^2 \sigma^2(Z, S, C) \left| C \right. \left. \right]^{-1} E \left\{ (U_{\psi^1} \epsilon^*)^* \left| Z, S, C \right. \right\} \\
= E \left[ \frac{(-1)^Z}{f(Z, S|C)} \right]^2 \sigma^2(Z, S, C) \left| C \right. \left. \right]^{-1} E \left\{ \mu(Z, S, C) \left| Z, S, C \right. \right\} \}

\[= E \left[ \frac{(-1)^Z}{f(Z, S|C)} \right]^2 \sigma^2(Z, S, C) \left| C \right. \left. \right]^{-1} \mu(Z = 1, S = 1, C) - \mu(Z = 1, S = 0, C) \]

\( \square \)

### B.6 Proofs of Theorems 3.5 & 3.6

**Proof.** For the proof of Theorem 3.5 the general result follows from taking the population least squares projections of \( U_{\psi^1} \) onto the set of elements in the orthocomplement of the the nuisance tangent space. Note that in order to do separate projections for \( m_{\text{opt}}(C) \) and \( h_{\text{opt}}(C) \), one must first project \( Q_2 \) onto \( Q_1 \). The refined result follows since \( E(Q_1 Q_2 | Z_2) = 0 \) follows if the residual variance does not depend on \( A, Z \) or \( S \).

Regarding the proof of Theorem 3.6 the result on the space of influence functions follows straightforwardly along the lines of Theorem 3 in Tchetgen Tchetgen and Vansteelandt (2013), following the steps of Theorem 3.1. Note that the space of influence functions can be written as:

\[
\left\{ \frac{Sh(C)(-1)^{+Z}}{f(A|Z, S = 1, C; \pi^1)f(Z|S = 1, C)} \epsilon(\psi^\dagger) + \frac{m(C)(-1)^{Z+S}}{f(Z, S|C)} \epsilon^*(\psi^\dagger) \\
+ Sg(Z, C)\{A - f(A = 1|Z, S = 1, C; \pi^1)\} : h(C), m(C), g(Z, C) \text{ unrestricted} \right\} \cap L_2^0
\]

for binary \( A \) and \( Z \). Then efficiency result can be shown after noting that the projections of the score \( U_{\psi^1, \pi^1} \) onto

\[
\left\{ \frac{Sh(C)(-1)^{+Z}}{f(A|Z, S = 1, C; \pi^1)f(Z|S = 1, C)} \epsilon(\psi^\dagger) + \frac{m(C)(-1)^{Z+S}}{f(Z, S|C)} \epsilon^*(\psi^\dagger) : h(C), m(C) \text{ unrestricted} \right\} \cap L_2^0
\]

43
and
\[
\{ Sg(Z, C) \{ A - f(A = 1 | Z, S = 1; \pi^\dagger) \} : g(Z, C) \text{ unrestricted} \} \cap L_0^0
\]
can be done individually, since
\[
\frac{Sh(C)(-1)^{A+Z}}{f(A | Z, S = 1, C; \pi^\dagger)} f(Z | S = 1, C) \epsilon + \frac{m(C)(-1)^{Z+S}}{f(Z, S | C)} \epsilon^*(\psi^\dagger)
\]
and \( Sg(Z, C) \{ A - f(A = 1 | Z, S = 1; \pi) \} \) are orthogonal for all \( m(C), h(C) \) and \( g(Z, C) \).

\[
\square
\]

B.7 Proof of theorem 3.7

B.7.1 Proof of part (a)

Proof. To obtain the efficient influence function for \( \psi \), we must find the random variable \( G \) which satisfies:
\[
\frac{\partial}{\partial r} \psi^*_t \biggr|_{r=0} = E\{GU(O; t)\} \biggr|_{r=0}
\]
for \( U(O; r) = \partial \log \{ f(O; r) \} / \partial r \), where \( f(O; r) \) is a one-dimensional regular parametric submodel of \( \mathcal{M}_{np} \). By the product rule,
\[
\frac{\partial}{\partial r} \psi^*_r \biggr|_{r=0} = \int \frac{\partial}{\partial r} \left( \frac{\delta f_r(c) - t_r(1,c)}{\delta r_A(c)} \right) \biggr|_{r=0} dF(c | A = 1, S = 1)
\]
\[
+ \int \beta(c)dF_r(c | A = 1, S = 1) / \partial r \biggr|_{r=0}
\]
\[= (i) + (ii)\]

If we first consider term \( (ii) \):
\[
(ii) = \frac{1}{f(A = 1, S = 1)} E \{ \beta(C)U(C | A = 1, S = 1) | A = 1, S = 1 \}
\]
\[= \frac{1}{f(A = 1, S = 1)} E \{ AS\beta(C)U(C | A, S) \}
\]
\[= \frac{1}{f(A = 1, S = 1)} E \{ AS\beta(C) [ E\{U(O) | C, A, S\} - E\{U(O) | A, S\} ] \}
\]
\[= \frac{1}{f(A = 1, S = 1)} E [AS \{ \beta(C) - \psi \} U(O) ]
\]

44
Considering now term (i), then
\[
(i) = \frac{1}{f(A = 1, S = 1)} E \left\{ \frac{\partial}{\partial r} \frac{\delta_\gamma(C)}{\delta_\tau^A(C)} |_{r=0} f(A = 1, S = 1|C) \right\}
\]

Following the steps in the proof of Theorem 5 in [Wang and Tchetgen Tchetgen (2018)],
\[
\frac{\partial}{\partial r} E_r(Y|Z = z, S = s, C)|_{r=0} = E \left\{ \frac{I(Z = z)I(S = s)}{f(Z, S|C)} \{Y - E(Y|Z, S, C)\} U(O) \right\} | C
\]
and therefore
\[
\frac{\partial}{\partial r} \{\delta_\gamma(C) - t_r(1,C)\}|_{r=0} = E \left\{ \frac{(2Z - 1)(2S - 1)}{f(Z, S|C)} \{Y - E(Y|Z, S, C)\} U(O) \right\} | C
\]
and
\[
\frac{\partial}{\partial r} \delta_\tau^A(C)|_{r=0} = E \left\{ \frac{(2Z - 1)S}{f(Z, S = 1|C)} \{A - E(A|Z, S = 1, C)\} U(O) \right\} | C
\]
which gives us
\[
(i) = \frac{1}{f(A = 1, S = 1)} E \left[ \frac{f(A = 1, S = 1|C)}{f(Z, S|C)} \frac{(2Z - 1)}{\delta_\tau^A(C)} \right. \\
\times \left\{ (2S - 1)(Y - E(Y|Z, S, C)) - S\beta(C)\{A - f(A = 1|Z, S = 1, C)\} \right\} U(O) \\
= \frac{1}{f(A = 1, S = 1)} E \left[ \frac{f(A = 1, S = 1|C)}{f(Z, S|C)} \frac{(2Z - 1)}{\delta_\tau^A(C)} \right. \\
\times \left\{ S[Y - E(Y|Z, S = 1, C) - \beta(C)\{A - f(A = 1|Z, S = 1, C)\}] \\
- (1 - S)(Y - E(Y|Z, S = 0, C)) \right\} U(O) \left\}
\]

We furthermore have that
\[
Y - E(Y|Z, S = 1, C) - \{A - E(A|Z, S = 1, C)\}\beta(C)
= Y - E(Y|Z = 0, S = 1, C) - \delta_\gamma(C)Z - \beta(C)A + \beta(C)f(A = 1|Z = 0, S = 1, C) + \beta(C)\delta_\tau^A(C)Z
= Y - E(Y|Z = 0, S = 1, C) - \beta(C)\delta_\tau^A(C)Z - t(1, C)Z
- \beta(C)A + \beta(C)f(A = 1|Z = 0, S = 1, C) + \beta(C)\delta_\tau^A(C)Z
= Y - E(Y|Z = 0, S = 1, C) - \beta(C)\{A - f(A = 1|Z = 0, S = 1, C)\} - t(1, C)Z
\]
such that
\[
(i) = \frac{1}{f(A = 1, S = 1)} \mathbb{E} \left\{ \frac{f(A = 1, S = 1|C)}{\delta^A(C)} \left( 2Z - 1 \right) 
\times \left( S[Y - E(Y|Z = 0, S = 1, C) - \beta(C)\{A - f(A = 1|Z = 0, S = 1, C)\} - t(1, C)Z \right)
- (1 - S)\{Y - t(1, C)Z - E(Y|Z = 0, S = 0, C)\} \right\} U(O)
\]
\[
= \frac{1}{f(A = 1, S = 1)} \mathbb{E} \left\{ \frac{f(A = 1, S = 1|C)}{\delta^A(C)} \left( 2Z - 1 \right) \left( 2S - 1 \right) 
\times [Y - E(Y|Z = 0, S, C) - \beta(C)\{A - f(A = 1|Z = 0, S = 1, C)\}] S - t(1, C)Z \right\} U(O)
\]

The main result then follows by combining (i) and (ii).

**B.8 Proof of part (b)**

*Proof.* In evaluating \( \partial \psi_0^* / \partial r \rvert_{r=0} \), the efficient influence functions of the functionals \( E(Y|A = 1, S = 1) \) and \( E\{E(Y|A = 0, Z, S = 1, C)|A = 1, S = 1\} \) are \( AS\{Y - E(Y|A = 1, S = 1)\}/f(A = 1, S = 1) \) and

\[
\frac{(1 - A)S}{f(A = 1, S = 1)} f(A = 0|Z, S = 1, C) \{Y - E(Y|A, Z, S = 1, C)\}
+ \frac{AS}{f(A = 1, S = 1)} \left[ E(Y|A = 0, Z, S = 1, C) - E\{E(Y|A = 0, Z, S = 1, C)|A = 1, S = 1\} \right]
\]

respectively, where the latter follows e.g. from [Hahn (1998)](Hahn1998). Furthermore, we have that,

\[
\frac{\partial}{\partial r} \left\{ - \int \gamma_r(c) dF_r(c) |A = 1, S = 1 \right\} \rvert_{r=0}
= \int \frac{\partial}{\partial r} \left( \frac{\delta_0^Y(c) - t_r(1, c)}{\delta_t^A(c)} \right) \rvert_{r=0} dF(c|A = 1, S = 1)
- \int \gamma(c) dF_r(c) |A = 1, S = 1) / \partial r \rvert_{r=0}
\]

The main result then follows by repeating the steps of the previous proof. \( \square \)

C Simulation studies

C.1 Additional estimators

C.1.1 Two-stage least squares

Under NEM, a two-stage least squares estimator can be obtained by solving the equations

$$0 = \sum_{i=1}^{n} S_i m(Z_i, C_i) \{ Y_i - \beta(A_i, C_i; \psi^\dagger) S_i - t(Z_i, C_i; \nu^\dagger) - b_0(C_i; \theta_0^\dagger) - b_1(C_i; \theta_1^\dagger) S_i \}$$

for $\psi^\dagger$ (Richardson and Tchetgen Tchetgen, 2021), where $m$ is of the same dimension of $\psi^\dagger$. In practice, the unknown values $\nu^\dagger$ and $\theta^\dagger$ can be substituted by the estimates $\tilde{\nu}$ and $\hat{\theta}$ as described in Section 3.2. Since this approach relies on a parametric model for the outcome, one can set $E(S|Z, C)$ to zero in the equations for $\theta^\dagger$; this is what was done to obtain the estimator $\hat{\psi}_{TSLS}$ in the simulations.

C.1.2 G-estimation: two strategies

One can construct a $g$-estimator via solving the equations

$$0 = \sum_{i=1}^{n} S_i [m(Z_i, C_i) - E\{m(Z_i, C_i)|S_i = 1, C_i; \tau^\dagger, \rho^\dagger\}] \times \{ Y_i - \beta(A_i, C_i; \psi^\dagger) S_i - t(Z_i, C_i; \nu^\dagger) - b_0(C_i; \theta_0^\dagger) - b_1(C_i; \theta_1^\dagger) S_i \}$$

for $\psi^\dagger$. Richardson and Tchetgen Tchetgen (2021) note that the above equations are doubly robust, and yield an estimator that is unbiased under the union model $M_{NEM} \cap (M_1 \cup M_2)$ i.e. so long as either $f(Z|S = 1, C)$ or $b_0(C)$ and $b_1(C)$ are correctly modelled. In order to obtain a doubly robust estimator, $\nu^\dagger$ must be estimated using an estimator consistent under the laws $M_1 \cap M_2$. In the simulations, $\nu^\dagger$ was estimated via the equations given in Section 3.2 for $\hat{\nu}$, with $b_0(C)$ fixed at zero; similarly, in the $g$-estimating equations used to estimate $\psi$ as $\hat{\psi}_{g-S}$, $b_0(C)$ and $b_1(C)$ were fixed at zero.

An alternative doubly $g$-estimator can be obtained as $\tilde{\psi}$ based on the equations in Section 3.2; the resulting estimator is then unbiased under the union model $M_1 \cap M_3$. In order to construct the estimator $\hat{\psi}_{g-S}$ in the simulations, we set $t(Z, C)$ and $b_0(C)$ at zero.
C.1.3 Inverse probability weighted estimation

An inverse probability weighted (IPW) estimator can be obtained via solving the estimating equations:

$$0 = \sum_{i=1}^{n} \phi(Z_i, S_i, C_i; \tau^\dagger, \alpha^\dagger, \rho^\dagger) \{Y_i - \beta(A_i, C_i; \psi^\dagger)S_i\}$$

for $\psi^\dagger$. One can show along the lines of the proof of Theorem 3.2 that the resulting estimator is unbiased under the model $M_{NEM} \cap M_4$. In the simulations, we estimated $\tau^\dagger$, $\alpha^\dagger$ and $\rho^\dagger$ as proposed in Section 3.2 in order to construct the estimator $\hat{\psi}_{IPW}$.
