EXISTENCE OF MAXIMUM LIKELIHOOD ESTIMATES IN
EXPONENTIAL RANDOM GRAPH MODELS

HENRY BAYLY, ADITYA KHANNA, AND KATHRYN LINDSEY

Abstract. We present a streamlined proof of the foundational result in the theory of exponential random graph models (ERGMs) that the maximum likelihood estimate exists if and only if the target statistic lies in the relative interior of the convex hull of the set of realizable statistics. We also discuss how linear dependence or “approximate linear dependence” of network statistics may lead to degeneracy during model fitting.

1. Introduction

Exponential Random Graph Models (ERGMs) are a family of probability distributions $\Pr_{\theta}$, parameterized by $\theta \in \mathbb{R}^p$, on the set $\mathcal{G}_k$ of all graphs with $k$ vertices. ERGMs are used to model real-world networks in numerous contexts, such as viral transmission through human networks [1, 11, 18, 21, 20, 17], scientific collaboration and knowledge dissemination [7, 25], and global migration [24, 16]. Computational scientists use known or estimated values for graph statistics (such as number of edges, numbers of subgraphs of certain types, measures of graph connectivity, etc.) about the network of interest to find a probability distribution $\Pr_{\hat{\theta}}$ that assigns a higher probability to graphs whose structures more closely match the target statistics; they then investigate the studied phenomenon on a sample of graphs selected randomly from $\mathcal{G}_k$ with respect to $\Pr_{\hat{\theta}}$. Open source tools to estimate and simulate networks in situations where values for statistics about the structure of the graph are known or can be estimated are now widely used [14, 15, 22]. Consequently, the question of existence and uniqueness of a parameter $\hat{\theta}$ so that $\Pr_{\hat{\theta}}$ maximizes the likelihood of the observed statistics is fundamental to the theory of ERGMs.

A well-known result ([13, 10]) is that there exists $\hat{\theta}$ that maximizes the likelihood estimate if and only if the target statistics lie in the relative interior of the convex hull of the set of realizable statistics; furthermore if such a $\hat{\theta}$ exists, it is unique. The standard reference for this result is [2], but [2] deals with a much more general class of functions – functions that are not necessarily differentiable – and so the route to this result passes through a lot of sophisticated mathematical machinery. The main result of this paper is a streamlined proof of this result. We hope this proof will be more transparent to scholars who are interested in ERGMs but who are not experts in convex analysis.

Consider \( z : \mathcal{G}_3 \to \mathbb{R}^3 \) to be the statistics (\#triangles, \#edges, \#mean vertex degree). The space \( \mathcal{G}_3 \) consists of 8 graphs (which form 4 isomorphism classes). The set of realizable statistics, \( z(\mathcal{G}_3) := \{ z(g) \mid g \in \mathcal{G}_3 \} \), are the 4 black points; the convex hull \( C \) of this set is shown in gray. Because number of edges and mean vertex degree are linearly dependent, the set \( C \) is not top-dimensional – it is a 2-dimensional polytope embedded in \( \mathbb{R}^3 \). The interior of \( C \) (viewed as a subset of \( \mathbb{R}^3 \)) is the empty set; the relative interior of \( C \) consists of all points in the interior of the gray triangle (viewed as a subset of its affine hull).

Before stating the theorem precisely, we establish notation. First, we specify that \( \mathcal{G}_k \) is the set of all labeled, undirected graphs with \( k \) vertices ("labeled" means that we do not identify isomorphic graphs). Fix a function \( z : \mathcal{G}_k \to \mathbb{R}^n \). We think of each coordinate of \( z(g) \) as recording one statistic about the graph \( g \) (for example, number of edges, number of triangles, measures of connectivity, etc.). Define \( C \) to be the convex hull (in \( \mathbb{R}^n \)) of \( z(\mathcal{G}_k) \), the set of realizable statistics. Recall that, if we denote the vertices (extreme points) of \( C \) by \( v_1, \ldots, v_m \), the relative interior of \( C \) may be defined as

\[
\text{rint}(C) := \left\{ \sum_{i=1}^{m} \lambda_i v_i \mid \lambda_i > 0, \sum_{i=0}^{m} \lambda_i = 1 \right\}.
\]

If the statistics that are the coordinate functions of \( z \) are all linearly independent on \( \mathcal{G}_k \), then \( C \) is a polytope of dimension \( n \) embedded in \( \mathbb{R}^n \); if not, we let \( V \) be the smallest linear subspace of \( \mathbb{R}^n \) that contains a translate of \( C \), i.e. \( V := \text{span}\{ z(g_1) - z(g_2) \mid g_1, g_2 \in \mathcal{G}_k \} \), and set \( V^\perp := \{ u \in \mathbb{R}^n \mid u \cdot v = 0 \text{ for all } v \in V \} \). We define the family of probability distributions \( \{ \text{Pr}_\theta \mid \theta \in \mathbb{R}^n \} \) on \( \mathcal{G}_k \) by

\[
\text{Pr}_\theta(g) := \frac{e^{\theta \cdot z(g)}}{\sum_{g \in \mathcal{G}_k} e^{\theta \cdot z(g)}}.
\]

Fix \( t \in \mathbb{R}^n \), the “target statistic.” The likelihood estimate \( L(\theta) \) is the weight assigned by \( \text{Pr}_\theta \) to a graph \( g \) such that \( z(g) = t \), i.e. \( L : \mathbb{R}^n \times \mathbb{R}^n \to (0, \infty) \).
is the function
\[ L(\theta) := \frac{e^{\theta \cdot t}}{\sum_{g \in \mathcal{G}_k} e^{\theta \cdot z(g)}}. \]

We will find it convenient to work with the logarithm of the likelihood; define \( \ell : \mathbb{R}^n \to \mathbb{R} \) by
\[ \ell(\theta) := \ln(L(\theta)). \]

**Theorem 1.** If \( \text{dim}(C) = n \), then
1. The log likelihood function \( \ell \) is strictly concave, and
2. There exists a parameter \( \hat{\theta} \in \mathbb{R}^n \) such that \( L(\hat{\theta}) = \sup_{\theta \in \mathbb{R}^n} L(\theta) \) if and only if \( t \) is in the interior of \( C \); furthermore such a \( \hat{\theta} \) is unique.

If \( \text{dim}(C) < n \), then
3. The log likelihood function \( \ell \) is concave but not strictly concave,
4. There exists a parameter \( \hat{\theta} \in V \) such that \( L(\hat{\theta}) = \sup_{\theta \in \mathbb{R}^n} L(\theta) \) if and only if \( t \) is in the relative interior of \( C \); furthermore there is a unique such \( \hat{\theta} \) in \( V \), and
5. \( L(\theta) = L(\theta + u) \) for all \( \theta \in \mathbb{R}^n \) and \( u \in V^\perp \).

The second result of the paper is a discussion about what happens when the target statistic \( t \) is outside \( C \), and implications for degeneracy of the associated ERGM model during the model training process. There are various algorithms used in practice (most based on Markov chain Monte Carlo methods – see e.g. [15],[19]) for seeking a parameter \( \hat{\theta} \) that maximizes \( L \); most or all work by stepping through the parameter space to obtain a sequence \( \{\theta_i\}_{i \in \mathbb{N}} \) of parameters along which \( L \) increases. If the associated sequence of probability measures, \( \{\Pr_{\theta_i}\}_{i \in \mathbb{N}} \), converges towards a probably measure whose mass is unrealistically concentrated on a small number of graphs – often the empty or complete graph – the model is said to be degenerate ([13]).

**Theorem 2.** Suppose \( t \notin C \). Then there exists a sequence of parameters \( \{\theta_i\}_{i \in \mathbb{N}} \in \mathbb{R}^n \) such that
1. \( \lim_{i \to \infty} L(\theta_i) \to \infty \) and
2. \( \lim_{i \to \infty} \Pr_{\theta_i} \{g \in \mathcal{G}_k \mid z(g) \text{ is on the boundary of } C\} = 1. \)

The qualitative meaning of \( z(g) \) being in the boundary of \( C \) is that the \( z(g) \) is “as extreme as possible” in some way. Handcock uses the term “near degenerate” for the situation when \( t \) is in \( C \) but is close to the boundary of \( C \), and states that in this case Markov chain techniques can have poor convergence to the true maximum \( \hat{\theta} \) ([13]). Theorem 2 suggests a complementary theoretical explanation for some cases of degeneracy observed during training – namely, that the \( t \) used to train the model lies outside of \( C \). If the set \( C \) is “skinny,” then even a small error in estimating the coordinates of \( t \) may push \( t \) outside of \( C \). The most extreme case in this regard is that \( \text{dim}(C) < n \), i.e. – when the graph statistics that are the coordinate functions of \( z \) are not linearly independent on \( \mathcal{G}_k \). However, even in cases where the graph statistics are linearly independent, there may be relationships among these statistics that dramatically constrain the width of \( C \) in some direction. We conclude by briefly mentioning a few theoretical
results about how certain graph statistics are determined by other graph statistics, i.e. how the geometry of \( C \) is constrained.

2. **Concavity of the Log Likelihood and Proof of Theorem 1**

Recall that a function \( f : \mathbb{R}^n \rightarrow \mathbb{R} \) is said to be concave if \( f(tx_1 + (1-t)x_2) \leq tf(x_1) + (1-t)f(x_2) \) for all \( x_1 \neq x_2 \in \mathbb{R}^n \) and \( t \in (0,1) \), and is strictly concave if strict inequality holds.

**Proposition 2.1.** The function \( \ell \) is concave; furthermore \( \ell \) is strictly concave if and only if \( \text{dim}(C) = n \).

Our proof of Proposition 2.1 uses the following simple case of Hölder’s Inequality (2).

For convenience, define \( c_g \) for every \( g \in \mathcal{G}_k \) as:

\[
\sum_{g \in \mathcal{G}_k} f(x) g(x) \leq \left( \sum_{x \in X} f(x)^p \right)^{1/p} \left( \sum_{x \in X} g(x)^q \right)^{1/q},
\]

with equality if and only if there exists a real number \( c \) such that \( f(x)^p = cg(x)^q \) for every \( x \in X \).

**Proof.** For convenience, define \( \kappa : \mathbb{R}^n \rightarrow \mathbb{R} \) by

\[
\kappa(\theta) := \ln \left( \sum_{g \in \mathcal{G}_k} e^{\theta \cdot z(g)} \right).
\]

Since \( \ell(\theta) = \theta \cdot t - \kappa(\theta) \), it suffices to prove that \( \kappa \) is always convex, and is strictly convex if and only if \( \text{dim}(C) = n \).

So fix any parameters \( \theta_1, \theta_2 \in \mathbb{R}^n \) and a real number \( 0 < \tau < 1 \). Define the functions \( F_{\theta_1,\tau}, G_{\theta_2,\tau} : \mathcal{G}_k \rightarrow [0, \infty) \) by

\[
F_{\theta_1,\tau}(g) := e^{\theta_1 \cdot z(g)} \quad \text{and} \quad G_{\theta_2,\tau}(g) := e^{\theta_2 \cdot z(g)}
\]

Since \( F_{\theta_1,\tau} \) and \( G_{\theta_2,\tau} \) are nonnegative, Hölder’s Inequality [2] using \( p := \frac{1}{\tau} \) and \( q := \frac{1}{1-\tau} \) gives

\[
\sum_{g \in \mathcal{G}_k} e^{z(g) \cdot (\theta_1 \cdot \tau + \theta_2 (1-\tau))} = \sum_{g \in \mathcal{G}_k} F_{\theta_1,\tau}(g) G_{\theta_2,\tau}(g)
\]

\[
\leq \left( \sum_{g \in \mathcal{G}_k} F_{\theta_1,\tau}(g)^{\frac{1}{\tau}} \right)^{\tau} \left( \sum_{g \in \mathcal{G}_k} G_{\theta_2,\tau}(g)^{\frac{1}{1-\tau}} \right)^{1-\tau}
\]

\[
= \left( \sum_{g \in \mathcal{G}_k} e^{\theta_1 \cdot z(g)} \right)^{\tau} \left( \sum_{g \in \mathcal{G}_k} e^{\theta_2 \cdot z(g)} \right)^{1-\tau},
\]

with equality if and only if the function \( F_{\theta_1,\tau}/G_{\theta_2,\tau}^q \) is constant on \( \mathcal{G}_k \). Taking the logarithm of both sides yields

\[
\kappa(\theta_1 \cdot \tau + \theta_2 (1-\tau)) \leq \tau \kappa(\theta_1) + (1-\tau) \kappa(\theta_2),
\]

with equality if and only if \( F_{\theta_1,\tau}/G_{\theta_2,\tau}^q \) is a constant function.
Thus, $\kappa$ is always convex, and is strictly convex if and only if for every $\theta_1 \neq \theta_2$ in $\mathbb{R}^n$ and $\tau \in (0,1)$, the function
\begin{equation}
(5) \quad g \mapsto \frac{F_{\theta_1,\tau}(g)}{G_{\theta_2,\tau}(g)} = e^{z(g) \cdot (\theta_1 - \theta_2)}
\end{equation}
is nonconstant on $\mathcal{G}_k$. Note that for any $g_1, g_2 \in \mathcal{G}_k$ and $\theta_1 \neq \theta_2$ in $\mathbb{R}^n$, $z(g_1) \cdot (\theta_1 - \theta_2) = z(g_2) \cdot (\theta_1 - \theta_2)$ if and only if $z(g_1) - z(g_2)$ is perpendicular to $\theta_1 - \theta_2$. Thus, there exist $\theta_1 \neq \theta_2$ in $\mathbb{R}^n$ such that the function (5) is constant on $\mathcal{G}_k$ if and only if $\text{Image}(z)$ is contained in an affine subset of $\mathbb{R}^n$ of dimension strictly less than $n$. □

Since $L$ is concave by Proposition 2.1, appealing to the standard (e.g. [3, Prop. 1.1.8]) fact that a differentiable, concave function on $\mathbb{R}^n$ attains its (global) supremum at precisely the set of points where its gradient is $\vec{0}$ immediately yields the following corollary, which underlies our Theorem 1 proof strategy.

**Corollary 2.2.** The function $L$ attains its supremum at $\hat{\theta}$ if and only if $\nabla L(\theta) = \vec{0}$.

**Lemma 2.3.** If $L$ attains its supremum, then $t \in \text{rint}(C)$.

**Proof.** Suppose $L$ attains its supremum at $\hat{\theta}$; then $\ell = \ln L$ attains its supremum at $\hat{\theta}$. Then by Corollary 2.2,
\[\hat{0} = \nabla \ell(\hat{\theta}) = t - \frac{1}{\sum_{g \in \mathcal{G}_k} e^{\hat{\theta} \cdot z(g)}} \sum_{g \in \mathcal{G}_k} e^{\hat{\theta} \cdot z(g)} z(g),\]
which implies
\begin{equation}
(6) \quad t = \sum_{g \in \mathcal{G}_k} \left( \frac{e^{\hat{\theta} \cdot z(g)}}{\sum_{g \in \mathcal{G}_k} e^{\hat{\theta} \cdot z(g)}} \right) z(g).
\end{equation}
Because the exponential functions is nonnegative, the coefficient on $z(g)$ in each term in (6) is positive, and the sum of these coefficients is 1 by construction. Therefore $t \in \text{rint}(C)$ (c.f. equation (1)). □

The following technical lemma will be key to proving the opposite (harder) direction of Theorem 1; its proof elucidates the geometrical importance of $t$ lying in the interior of $C$.

**Lemma 2.4.** Suppose $\dim(C) = n$ and $t \in \text{interior}(C)$. Fix any unit vector $\gamma \in S := \{s \in \mathbb{R}^n : |s| = 1\}$. Then there exists an open neighborhood $U$ in $S$ of $\gamma$, a graph $g_\gamma \in \mathcal{G}_k$ and a real number $\delta > 0$ such that $z(g_\gamma) \cdot u - t \cdot u \geq \delta$ for all $u \in U$.

**Proof.** For any $s \in S$, denote by $H_s$ the hyperplane in $\mathbb{R}^n$ that has normal vector $s$ and passes through the point $t$. Then $\mathbb{R}^n \setminus H_s$ consists of two open half-spaces; denote by $A^+_s$ the half-space that $s$ points into (i.e. that contains points of the form $t + \epsilon s$ for all $\epsilon > 0$).
Because $t$ is in the interior $C$ and $C$ is top-dimensional, we may pick a vertex $v_{\gamma} \in A^+_u$ of $C$. Also, we may pick a graph $g_{\gamma} \in \mathcal{G}_k$ such that $z(g_{\gamma}) = v_{\gamma}$. This is because $C \setminus v_{\gamma}$ is a convex set that is strictly smaller than $C$, but $C$ is, by definition, the smallest convex set that contains $\{z(g) \mid g \in \mathcal{G}_k\}$, so $v_{\gamma}$ must be in that set. Since $v_{\gamma}$ is in open half-space $A^+_u$, there exists an open neighborhood $U$ of $\gamma$ in $S$ such that $v_{\gamma} \in A^+_u$ for all $u \in U$. Furthermore, we may choose the neighborhood $U$ of $\gamma$ to be small enough that there exists some distance $\delta > 0$ such that $d(v_{\gamma}, H_u) \geq \delta$ for all $u \in U$.

Recall that for any $x \in \mathbb{R}^n$ and unit vector $u$, $u \cdot x$ is the signed distance of $x$ in direction $u$ from the origin (technically, the scalar projection of $x$ onto $u$). Since $t \in H_u$ and $u$ “points into” $A^+_u$, every point $x \in A^+_u$ satisfies $x \cdot u > t \cdot u$, and $x \cdot u - t \cdot u = d(x, H_u)$. Consequently, for all $u \in U$, $v_{\gamma} \cdot u - t \cdot u \geq \delta$. \hfill $\Box$

**Lemma 2.5.** Suppose $C$ is top-dimensional and $t \in \text{interior}(C)$. Then there exists a unique $\hat{\theta} \in \mathbb{R}^n$ such that $\hat{\theta}$ maximizes $L$, i.e.,

$$L(\hat{\theta}) = \sup_{\theta \in \mathbb{R}^n} L(\theta).$$

**Proof.** Suppose $\sup_\theta L(\theta)$ is not attained; then $\sup_\theta \ell(\theta)$ is not attained. Fix any constant $k < \sup_\theta \ell(\theta)$. Since $\ell$ is continuous, it attains its maximum on any compact set. Thus, there exists a sequence of points $\{\theta_j\}_{j \in \mathbb{N}}$ with $|\theta_j| \to \infty$ such that

$$\ell(\theta_j) \geq k$$

for all $j$. By passing to a subsequence, if necessary, we may assume that the sequence $\left\{\frac{\theta_j}{|\theta_j|}\right\}_{j \in \mathbb{N}}$ converges (since $S := \{x \in \mathbb{R}^n : |x| = 1\}$ is compact).
Set $\gamma \in S$ to be the vector

\[ \gamma := \lim_{j \to \infty} \frac{\theta_j}{|\theta_j|}. \]

By Lemma 2.4, there exists an open neighborhood $U$ of $\gamma$ in $S$, a graph $g_\gamma \in G_k$, and a constant $\delta > 0$ such that

\[ u \cdot (t - z(g_\gamma)) < -d \]

for all $u \in U$.

By (8), there exists $M \in \mathbb{N}$ such that $\frac{\theta_j}{|\theta_j|} \in U$ whenever $j \geq M$. Thus, whenever $j \geq M$,

\[ \ell(\theta_j) = \theta_j \cdot t - \ln \left( \sum_{g \in G_k} e^{(\theta_j) \cdot z(g)} \right) \leq \theta_j \cdot t - \ln \left( e^{\theta_j \cdot z(\bar{g})} \right) = \theta_j \cdot (t - z(\bar{g})) = |\theta_j| \cdot (t - z(g_\gamma)) \leq |\theta_j| (-\delta). \]

But then

\[ \lim_{j \to \infty} \ell(\theta_j) \leq \lim_{j \to \infty} |\theta_j| (-\delta) = -\infty, \]

which contradicts (7).

For uniqueness, note that $\ell$ is strictly concave by Proposition 2.1, and it is straightforward to prove that a strictly concave function attains its maximum at at most one point.

We now consider the case that $C$ is not top-dimensional. Recall that $V$ denotes the smallest linear subspace of $\mathbb{R}^n$ that contains a translate of $C$, i.e.

\[ V := \text{span}\{ z(g_1) - z(g_2) \mid g_1, g_2 \in G_k \} \]

and set $V^\perp = \{ u \in \mathbb{R}^n \mid u \cdot v = 0 \text{ for all } v \in V \}$.

**Lemma 2.6.** Suppose $C$ is not top-dimensional and $t \in \text{rint}(C)$. Then there exists a unique $\theta \in V \subset \mathbb{R}^n$ such that $\theta$ maximizes $L$, i.e.

\[ L(\hat{\theta}) = \sup_{\theta \in \mathbb{R}^n} L(\theta). \]

**Proof.** Consider any $n_1, n_2 \in V^\perp$, $\epsilon_1, \epsilon_2 \in \mathbb{R}$, and $\theta \in \mathbb{R}^n$. Algebraic manipulation and the fact that $z(g) - t \in V^\perp$ for all $g \in G_k$ gives

\[ (t + \epsilon_1 n_1) \cdot (\theta + \epsilon_2 n_2) - \ln \left( \sum_{g \in G_k} e^{(z(g) + \epsilon_1 n_1) \cdot (\theta + \epsilon_2 n_2)} \right) \]

\[ = t \cdot \theta - \ln \left( \sum_{g \in G_k} e^{z(g) \cdot \theta + (z(g) - t) \cdot \epsilon_2 n_2} \right) = t \cdot \theta - \ln \left( \sum_{g \in G_k} e^{z(g) \cdot \theta} \right), \]

i.e. $\ell$ is invariant under translating $t$ and all points $z(g)$ by any fixed vector in $V^\perp$, as well as under changing the $V^\perp$ component of $\theta$. Consequently, without loss of generality, we may assume that $C \subset V$ and consider only parameters $\theta$ that lie in $V$. Thus, we may view $C$ as a top-dimensional
polytope embedded in $V$, with $t$ in the interior of $C$, and apply Lemma 2.5. □

Proof of Theorem 1. Lemma 2.3 proves $t \in \text{rint}(C)$ is a necessary condition for the maximum likelihood to be attained.; Lemmas 2.5 and 2.6 prove the condition is sufficient and the uniqueness (in all of $\mathbb{R}^n$ if $C$ is top-dimensional, and in $V$ otherwise) of the maximizing parameter $\hat{\theta}$. □

3. Implications of approximate linear dependence of statistics for degeneracy

What happens if a modeler attempts to calibrate an ERGM model (i.e. find a value of $\hat{\theta}$ that maximizes $L$) based on a value of $t$ that is estimated from empirical data and lies outside of $C$? We prove the following (slightly more precise version) of Theorem 2:

Theorem 2. Suppose $t \notin C$. Let $H$ be any hyperplane in $\mathbb{R}^n$ that separates $t$ from $C$, and let $\theta$ be a normal vector to $H$ that points into the half space that contains $t$. Then

(i) $\lim_{r \to \infty} L(r\theta) = \infty$, and
(ii) $\lim_{r \to \infty} \Pr_{r\theta}\{g \in G \mid z(g) = \max_{\bar{g} \in G} \theta \cdot z(\bar{g})\} = 1$.

The condition $z(g) = \max_{\bar{g} \in G} \theta \cdot z(\bar{g})$ in item (ii) above implies that $z(g)$ is in the relative (meaning viewing $C$ as a subset of its affine hull) boundary of $C$, i.e. the statistic $z(g)$ is “as extreme as possible” in some sense.

Proof. The assumptions immediately imply $\theta \cdot t > \theta \cdot z(g)$ for all $g \in G$ (since $t$ is “farther” in the positive $\theta$ direction than points in $C$ are). Since $z(G_k)$ is discrete, it follows that there exists $\epsilon > 0$ such that $z(g) \cdot \theta < (1 - \epsilon)t \cdot \theta$ for all $g \in G_k$.

Case 1: $\theta \cdot t > 0$. Then for any $r > 0$,

$$\ell(r\theta) = r\theta \cdot t - \ln \left( \sum_{g \in G_k} e^{z(g) \cdot r\theta} \right) \geq r\theta \cdot t - \ln \left( \sum_{g \in G_k} e^{(1-\epsilon)r\theta \cdot t} \right) = r\theta \cdot t - \ln |G_k| - (1 - \epsilon)r\theta \cdot t = r\theta \cdot t - \ln |G_k|.$$ 

Case 2: $\theta \cdot t \leq 0$. Then $z(g) \cdot \theta < 0$ for all $g \in G_k$. Then for any $r > 0$ and any fixed $g_0 \in G_k$,

$$\ell(r\theta) \geq - \ln \left( \sum_{g \in G_k} e^{z(g) \cdot r\theta} \right) \geq - \ln(e^{z(g_0) \cdot r\theta}) = -rz(g_0) \cdot \theta.$$ 

In both cases, (i) follows immediately.

The limit (ii) follows immediately from the fact that $z(G_k)$ is a discrete set, and the weight $P_{r\theta}$ assigns to a graph $g$ is proportional to $e^{r\theta \cdot z(g)}$. □

Theorem 2 may be of particular potential importance to modelers when $C$ is “skinny,” since even a tiny error estimating the coordinates of $t$ could push $t$ outside of $C$. When $\text{dim}(C) < n$ – i.e. when the statistics that are the component functions of $z$ are not linearly independent – the set $C$ has...
zero measure, so it is unlikely for an empirically estimated value of $t$ to lie in $C$. An example of two graph statistics that can easily be seen to be linearly dependent are mean vertex degree and total number of edges (c.f. Figure 1); while ERGMs practitioners know to avoid simultaneously using both of these statistics, there may be other collections of statistics that are linearly dependent but cannot be determined to be so. There is, to the best of our knowledge, no general method (other than directly computing a sufficient collection of graph statistics) for verifying that a collection of graph statistics is linearly independent.

Even when a collection of graph statistics are linearly independent, it is possible that they are “approximately linearly dependent,” meaning that the value of one statistic is constrained to lie in a “small” interval by the values of the other statistics. Extremal graph theory provides a wealth of results governing how big or small some graph statistic can be, given constraints on other statistics about the graph. For example, Turán’s Theorem, a cornerstone of extremal graph theory, gives an upper bound on the number of edges that a graph with $n$ vertices that does not contain a $(r + 1)$-clique can have. For a survey of results in extremal graph theory, we refer the interested reader to [4] and [23]. Restricting attention to empirically observed social network graphs, work by Faust asserts that the number of triangles is “well-predicted by lower order graph features (density and dyads), accounting for around 90% of the variability in triad distributions” [8]. Triangle counts are known to be associated with degenerate models ([15, 12]). On the algorithmic side, developing techniques for estimating the number of $k$-cliques in a graph based on partial information about the graph is an active area of inquiry (see, e.g. [6]). Approximate linear dependence of statistics, coupled with imperfectly estimated values of $t$, may be a mechanism through which degeneracy arises during model training.
