Abstract—Few-shot object detection (FSOD) has thrived in recent years to learn novel object classes with limited data by transferring knowledge gained on abundant base classes. FSOD approaches commonly assume that both the scarcely provided examples of novel classes and test-time data belong to the same domain. However, this assumption does not hold in various industrial and robotics applications (e.g., object grasping and manipulation), where a model can learn novel classes from a source domain while inferring on classes from a different target domain. In this work, we address the task of zero-shot domain adaptation, also known as domain generalization, for FSOD. Specifically, we assume that neither images nor labels of the novel classes in the target domain are available during training. Our approach for solving the domain gap is two-fold. First, we leverage a meta-training paradigm, where we learn domain-invariant features on the base classes. Second, we propose various data augmentations techniques on the few shots of novel classes to account for all possible domain-specific information. To further constraint the network into encoding domain-agnostic class-specific representations only, a contrastive loss is proposed to maximize the mutual information between foreground proposals and class prototypes, and to reduce the network’s bias to the background information. Our experiments on the T-LESS dataset show that the proposed approach succeeds in alleviating the domain gap considerably without utilizing labels or images of novel categories from the target domain.

I. INTRODUCTION

Autonomous robotic systems are required to understand and interact with their surrounding environment. With the advent of deep learning, object detection (OD) is a core functional module in the robot’s perception pipeline. In various industrial applications, a situation may arise where novel classes are encountered and ought to be learned, such as a pick and place, where a robot is tasked to handle new objects. However, acquiring meaningful samples can be limited, impeding the training of a data-hungry object detector. Moreover, the few provided examples of novel classes might be drawn from a different domain distribution than those encountered at test-time. For instance, the new classes during training can be provided in the form of CAD-rendered images only, which entails a synthetic-to-real domain gap. Another possible scenario would feature data that might have been collected with a camera sensor in a limited environment (for example, by taking mobile images of objects on a table), while the robot should detect the objects for example with a different in-hand camera.

Fig. 1. A highlight of the difference among various related learning problems: (i) object detection (OD), (ii) few-shot object detection (FSOD), (iii) domain-adaptive object detection (DA-OD), and (iv) our proposed zero-shot domain adaption task for few-shot object detection (ZDA-FSOD). The available data for each problem during training is shown inside each block. The dashed box denote that the data may not be available.

Assuming the same domain distribution for training and test-time may result in a suboptimal detection accuracy.

In this paper, we address the task of detecting novel objects in a target domain, given limited data in a source domain. This complex task is at the intersection of two learning paradigms: few-shot learning (FSL) and domain adaptation (DA) - see Fig. 1. FSL [1] addresses the data scarcity problem by transferring knowledge from base classes with abundant data to novel classes with scarce data, in an attempt to mimic the human cognitive ability to learn new concepts from limited examples. Few-shot object detection (FSOD) is a sub-discipline of FSL. A typical approach for FSOD is based on meta-learning [2], [3], [4], [5], [6], [7], [8], [9], which seeks to rapidly learn novel classes by leveraging class-agnostic representations extracted in an episodic training manner. In each episode, different tasks are being solved, where a task may be the localization of different objects in a set of query images, given a small set of support images of the same classes. However, the aforementioned FSL methods operate under the assumption that train and test images share the same data distribution. This assumption is often violated in the real world, where multi-level domain shifts on both the image-level (e.g., texture, illumination, resolution and background clutter) and instance-level (e.g., object size and appearance) can occur. Current meta-detectors are not optimized to operate across domains, and are susceptible towards encoding domain-specific and class-specific information as it has been shown that convolutional networks are often biased towards texture [10].
Unsupervised domain adaptation (UDA) [11], [12] is a closely related learning paradigm that transfers knowledge from abundant labeled source domain, $\mathcal{D}_S = \{X_S, Y_S\}$, to a label-scarce target domain, $\mathcal{D}_T = \{X_T\}$. $X$ and $Y$ denote the input data samples and the labels, respectively. Zero-shot domain adaptation (ZDA) [13], [14], [15], also known as domain generalization, further assumes that the data samples in the target domain, $X_T$, are not available. ZDA thrives to learn domain-agnostic features on multiple source domains [16], or to learn the domain shift from an irrelevant task and transfer it to the task of interest using only source domain data [15], [17], [14]. Nevertheless, these frameworks were designed for the classification task and are not applicable in FSOD for two reasons. First, the existence of paired samples in the irrelevant task is often assumed, which is rarely the case in OD datasets. Second, they involve generative adversarial networks (GANs) [18] to synthesize samples of individual objects in the target domain. However, OD datasets contain complex scenes with many objects per image, which in turn imposes a great challenge on GANs to generate meaningful images. Besides DA, domain randomization (DR) [19] also shares a similar interest, where it mimics the possible physical world scenario through various object simulations (e.g., illumination, pose, size) to learn a rich distribution covering the test-time data distribution.

In this work, we introduce the zero-shot domain adaption task for FSOD (ZDA-FSOD), where we learn to detect novel classes in a target domain given only limited samples from the source domain. We leverage a meta-learning based framework and propose a two-fold approach to address this challenging problem. First, a mixed domain training strategy (MDTS) is performed on the base task, and second a domain randomization (DR) step is conducted on the novel task. On the base task, target data is mixed with source data across various episodes in the meta-training to extract domain-invariant knowledge. On the novel task, we propose a number of pixel-level and feature-level augmentations on both the query and support images. To promote domain-agnostic class-specific feature embeddings, the mutual information between foreground proposals from the query image and the associated class prototype is maximized by encouraging their embeddings to be closer in the feature space while being further apart from a negative class prototype. We perform experiments on the T-LESS [20] dataset to validate the effectiveness of our approach.

II. RELATED WORKS

A. Few-Shot Object Detection

FSOD methods are either transfer learning or meta-learning based. Firstly, the transfer learning based few-shot detectors [21], [22], [23], [24], [25] aim to transfer knowledge from base classes to novel classes via fine-tuning. Conversely, meta-detectors strive to extract knowledge across different detection tasks in order to generalize better on new tasks. Meta-detectors can be grouped into two main approaches: learn to finetune [8] and learn to measure [22], [7], [6], [5], [4], [3]. The former seeks to learn category-agnostic parameters that enable the learning of novel category-specific weights on the new task [8]. In contrast, the latter performs an exemplar search at the instance level given a support set with few images. This search is accomplished through a feature fusion between query and support features. However, the models vary in 3 aspects: where to fuse, how to fuse and the training strategy. MetaYOLO [7] performs feature fusion directly before the detection head. Similarly, the fusion in two-stage detectors like MetaRCNN [6] and FsDetView [4] occurs at the instance-level after the region proposal network (RPN). FSOD-RPN [5] adds feature fusion before the RPN to filter the proposals by class category. Moreover, it is the only framework which employs a two-way contrastive training strategy. CME [3] maximizes the margin space between base classes during base training to accommodate the novel classes while seeking margin equilibrium during fine-tuning to avoid high variations in novel features.

B. Domain Adaptation

Recent domain adaptation methods via label-scarce or none target domain data can be summarized into three main approaches: unsupervised domain adaptation (UDA), domain randomization (DR), and zero-shot domain adaptation (ZDA). UDA [12] strives to transfer knowledge across various domains by mitigating the distributional variations. Commonly, UDA methods attempt either a feature-level adaptation in latent space or a pixel-level adaptation via image-to-image translation techniques. Chen et al. proposed domain adaptive Faster R-CNN (DA-FRCNN) [26] that integrates Faster R-CNN [27] with adversarial training to align both the image and instance distributions across domains whilst applying a consistency regularization to learn a domain-invariant RPN. A variety of adversarial-based methods later followed [28], [29], [30], [31], [32], [33], [34].

DR [19], on the other hand, learns domain-invariant features via rendering images with random illumination, pose, background, etc, which attempts to mimic the real world distribution. Defying the common assumption of task-relevant target domain data availability, ZDA [13], [14], [15] leverages task-irrelevant dual-domain pairs with neither images nor labels from the task-relevant target domain. Recently, various DR methods were introduced in robotics applications like 6D object detection [35], 6D object tracking [36], object localization [37], person detection [38] and segmentation [39]. Nevertheless, the aforementioned DR methods mostly rely on a blender or a game engine to generate semi-realistic images. In contrast, we introduce pixel-level and feature-level data augmentations which are applicable to any domain gap.

III. METHODOLOGY

In this section, we formulate the zero-shot domain adaptation problem for few-shot 2D object detection before presenting our approach. We define the base task as $T_B = \{X_B, Y_B, P(Y_B|X_B)\}$ and the novel task as $T_N = \{X_N, Y_N, P(Y_N|X_N)\}$, where $X$ refers to the data samples and $Y$ refers to the set of object annotations comprising
bounding box coordinates and class labels. The base classes \( \mathcal{C}_B \) and novel classes \( \mathcal{C}_N \) are disjoint (i.e., \( \mathcal{C}_B \cap \mathcal{C}_N = \emptyset \)). In ZDA, it is often assumed that abundant base target domain data is available and labeled, that is \( X_B = \{ X^S_B, X^T_B \} \) and \( Y_B = \{ Y^S_B, Y^T_B \} \), where \( X^S \) and \( X^T \) refer to the source and target domain data samples, respectively. \( Y^S \) and \( Y^T \) represent the set of object annotations for the source and target domain data samples, respectively. In contrast, in the novel task only a few-shot of source domain data is available, \( X_N = \{ X^S_N \} \) and \( Y_N = \{ Y^S_N \} \). In this work, we further relax this assumption and experiment under two settings: single-domain samples (S-I), where only source data is available in the base task, and dual-domain samples (S-II), where we assume that at least a few examples in \( \{ X^S_B, X^T_B \} \) exist. The former is harder than the latter since no knowledge about the target domain is present at all.

### A. Baseline Description

Our approach extends the FSOD-RPN [5] framework to tackle the ZDA-FSOD task. FSOD-RPN [5] is a two-stage meta-detector built upon Faster-RCNN [27]. Given a query image, and support images, FSOD-RPN extracts a class prototype from the support images and seeks to detect the objects in the query that belong to the same class. Specifically, it modifies the RPN to filter irrelevant object proposals by fusing the query and support features. The detection head is also modified to integrate a fusion between the query and support feature embeddings via concatenation, followed by an attention mechanism on a global, pixel and patch level. We opt for FSOD-RPN [5] as our baseline since it was the state-of-the-art meta-detector at the start of this work. The baseline along with our contributions in the meta-testing phase is shown in Fig. 2.

### B. Mixed Domain Training Strategy on the Base Task

To tackle the ZDA-FSOD problem, we first propose to adapt the network on the base task. To avoid overfitting on domain-specific features, we hypothesize that the model should be exposed to more than one domain during training. To this end, we leverage the meta-learning paradigm by redefining the episodic base tasks during the meta-training phase. Rather than solely learning the base tasks on source domain data, instead we augment the base source data with a few-shots from the target domain (i.e. \( \{ (X^S_B, Y^S_B), (X^T_B, Y^T_B) \} \)), to extract cross-domain knowledge. We propose to perform mixed domain training on both the query and support levels. Specifically, during each episode in the meta-training, the network observes query images drawn from either the source or target domain, while the support images might be sampled from a single domain or a mixture of both. The proposed mixed domain training strategy (MDTS) allows the network to observe visual cues in the query image that are less domain-dependent and to transfer the acquired domain knowledge to the novel task by freezing the feature extractor and fine-tuning the region-of-interest (RoI) and detection heads. In a more challenging setting, where no target domain data is available in the base task, we leverage data augmentations presented in Section III-C on the source data. The training set becomes \( \{ (X^S_B)^t, Y^S_B \} \), where \( t \in \mathcal{T} \) is a transform. It is essential that the model observes more than one domain at this stage, since the feature extractor is frozen in the next stage. Compared to training only on target domain data in the base task \( \{ (X^T_B, Y^T_B) \} \), the proposed MDTS is shown to work better under the two aforementioned settings (Sec. V) because it prevents overfitting on a single domain.

### C. Data Augmentation Schemes for Domain Randomization

Since the learning of novel classes is conducted in a supervised manner, the data scarcity makes the model highly prone to overfitting on the domain information. To this end, we propose to leverage various data augmentation techniques during the meta-testing phase. Contrary to previous approaches in domain randomization [37], [35], [39], [38],
we do not use a blender or a game engine to generate multiple poses and lighting conditions. Instead, we leverage pixel-level and feature-level augmentations which allow for the proposed method to tackle any domain gap, rather than being restricted to a sim2real application. The following augmentations are proposed:

1) Color Jittering: To mimic diverse point-wise lighting conditions, we randomly apply color jittering by changing the brightness, contrast, hue, and saturation of both the query and support images. Moreover, this helps the network to be less prone to overfitting the synthetic colors.

2) Gaussian Blur: In case of a moving camera and/or the object of interest, or a low resolution camera sensor, the resulting captured image may be out of focus and blurred. Consequently, we propose to randomly apply Gaussian blur with random kernel sizes and standard deviations on both the support and query images to account for such distortion.

3) Gaussian Noise: The scarcity of novel examples can generate a highly noisy learning signal resulting in adverse consequences on the computed features. As a remedy, we randomly add Gaussian noise with various small standard deviation values on both the support and query images. This augmentation was inspired from the work on adversarial attacks on neural networks [40], where it was found that even a small imperceptible perturbations can fool the network’s decision and push a sample away of the classifier’s decision boundary. The aim is to encourage the network to be less sensitive to the absolute pixel values of the few available support and query images, in order to decrease the number of false positives and negatives. The increased network’s robustness against pixel perturbations results in a higher transferability across domains.

4) Background Augmentation: Training on abundant source domain data may result in overfitting the backgrounds of the training images, which are non-transferable across domains. In contrast, foreground object classes should have the same feature representation across domains. To avoid domain confusion caused by a different background at test-time, we propose to extract the objects from the given source query images using their masks or bounding boxes and paste it on real background images using the PASCAL VOC [41] 2007 and 2012 datasets, similar to [35]. Rather than applying this augmentation to a single object, we opt to apply it on the query image which contain multiple foreground objects. Specifically, an image is randomly sampled from the VOC dataset and resized to the resolution of the source query image. The extracted objects are then placed at the exact same location in the VOC image to keep the bounding box labels unchanged. The aforementioned data augmentations are presented in Fig. 3.

D. Contrastive Proposal-Prototype Loss

Learning discriminative features for the novel classes across domains with limited data samples is quite challenging. An often observed drawback is that the model becomes highly confused (i.e., increased false positives/negatives) between classes with similar appearance, or between foreground and background in the new domain. A crucial property of a robust feature representation is that it should encode class-specific domain-agnostic information, meaning it should only be sensitive to the shape of the foreground object. To enforce semantic consistency between foreground and background embeddings, we propose a contrastive proposal-prototype loss (CP$^2$) between the foreground proposals from the query image and both the positive and negative support prototype classes. Contrastive losses have been successfully utilized to map two different views of the same scene to a similar point in the representation space [42], [43], [44], [45]. In this work, they are utilized to maximize the mutual information between instance-level features in the query and class-prototypes from the support images, regardless of their augmentations. Our aim is to make the decision boundary of the detector biased towards...
the topology and semantics of the object classes and not to the domain information.

We define the features of the foreground query proposals as \( \{ z_i \}_{i=1}^{P_f} \), where \( P_f \) is the number of foreground proposals. Let \( \{ z_i^+ \}_{i=1}^{K} \) denote positive supports features (that should be detected in the query) while \( \{ z_i^- \}_{i=1}^{K} \) denotes negative support features (a randomly sampled class not to be detected). \( s_i \) denotes the \( i^{th} \) support image and \( K \) is the total number of support shots per class. \( c^+ \) and \( c^- \) are the positive and negative class prototypes and are computed by averaging \( \{ z_i^+ \}_{i=1}^{K} \) and \( \{ z_i^- \}_{i=1}^{K} \), respectively, as in our baseline [5]. Our aim is to map foreground proposals of the query image \( q \) within the vicinity of \( c^+ \) while pushing them away from \( c^- \). Specifically, we utilize a triplet margin contrastive loss, which attempts to shorten the distance between \( z_i^+ \) and \( c^+ \) smaller, and to make the distance between \( z_i^- \) and \( c^- \) larger than a hyperparameter margin \( m \). The triplet margin loss enables a more relaxed feature space that accommodates two similar data objects whose features have a large magnitude in feature space, will have a large Euclidean distance but a smaller angle between them. The CP² loss is expressed as follows:

\[
L_{CP^2} = \frac{1}{P_f} \sum_{j=1}^{P_f} \max \left( d(z_i^+, c^+) - d(z_i^-, c^-) + m, 0 \right),
\]

\[
d(v_1, v_2) = \frac{v_1 \cdot v_2}{\| v_1 \| \| v_2 \|}.
\]

However, we observe that computing the class prototypes by directly averaging the \( K \)-support shot features might not depict the true class prototype distribution due to the scarcity of support shots. Moreover, if the standard deviation between support features is high, the averaging might yield a less informative class prototype. To tackle the aforementioned issues, we propose a data augmentation scheme on the support feature level. Specifically, assuming that the support feature representation follows a Gaussian distribution, we compute the mean feature \( f \) over the \( K \)-shots, and their standard deviation, \( \sigma_f \). During each iteration in the meta-testing phase, a latent vector is sampled from the Gaussian distribution \( \mathcal{N}(f, \sigma_f^2) \) and is considered as the class prototype. This feature-level augmentation strategy is also implemented during inference to enhance the class prototypes.

The contrastive losses and data augmentations complement each other. The augmentations introduce perturbations in the feature space enabling the network to explore more examples. A data augmentation might even push an object beyond the detector’s decision boundary, simulating the effect of a new domain during inference (see Figure 4). In our experiments, we observe that strong augmentations can sometimes destabilize the training on the novel task. On the other hand, the contrastive losses attract these far-away features back together by enforcing a semantic consistency, which enables a smoother training and a higher average precision.

### IV. Experimental Setup

#### A. Dataset

To evaluate the proposed ZDA-FSOD, a dataset featuring multiple domains is required. Due to the nature of this problem, the most suitable publicly available dataset is T-LESS [20]. T-LESS comprises 30 industrial objects without any notable texture, distinct color, or reflectance features. There are two available sets of data: synthetic rendered images including a total of 50 scenes with \( \sim 1000 \) images each (source domain) and real images featuring 20 different scenes (target domain). For the real data, we use only the data captured by the PrimeSense CARMINE 1.09 RGB-D sensor. However, all the experiments utilize only the RGB data without incorporating any depth information.

To prepare the T-LESS dataset to the FOSD task, we propose a train and test splits for the base and novel classes. We split the T-LESS objects into 19 base classes and 11 novel classes. A detailed summary of the utilized splits is presented in Table I. Moreover, we split the 20 scenes of real images into 8 training scenes, \( \{2, 3, 5, 6, 7, 9, 11, 12\} \), featuring mainly the base classes, and the remaining 12 containing novel training and testing scenes. The inference is done on unseen classes featuring the 11 novel objects. We report the inference results with \( K = 5 \) and \( K = 10 \).

#### B. Evaluation Metrics

The utilized evaluation metrics are average precision (AP) and average recall (AR) averaged over 10 intersection over union (IoU) thresholds ranging from 0.5 to 0.95 with a 0.05 step. The reported AP and AR values are averaged across all classes. Moreover, we report AP50 and AP75 denoting the AP at IoU = 0.5 and IoU = 0.75, respectively.

#### C. Implementation Details

For a fair quantitative comparison, we meta-train all models on the base task for 5 epochs with an SGD optimizer using the default parameters as [5] and a batch size of 8. The base learning rate is 0.004 for the first 3 epochs and 0.0004 for another 2 epochs. For meta-testing, we perform 6k iterations with a learning rate of 0.001. Similar to [5], the shorter side of the query image is resized to 600 pixels while the longer side is resized to 1000. Moreover, each support image is cropped around the target object with 16-pixel image context, zero-padded, and then resized to 320 × 320.

In the following sections, we refer to the proposed data augmentations and contrastive proposal-prototype loss during meta-testing as the domain randomization approach (DR).
V. RESULTS

In the following section, we evaluate the proposed approach on T-LESS [20] dataset. We consider FSOD-RPN [5] as our baseline model. As mentioned in Section III, two data settings are considered during meta-training: S-I single-domain samples and S-II dual-domain samples. Under S-II, the MDTS strategy mixes source and target samples during training, while it simulates the target domain samples via the proposed data augmentations in III-C under S-I.

A. Main Results

In Table II, we report the results on the T-LESS dataset under K = 5, 10-shot settings. This set of experiments is designed to show the impact of the MDTS on the detector’s performance during meta-training, with and without the proposed DR approach during meta-testing. First, we notice that without any DR, the baseline exhibits a large performance drop in AP and AR, from 51.7 to 6.1, and 62.7 to 13.3, respectively. Second, the MDTS is shown to surpass meta-training on either domain alone under settings S-I and S-II. Specifically, MDTS surpasses even target-only meta-training. This can be attributed to the fact that the model reaches a better optimum when two different data distributions of the same classes are observed during meta-training.

Third, the proposed DR approach is able to considerably improve the AP and AR on different meta-training settings.

When performed on a source-only meta-trained model, DR boosts the AP by 11.2 points under the 10-shot setting (row 5). The model can even reach an AP of 26.3, almost 51% of the oracle’s performance, without seeing any target domain sample in the meta-training and meta-testing phases (row 7 in Table II). The best performance on 5 and 10-shot, 17.4 and 31.2, were reached using dual-domain samples in meta-training and DR in meta-testing (row 8 in Table II). However, the relative performance gain is higher under the 10-shot settings (60% of the oracle) than under the 5-shot settings (46.4% of the oracle), due to the very sparse nature of the latter setting.

It is important to note that under the dual-domain setting, we train with source domain samples and a few-shot of the target samples (10-shot per class). We have also experimented a setting where both datasets are fully available, but the training did not converge. We hypothesize that either the partially frozen ImageNet pretrained feature-extractor or the fusion mechanism in the Attention-RPN is a limiting factor. However, more investigations are needed.

B. Ablation Study on Domain Randomized Meta-Testing

In Table III, we conduct different experiments to study the impact of different proposed augmentations during meta-testing. In all experiments, we use a meta-trained network on source and few-shot target domain data, S-II. Starting from

source only meta-testing (configuration A), we incrementally apply augmentations and report the results. First, we note that the color jittering, in configuration B, significantly boosts the AR by 10 points denoting a steep decrease in the false negatives, and a 2.2 points improvement in the AP. While introducing the Gaussian blur (C) further improves the AP by 0.6 points and slightly deteriorates the AR by 0.9 points, the Gaussian noise (D) enhances the AP by 2.5 points and recovers the AR by a surplus with a total of 1.1 points. This illustrates the important role played by introducing the pixel-level perturbations in yielding a more robust model towards simple distortions. Next, in configuration E, we add the VOC background augmentation on the query images, and notice an improved AP. Finally, the best result in our experiments was achieved by adding the CP loss which boosts the AP by 1 point, and the AR by 3.4 points to a value of 61.0, which is close to the oracle’s AR, 62.7. We have also observed that the introduced contrastive loss and feature-level augmentation stabilize the meta-testing, besides decreasing the number of false negatives and positives.

C. Ablation Study on Cross-Domain Training

This set of experiments is designed to explore different cross-domain settings with the aim to analyze the existing domain gaps in meta-training and meta-testing, as a guide to future research in this direction. The proposed DR approach is only used in the highlighted rows in Table IV. We can draw 3 conclusions from the results. First, the existence of target-domain samples for novel classes can almost bridge the domain gap, even if no target domain samples were seen during meta-training. Second, the model can still benefit with the MDTS in the meta-training, regardless of the seen samples during meta-testing. This is shown in rows 3, 4, 7, 8 in Table IV where the model can achieve an AR higher than the oracle under the 5, 10-shot settings, a higher AP under the 5-shot setting and an AP close to the oracle under the 10-shot setting. Third, even when the DR approach is applied during target-only meta-testing, it improves upon the oracle in 5-shot settings (AR and AP) and 10-shot settings (AR).

However, we note that the existence of target domain samples during meta-testing is an assumption that does not hold in many applications, as there exists often a difference in the background, the camera sensor, or a sim2real domain gap. Additionally, it is not practical to finetune the pretrained model on a new domain, every time a new camera is installed, or a change in the environment occurs.

VI. Conclusion

In this paper, we introduced the task of learning to detect new classes in an unseen domain, given a few-shots from a source domain. This paves the way towards a wide variety of applications in different robotics and industrial use-cases. To this end, we proposed to mimic the domain shifts that may be encountered during the test-time by designing a domain randomization strategy in a meta-learning paradigm. We proposed a novel contrastive loss that, besides stabilizing the novel task learning, fosters the network to encode domain-agnostic class-specific feature embeddings that are less sensitive to the surrounding environment variations. We also highlighted the effect of meta-training with a mixed domain samples, which either include source and target samples or augmented source samples, that simulate various domains. The experiments have shown that we successfully readjusted a meta-detector trained using source domain samples, to tackle the existing domain gap for an unseen domain under a few-shot setting. We believe that the proposed method is beneficial to numerous practical real-world robotic autonomous systems and encourages further research on tackling domain shifts when learning novel objects in unseen domains.
