Circular photon orbit and black hole shadow are significantly important issues in physics and astronomy, and a number of breakthroughs have been witnessed in recent years. Conventionally, the stable and unstable circular photon orbits are obtained using the effective potential of test particles moving in black hole spacetime. In this work, a pure geometric approach is developed to calculate these circular photon orbits and black hole shadow radius. Furthermore, it can be proved that our geometric approach is completely equivalent to the conventional approach based on effective potentials of test particles.

Backgrounds and Introduction: Black holes are massive compact objects predicted by Einstein’s general theory of relativity. They have attracted large numbers of interests in high-energy physics, astrophysics and astronomy over the past decades. Significantly important information on gravitation, galaxies, thermodynamics and quantum effects in curved spacetime can be revealed from black holes [1–5]. Recently, huge progresses in black hole physics have been witnessed. The gravitational wave signals from binary black hole mergers were detected by LIGO and Virgo [6, 7]. The high resolution images of supermassive black hole at the center of galaxy M87 were captured by Event Horizon Telescope (EHT) [8, 9].

The circular photon orbit and shadow radius are important features for black holes. The particle motions, gravitational lensing, optical imaging and other aspects of black hole can be studied from these quantities. Since the observation of black hole image in galaxy M87 by EHT collaboration, the circular photon orbits and black hole shadow have became extremely hot topics in physics and astronomy. Conventionally, these circular photon orbits and black hole shadow radius can be calculated from the effective potential of test particles moving in black hole spacetime [10–18].

In the present work, a pure geometric approach is developed to obtain the stable and unstable circular photon orbits, as well as black hole shadows. Our approach is implemented in the optical geometry of black hole spacetime. In this approach, the geodesic curvature and Gauss curvature in optical geometry turn out to be crucial quantities to determine the circular photon orbits. The stability of circular photon orbits is reflected by an elegant theorem in differential geometry and topology —— the Hadamard theorem. Furthermore, in this work, we also prove that the geometric approach developed in this work is completely equivalent to the conventional approach based on effective potential of test particles.

Optical Geometry of Black Hole Spacetime: The optical geometry is a powerful tool to study the motions of photons (or other massless particles which travel along null geodesics) in gravitational field. [19–22]. For a four dimensional spacetime, its optical geometry can be constructed from the null constrain \( dt^2 = 0 \).

\[
dt^2 = g_{\mu\nu}dx^\mu dx^\nu \quad \text{Spacetime Geometry} \quad dt^2 = 0 \quad \implies dt^2 = g_{ij}^{OP}dx^i dx^j \quad \text{Optical Geometry}
\]

The properties of optical geometry are strongly depend on the symmetry of gravitational field and black hole spacetime. For a spherically symmetric black hole, its optical geometry gives a Riemannian manifold [19–21]. For a rotational black hole, the correspond optical geometry is a Randers-Finsler manifold [22–25]. Further, if we consider particle motions in the equatorial plane, a two dimensional manifold can be constructed from the optical geometry.

\[
dt^2 = g_{ij}^{OP}dx^i dx^j \quad \text{Optical Geometry} \quad \theta = \frac{\pi}{2} \quad \implies dt^2 = g_{ij}^{OP}dx^i dx^j \quad \text{Optical Geometry (Two Dimensional)}
\]

In two dimensional manifold, a number of elegant and classical theorems in surface theory and differential geometry could provide useful tools to study the particle motions and particle orbits. In this work, our new geometric approach on circular photon orbits and black hole shadow is implemented in two dimensional optical geometry.

Gauss Curvature and Geodesic Curvature: There are several key quantities which describe the geometric properties of optical geometry. It would be turned out that Gauss curvature and geodesic curvature in optical geometry play central roles in determining the circular photon orbits for black holes. The Gauss curvature is the intrinsic curvature of a two dimensional surface. The geodesic curvature is the curvature of one dimensional curves lived in two dimensional curved surface, which measures how far these curves are from being geodesics. If \( \gamma \) is a geodesic curve in surface \( S \), its geodesic curvature \( k_g(\gamma) \) automatically vanishes. Notably, both Gauss
curvature and geodesic curvature only rely on the intrinsic metric of two dimensional surface $S$, regardless of the embedding of this surface into higher dimensional spacetime [26].

**Circular Photon Orbit:** The circular photon orbits are important features of black holes. They are closely connected with particle motions, gravitational lensing and black hole shadows. The circular photon orbits are classified into two categories: the stable and unstable circular photon orbits. They may exhibit significantly different features, especially for the geodesics nearby. For unstable circular photon orbit, when photon beams have a departure from the circular orbit, they would either fall into black hole or move to infinity. No elliptical photon orbits are admitted near the unstable circular photon orbit. Conversely, there are many elliptical photon orbits near the stable circular photon orbit. The stable and unstable circular photon orbits are illustrated schematically in figure 1.

In this work, a pure geometric approach is developed to obtain these circular photon orbits. We choose the spherical symmetric black holes to show our geometric approach. The cases of rotational black holes are left for incoming study. For spherical symmetric black hole

$$d\tau^2 = f(r)dt^2 - \frac{1}{f(r)}dr^2 - r^2(d\theta^2 + r^2 \sin^2 \theta d\phi^2)$$ (3)

the optical geometry restricted in the equatorial plane $\theta = \pi/2$ gives

$$dt^2 = \tilde{g}_{ij}dx^i dx^j = \frac{1}{[f(r)]^2}dr^2 + \frac{r^2}{f(r)}d\phi^2$$ (4)

The circular photon orbits could be determined by Gauss curvature and geodesic curvature in optical geometry. Firstly, for circular photon orbit $r = r_{ph}$, which is a geodesic curve in optical geometry [34], its geodesic curvature vanishes naturally [28, 29, 36]

$$\kappa_g(r = r_{ph}) = \frac{1}{2 \sqrt{\tilde{g}_{rr}}} \left. \frac{\partial \log(\tilde{g}_{\phi\phi})}{\partial r} \right|_{r=r_{ph}} = \left[ \frac{f(r)}{r} - \frac{1}{2} \cdot \frac{\partial f(r)}{\partial r} \right]_{r=r_{ph}} = 0$$ (5)

In this way, the radius of circular photon orbit is obtained. The following question is how to distinguish stable photon orbits from unstable photon orbits. The following Hadamard theorem in differential geometry would answer this question appropriately.

**Hadamard Theorem:** For a two dimensional complete Riemannian manifold with nonpositive Gauss curvature, there is only one geodesic curve from $p$ to $q$ belong to the same homotopy class, and this geodesic curve minimizes the length in this homotopy class [30, 31].

For spherical symmetric black hole, if we restrict the optical geometry in two dimensional equatorial plane, the Gauss curvature in the Hadamard theorem can be calculated through [28, 29]

$$\mathcal{K} = -\frac{1}{\sqrt{\tilde{g}^{OP}}} \left[ \frac{\partial}{\partial \phi} \left( \frac{1}{\sqrt{\tilde{g}^{OP}}} \frac{\partial \sqrt{\tilde{g}^{OP}}}{\partial \phi} \right) + \frac{\partial}{\partial r} \left( \frac{1}{\sqrt{\tilde{g}^{OP}}} \frac{\partial \sqrt{\tilde{g}^{OP}}}{\partial r} \right) \right]$$

$$= -\frac{1}{2} \cdot \frac{d^2 f(r)}{dr^2} - \left[ \frac{1}{2} \cdot \frac{df(r)}{dr} \right]$$ (6)

where $\tilde{g}^{OP} = det(\tilde{g}^{OP}_{ij})$ is determinant of optical metric.

For stable circular photon orbit, because of the elliptical photon orbits nearby, there are many geodesic curves which can be homotopic to the circular photon orbit (the circular photon orbit and elliptical photon orbit belong to the same homotopy class). In this case, the Gauss curvature of optical geometry must be positive, otherwise it would violate the Hadamard theorem. On the contrary, for unstable circular photon orbit, no elliptical orbits homotopic to circular photon orbit exist. Then unstable circular photon orbit itself forms the whole homotopy class, which correspond to the negative Gauss curvature in the Hadamard theorem (we assume the Gauss curvature of optical geometry is nonzero, otherwise the black hole spacetime would be flat). From the Hadamard
Theorem, we obtain the following criterion to determine whether the circular photon orbit is stable or unstable [35].

\[ \mathcal{K} < 0 \Rightarrow \text{The circular photon orbit } r = r_{ph} \text{ is unstable} \]

\[ \mathcal{K} > 0 \Rightarrow \text{The circular photon orbit } r = r_{ph} \text{ is stable} \]

**Black Hole Shadow:** Black hole shadow is the dark silhouette of black hole image in a bright background. The size and shape of black hole shadow depends not only on black hole parameters, but also on the position of observers [17]. In this work, we concentrate on the idealized situation where observer is located at infinity, and there are no light sources between the observer and black hole. In this case, the radius of black hole shadow detected by observer is just the critical value of impact parameter \( b = b_{\text{critical}} \). In the gravitational field, light beams emitted from infinity with impact parameter \( b < b_{\text{critical}} \) would reach the unstable circular photon orbit exactly. The light beam emitted with impact parameter \( b = b_{\text{critical}} \) would reach the unstable circular photon orbit exactly. The light beam emitted from infinity with impact parameter \( b > b_{\text{critical}} \) would fall into the black hole.

**Black Hole Shadow**

The radius of black hole shadow detected by observer located at infinity, and it is consistent with previous results [13, 17]. Based on above procedures, the shadow radius for arbitrary spherical symmetric black hole can be calculated. In the present work, we choose two typical examples in general relativity —- Schwarzschild black hole and Reissner-Nordström black hole. The circular photon orbits and black hole shadow radius for these black holes are summarized in table I.

**Equivalence between Our Geometric Approach and Conventional Approach:** The geometric approach developed in this work is completely equivalent to the conventional approach based on effective potentials of test particles moving in the gravitational field. In conventional approach, the circular photon orbit can be solved by analyzing the extreme points of effective potential \( V_{\text{eff}}(r) \). Particularly, the unstable circular photon orbit \( r = r_{\text{unstable}} \) corresponds to local maximum of effective potential, and the stable circular photon orbit \( r = r_{\text{stable}} \) is the local minimum of effective potential.

We now demonstrate the equivalence between these two approaches. In spherical symmetric black hole spacetime, if we restrict test particles moving in the equatorial plane \( \theta = \pi/2 \), the equation of motion eventually reduces to [14]

\[ \frac{1}{2} \left( \frac{dr}{d\lambda} \right)^2 + V_{\text{eff}}(r) = \frac{1}{2} \cdot E^2 \]  

(11)

where effective potential of test particles is defined by

\[ V_{\text{eff}}(r) \equiv \frac{f(r)}{2} \cdot \left( \frac{L^2}{r^2} + \epsilon \right) \]  

(12)
TABLE I. The circular photon orbit and black hole shadow radius detected by observer at infinity. This table summarize the results for Schwarzschild black hole and Reissner-Nordström black hole. All quantities calculated using our new geometric approach agree with the results obtained using conventional approach based on effective potential.

*Note that optical geometry is defined outside the black hole horizon, which is \( r > 2M \) for Schwarzschild black hole and \( r > M + \sqrt{M^2 - Q^2} \) for Reissner-Nordström black hole.*

Here, for massless particles \( \epsilon = 0 \), and for massive particles \( \epsilon = 1 \). The circular photon orbit \( r = r_{ph} \) correspond to the extreme point of effective potential [14, 15]

\[
\left. \frac{dV_{eff}(r)}{dr} \right|_{r=r_{ph}} = 0
\]

\[
\Rightarrow \left[ \frac{L^2}{2r^2} \cdot \frac{df(r)}{dr} - \frac{L^2 \cdot f(r)}{r^3} \right]_{r=r_{ph}} = 0 \tag{13}
\]

where we have used \( \epsilon = 0 \) for massless photons. Note that the angular momentum \( L \) is a conserved quantity along photon orbit, which is independent of \( r \). Comparing equation (13) with equation (5), it is clearly demonstrated that they are equivalent to each other. When \( r = r_{ph} \) is the extreme point of effective potential \( V_{eff}(r) \), the geodesic curvature along the circle \( r = r_{ph} \) vanishes precisely, which makes it to be the circular photon orbit for spherical symmetric black holes.

Then we analyze the stability of circular photon orbits. For unstable circular photon orbit \( r = r_{unstable} \), the effective potential should reach its local maximum [15, 18]

\[
\left. \frac{d^2V_{eff}(r)}{dr^2} \right|_{r=r_{unstable}} < 0
\]

\[
\Rightarrow \left[ \frac{L^2}{2r^2} \cdot \frac{d^2f(r)}{dr^2} - \frac{2L^2}{r^3} \cdot \frac{df(r)}{dr} + \frac{3L^2 \cdot f(r)}{r^4} \right]_{r=r_{unstable}} < 0
\]

\[
\Rightarrow \left[ \frac{L^2}{2r^2} \cdot \frac{d^2f(r)}{dr^2} - \frac{L^2 \cdot f(r)}{r^4} \right]_{r=r_{unstable}} < 0
\]

\[
\Rightarrow \left[ \frac{f(r)}{2} \cdot \frac{d^2f(r)}{dr^2} - \frac{f(r) \cdot f(r)}{r^2} \right]_{r=r_{unstable}} < 0
\]

\[
\Rightarrow \left[ \frac{f(r)}{2} \cdot \frac{d^2f(r)}{dr^2} - \left( \frac{1}{2} \frac{df(r)}{dr} \right)^2 \right]_{r=r_{unstable}} < 0 \tag{14}
\]

In the derivation, we have used the relation \( df(r)/dr = 2f(r)/r \) in equation (13) for unstable circular photon orbit repeatedly. Recall the expression for Gauss curvature in equation (6), the last line of this inequality implies that Gauss curvature must be negative (\( K < 0 \)). On the contrary, the stable photon orbit, which correspond to the local minimum of effective potential, would imply the Gauss curvature to be positive (\( K > 0 \)). In this way, the equivalence between our geometric approach developed in this work and the conventional approach is demonstrated. The features of these two approaches and their equivalence are summarized in table II.

**Summary and Prospects:** In this work, a pure geometric approach is developed to calculate the circular photon orbit and black hole shadow radius. This approach is quite simple and general, regardless of particular metric forms of black hole spacetime. The Gauss curvature, geodesic curvature in optical geometry and Hadamard theorem in differential geometry offer a new pathway to calculate the circular photon orbits and black hole shadows. This approach indicates that the optical geometry may give us profound insights on black hole properties, and it is worthy of extensive investigations. Furthermore, we demonstrate that our approach is completely equivalent to the conventional approach based on effective potentials of test particles.

There are several possible extensions of our geometric approach in the near future. Firstly, the similar algorithm can be apply to rotational black holes, whose optical geometry is a Randers-Finsler manifold. Secondly, the approach developed in this work, which is given for massless photons, can also be generated to the cases of massive particles. For circular orbits of massive particles, the utilization of Gauss curvature, geodesic curvature and Hadamard theorem may take place in the Jacobi geometry of black hole spacetime, rather than the optical geometry. The Jacobi geometry can be constructed from the action principle and constrained canonical momenta of massive test particles [32, 33].

**SUPPLEMENTARY MATERIAL**

The supplementary material gives an introduction of the Gauss curvature and geodesic curvature in surface theory and differential geometry. The Gauss curvature is the intrinsic curvature of a two dimensional surface $S$. The geodesic curvature is the curvature of a curve $\gamma(s)$ lived in this surface, which measures how far this curve is from being a geodesic in surface $S$. There are many equivalent ways to define geodesic curvature and Gauss curvature. For instructive reasons, we embed the two dimensional curved surface $S$ into higher dimensional Euclidean space. However, both Gauss curvature and geodesic curvature are intrinsic properties, irrespective of the embedding into higher dimensional space.

Consider a two dimensional surface $S$ embedded into three dimensional Euclidean space, which is illustrated in figure 3. For a curve $\gamma = \gamma(s)$ lived in surface $S$ with arc length parameter $s$, its unit tangent vector is $T = dr/ds$, and its curvature is defined to be the module of derivative $dT/ds$ \[ K = \frac{dT}{ds} = \left| \frac{d^2 r(s)}{ds^2} \right| \] (15)

For any point $p$ along this curve, we can assign the frame fields $\{p; e_1, e_2, e_3\}$ such that $e_1 = T$ is the unit tangent vector of curve $\gamma = \gamma(s)$ and $e_3 = n$ is the unit normal vector of surface $S$. The tangent plane of curved surface $S$ at point $p$ can be generated by frames $e_1$ and $e_2$. In this case, the geodesic curvature of curve $\gamma = \gamma(s)$ is defined as the projection of curvature $\kappa = |dT/ds|$ on tangent space $\kappa_g = \frac{dT}{ds} \cdot e_2 = \frac{d^2 r(s)}{ds^2} \cdot e_2$ (16)

Furthermore, the normal curvature $\kappa_n$ is defined as the projection of curvature $\kappa = |dT/ds|$ on normal vector $n$ $\kappa_n = \frac{dT}{ds} \cdot n = \frac{d^2 r(s)}{ds^2} \cdot e_3$ (17)

The geodesic curvature $\kappa_g$ depends only on the intrinsic properties of surface $S$, while the normal curvature $\kappa_n$ relies on the embedding of surface $S$ into higher dimensional Euclidean space. Using geodesic curvature and normal curvature, the total curvature $\kappa$ of a curve $\gamma(s)$ in three dimensional Euclidean space can be expressed by the square root $\kappa = \sqrt{\kappa_g^2 + \kappa_n^2}$. In particular, the curves with zero geodesic curvature can be viewed as “straight line”, and they are geodesics in curved surface $S$.

The normal curvature of a curve at point $p$ can be changed when $\gamma = \gamma(s)$ varies (we assume all curves $\gamma = \gamma(s)$ should pass through point $p$ as they varies). In some circumstances, the normal curvature $\kappa_n$ could reach its maximum and minimum. These extreme values rely on the geometric properties of two dimensional surface $S$, and they measure the principle curvature of this surface at point $p$. $K_1 = \max\{\kappa_n\}, \quad K_2 = \min\{\kappa_n\}$ (18)

The Gauss curvature of surface $S$ at point $p$ is defined to be the product of principal curvatures \[ K = K_1 K_2 \] (19)

An elegant theorem in surface theory (the Gauss Theorema Egregium) suggests that: although principal curvatures $K_1$ and $K_2$ depend on the embedding of $S$ in higher dimensional space, the Gauss curvature $K = K_1 K_2$ is an intrinsic geometric quantity of surface $S$ regardless of embedding [26].

Both geodesic curvature and Gauss curvature can be calculated from the intrinsic metric of two dimensional surface. If we assign the curving linear coordinates $(x_1, x_2)$ in two dimensional surface $S$ such that its intrinsic metric is expressed as $ds^2 = g_{11} dx_1^2 + g_{22} dx_2^2$ (20)

For any curve $\gamma = \gamma(s) = (x_1(s), x_2(s))$ lived in two dimensional surface $S$ with the arc length parameter $s$, its geodesic curvature can be calculated through the following equation $\kappa_g(\gamma) = \frac{d\alpha}{ds} - \frac{1}{2\sqrt{g_{22}}} \frac{\partial \log(g_{11})}{\partial x_2} \cos \alpha + \frac{1}{2\sqrt{g_{11}}} \frac{\partial \log(g_{22})}{\partial x_1} \sin \alpha$ (21)
The Gauss curvature of two dimensional surface $S$ here, $\alpha$ vector of surface $S$ \{embedded into three dimensional Euclidean space, $\gamma = \gamma(s)$ is a curve lived in surface $S$, and $p$ is the point along this curve. The $\{p; e_1, e_2, e_3\}$ are frame fields such that $e_1 = T$ is the unit tangent vector of curve $\gamma = \gamma(s)$ and $e_3 = n$ is the unit normal vector of surface $S$. The curve $\tilde{\gamma} = \tilde{\gamma}(s)$ is the projection of $\gamma = \gamma(s)$ on tangent plane of surface $S$ at point $p$.

Here, $\alpha$ is the angle between tangent vector of $\gamma$ and coordinate axis $x_1$. Further, the vanishing of geodesic curvature indicates that $\gamma = \gamma(s)$ is a geodesic curve in this surface.

$$\kappa_g(\gamma) = 0 \iff \nabla_T T\big|_{\gamma = \gamma(s)} = 0 \iff \left[ \frac{d^2 x_i}{ds^2} - \Gamma^i_{jk} \frac{dx_j}{ds} \frac{dx_k}{ds} \right]_{\gamma = \gamma(s)} = 0$$

(22)

The Gauss curvature of two dimensional surface $S$ is calculated by

$$K = K_1 K_2 = \frac{R_{1212}}{g_{11}g_{22} - (g_{12})^2} = -\frac{1}{\sqrt{g_{11}g_{22}}} \left[ \frac{\partial}{\partial x_2} \left( \frac{1}{\sqrt{g_{22}}} \frac{\partial \sqrt{g_{11}}}{\partial x_2} \right) + \frac{\partial}{\partial x_1} \left( \frac{1}{\sqrt{g_{11}}} \frac{\partial \sqrt{g_{22}}}{\partial x_1} \right) \right]$$

(23)

where $R_{1212}$ is the Riemannian curvature of this surface. In this supplementary material, we adopt the notation in surface theory, where covariant and contravariant coordinates are not distinguished.

In the optical geometry of spherical symmetric black holes, if we restrict test particles moving in the equatorial plane $\theta = \pi/2$ and assign the coordinates $(x_1, x_2) = (r, \phi)$, then the metric of two dimensional optical geometry becomes

$$dt^2 = \tilde{g}^{OP} dx^i dx^j = \frac{1}{f(r)^2} dr^2 + \frac{r^2}{f(r)} d\phi^2$$

(24)

Here $t$ is the arc length parameter in optical geometry. For circular photon orbit $r = r_{ph}$, the angle between this orbit and coordinate axis $r$ is $\alpha = \pi/2$, then its geodesic curvature reduces to

$$\kappa_g(r = r_{ph}) = \left[ \frac{d\alpha}{ds} - \frac{1}{2\sqrt{\tilde{g}^{OP}} \frac{\partial \log(\tilde{g}^{OP})}{\partial \phi}} \cos \alpha + \frac{1}{2\sqrt{\tilde{g}^{OP}} \frac{\partial \log(\tilde{g}^{OP})}{\partial r}} \sin \alpha \right]_{r = r_{ph}} = \left[ \frac{1}{2\sqrt{\tilde{g}^{OP}} \frac{\partial \log(\tilde{g}^{OP})}{\partial r}} \right]_{r = r_{ph}}$$

(25)

The Gauss curvature of two dimensional optical geometry becomes

$$K(r, \phi) = -\frac{1}{\sqrt{\tilde{g}^{OP}}} \left[ \frac{\partial}{\partial \phi} \left( \frac{1}{\sqrt{\tilde{g}^{OP}}} \frac{\partial \sqrt{\tilde{g}^{OP}}}{\partial \phi} \right) + \frac{\partial}{\partial r} \left( \frac{1}{\sqrt{\tilde{g}^{OP}}} \frac{\partial \sqrt{\tilde{g}^{OP}}}{\partial r} \right) \right]$$

(26)

where $\tilde{g}^{OP} = det(\tilde{g}^{OP}) = \tilde{g}_{rr} \tilde{g}_{\phi\phi}$ is the determinant of optical metric. These results coincide with equation (5) and equation (6) in the main text exactly.
