ARTICLE HISTORY
Compiled April 19, 2022

ABSTRACT
Intermittent demand forecasting is a ubiquitous and challenging problem in operations and supply chain management. There has been a growing focus on developing forecasting approaches for intermittent demand from academic and practical perspectives in recent years. However, limited attention has been given to forecast combination methods, which have been proved to achieve competitive performance in forecasting fast-moving time series. The current study aims to examine the empirical outcomes of some existing forecast combination methods, and propose a generalized feature-based framework for intermittent demand forecasting. We conduct a simulation study to perform a large-scale comparison of a series of combination methods based on an intermittent demand classification scheme. Further, a real data set is used to investigate the forecasting performance and offer insights with regards the inventory performance of the proposed framework by considering some complementary error measures. The proposed framework leads to a significant improvement in forecast accuracy and offers the potential of flexibility and interpretability in inventory control.

1. Introduction

Intermittent demand with several periods of zero demand is ubiquitous in practice. Over half of inventory consists of spare parts, in which demand is typically intermittent (Nikolopoulos 2021). Given the high purchase and shortage cost associated with intermittent demand applications, accurate forecasts could be coupled with improved inventory management in the field of manufacturing, aerospace, military and so on (Babai et al. 2019; Jiang, Huang, and Liu 2020).

What makes intermittent demand challenging to forecast is that there are two sources of uncertainty: the sporadic demand occurrence, and the demand arrival timing. Seminal work on intermittent demand forecasting (Croston 1972) proposed to forecast the sizes of demand and the inter-demand intervals separately. Then some scholars followed this idea and put forward some developments. For example, Syntetos-Boylan Approximation (SBA) proposed by Syntetos and Boylan (2005) delivered approximately unbiased estimates and constituted the benchmark in subsequently proposed methodologies for intermittent demand forecasting. However, Croston (1972)’s method and SBA update demand sizes and intervals, which leads to inapplicability in periods of zero demand when considering inventory obsolescence. To overcome this shortcoming, Teunter, Syntetos, and Babai (2011) proposed a new method, referred to as Teunter-Syntetos-Babai (TSB), to update the demand probability instead of the demand interval. TSB has been shown to have good empirical performance for the demands within linear and sudden obsolescence (Babai, Syntetos, and Teunter 2014).

The above mentioned forecasting methods for intermittent demand are all parametric methods, which suppose that the future demand has a statistical distribution. Their unknown parameters can be estimated from historical data. Instead, non-parametric intermittent demand methods directly estimate empirical distribution based on the past data, with no need for any assumption of a standard probability distribution. The bootstrapping methods, and the overlapping and non-overlapping aggregation methods dominate the research field of non-parametric intermittent demand forecasting (Willemain, Smart, and Schwarz 2004; Hasni et al. 2019b,a; Boylan and Syntetos 2021; Boylan and Babai 2016).

In particular, temporal aggregation is a promising approach to forecast intermittent demand, in which a lower-frequency time series can be aggregated to a higher-frequency time series. Latent characteristics of the demand, such as trend and season-
ality, appear at higher levels of aggregation. Nikolopoulos et al. (2011) first introduced temporal aggregation to intermittent demand forecasting and proposed the Aggregate–Disaggregate Intermittent Demand Approach (ADIDA). To tackle the challenge of determining the optimal aggregation level, Petropoulos and Kourentzes (2015) considered combinations of forecasts from multiple temporal aggregation levels simultaneously. This approach is called Intermittent Multiple Aggregation Prediction Algorithm (IMAPA). The overall results in their work suggested that combinations of forecasts from different frequencies led to improved forecasting performance.

Recently, some attention has been paid to applying machine learning approaches to improve forecasting accuracy for intermittent demand, such as neural networks (Lolli et al. 2017), support vector machines (Kaya and Turkyilmaz 2018; Jiang, Huang, and Liu 2020), and so on.

Despite that intermittent demand forecasting has obtained some research achievements in recent decades (Nikolopoulos et al. 2011; Petropoulos and Kourentzes 2015; Kourentzes and Athanasopoulos 2021), there is still a lot of scope for improvements (Nikolopoulos 2021). For example, limited attention has been given to the combination schemes for intermittent demand forecasting. The literature indicates that forecast combination can improve forecast accuracy in modelling fast-moving time series (Bates and Granger 1969; De Menezes, Bunn, and Taylor 2000; Kang et al. 2021). In this study, we expand on the study by Petropoulos and Kourentzes (2015) and aim to examine whether forecast combination improves the forecasts of intermittent demand. The contributions of our work are: 1) a systematic evaluation of classical forecast combination methods in the context of intermittent demand forecasting, 2) a novel combination framework for intermittent demand, which can determine optimal combination weights for each time series automatically, 3) the investigation of the effects of time series features and forecast diversity on forecast combinations for intermittent demand, and 4) the evaluation of forecast accuracy and inventory-related measures based on a large set of real series and error measurements.

The rest of the paper is organized as follows. Section 2 reviews a series of forecast combination methods used in this work. Section 3 proposes a generalized forecast combination framework for intermittent demand and discusses error metrics. Section 4 performs a comparison of the proposed approaches and some classic combination methods through a simulation study. Further, in Section 5, we apply our framework to
real data and offer results based on forecast accuracy and inventory-related measures. Section 6 provides discussions and Section 7 concludes the paper.

2. A review of forecast combinations

Combining forecasts from different methods or models has shown to perform well in practice. The Simple Average (SA) has been proved to be a hard-to-beat forecast combination method (Clemen 1989; Stock and Watson 2004; Lichtendahl Jr and Winkler 2020), which simply combines forecasts with an equal weight of 1/M (M is the number of forecasting methods). Clemen (1989) reviewed over two hundred articles and concluded that SA should be used as a benchmark when proposing more complex weighting schemes. Palm and Zellner (1992) emphasized that SA could reduce the variance of forecasts and avoid the uncertainty of weight estimation. The phenomenon that SA outperforms more complicated combination methods is referred to “forecast combination puzzle” (Stock and Watson 2004; Smith and Wallis 2009; Claeskens et al. 2016).

Because SA is sensitive to extreme values, some attention has been paid to other more robust combination schemes, including the median and trimmed means (Stock and Watson 2004; Lichtendahl Jr and Winkler 2020; Petropoulos and Svetunkov 2020). Jose and Winkler (2008) studied two simple robust methods, trimmed and Winsorized means, and verified their improved combined forecasts. The simple combination schemes based on the mean and median are easy to calculate and do not have to deal with parameter estimation error. However, there is still no consensus whether the mean or the median of individual forecasts performs better.

In the field of intermittent demand forecasting, forecast combination methods have been largely overlooked. To the best of our knowledge, only SA was applied to improving intermittent demand forecasting (Petropoulos and Kourentzes 2015). Recently, the organisers of the M5 competition (Makridakis, Spiliotis, and Assimakopoulos 2020), which focused on forecasting retail sales with a mass of intermittent time series, used SA as one of the combination benchmarks.

To further investigate the value of forecast combinations, a number of scholars over the past half century have focused on finding optimal weights for combining different forecasting models. The seminal work by Bates and Granger (1969) proposed the idea
of weighted forecast combinations. Newbold and Granger (1974) continued this stream of research and investigated more forecasting models and multiple forecast horizons. In their work, a weighted combination can be expressed as a linear function such that

\[ \hat{y}_{T+1} = \sum_{i=1}^{M} w_{i,T+1} \hat{y}_{i,T+1} = w_{T+1}' \hat{y}_{T+1}, \]

where \( \hat{y}_{T+1} \) is the column vector of forecasts at time \( T+1 \) generated from \( M \) forecasting models, and \( w \) is the column vector of weights.

Bates and Granger (1969) produced an unbiased combined forecast by minimizing the error variance, in which the combination weights can be determined by

\[ w_{T+1} = \frac{\Sigma^{-1} 1}{1' \Sigma^{-1} 1}, \]  

(1)

where \( 1 \) is an \( m \)-dimensional column vector of ones, and \( \Sigma \) is the covariance matrix of forecast errors. The method is represented as **Optimal** hereafter.

As the covariance matrix \( \Sigma \) in Equation (1) is often unknown in practice, Bates and Granger (1969) provided five methods to weight the individual forecasts based on their historical performance. These five alternatives, expressed as **BG1**, **BG2**, **BG3**, **BG4** and **BG5**, can be formulated as follows:

\[ w_{BG1}^i,T+1 = \frac{(E_{i,T+1})^{-1}}{\sum_{i=1}^{M} (E_{i,T+1})^{-1}}; \]

\[ w_{BG2}^T+1 = \frac{\Sigma_{T+1}^{-1} 1}{1' \Sigma_{T+1}^{-1} 1}, \left( \Sigma_{T+1}^{-1} \right)_{ij} = \nu^{-1} \sum_{t=T-\nu+1}^{T} e_{it} e_{jt}; \]

\[ w_{BG3}^i,T+1 = \alpha w_{i,T} + (1 - \alpha) \frac{(E_{i,T+1})^{-1}}{\sum_{i=1}^{M} (E_{i,T+1})^{-1}}, \quad 0 < \alpha < 1; \]

\[ w_{BG4}^i,T+1 = \frac{(S_{i,T+1})^{-1}}{\sum_{i=1}^{M} (S_{i,T+1})^{-1}}, \quad S_{i,T+1} = \sum_{t=1}^{T} \gamma^t (e_{it})^2, \quad \gamma \geq 1; \]

\[ w_{BG5}^T+1 = \frac{\Sigma_{T+1}^{-1} 1}{1' \Sigma_{T+1}^{-1} 1}, \left( \Sigma_{T+1}^{-1} \right)_{ij} = \frac{\sum_{t=1}^{T} \gamma^t e_{it} e_{jt}}{\sum_{t=1}^{T} \gamma^t}. \]

(2)

where \( e_{it} \) is the forecast error of the \( i \)-th model at time \( t \), and \( E_{i,T+1} = \sum_{t=T-\nu+1}^{T} e_{it} \), using the recent \( \nu \) observations for the estimation.

The last four methods are variations of **BG1**. **BG2** considers cross-correlations be-
tween the residuals from the fitted models, and \( BG3 \) contains an autocorrelation pattern. \( BG4 \) and \( BG5 \) give most weight to the forecast which has performed best in the recent past with the aid of a parameter \( \gamma \). Through an empirical investigation based on 80 monthly time series, Newbold and Granger (1974) found that the methods \( BG1, BG3 \) and \( BG4 \), which ignored the correlation of forecast errors, outperformed \( BG2 \) and \( BG5 \), which considered the correlation.

Granger and Ramanathan (1984) further investigated some regressive approaches to obtain linear combinations. They demonstrated that the method with a constant term and unrestricted weights performed better. The combination weights can be estimated by Ordinary Least Squares (OLS). Linear combination has a long and successful history in forecasting. However, the issue related to determining the best set of forecasting models to combine is also worthy of attention. Lasso-based methods can do this trick by producing the selection and shrinkage toward zero (Tibshirani 1996). Diebold and Shin (2019) proposed a variant of Lasso, partially-egalitarian LASSO (peLASSO), which set the weights of some forecasting methods to zero and shrunk the survivors toward equality. They provided an empirical assessment to forecast Eurozone GDP growth and found that peLASSO outperformed SA and the median (Diebold and Shin 2019).

Nonetheless, the above-mentioned forecast combination methods simply estimate the combining weights for each time series separately. Recent studies indicate that global methods that uses all time series to estimate the combining weights show puzzlingly good performance in forecasting fast-moving time series (Montero-Manso and Hyndman 2021). One main stream is feature-based forecast combinations. For example, Montero-Manso et al. (2020) developed FFORMA (Feature-based FORecast Model Averaging), which used 42 features to estimate the optimal combination weights based on a meta-learning algorithm.

Different feature-based combination approaches applied different time series features to improve forecasting performance (Wang, Smith-Miles, and Hyndman 2009; Petropoulos et al. 2014; Talagala, Li, and Kang 2021). The selection of appropriate features mainly depends on expert knowledge. Especially for intermittent demand series, a significant characteristic is that there exist a large number of zeros and irregular patterns, which makes the feature extraction procedure more difficult. Theodorou et al. (2021) proposed a methodological approach for feature extraction and selection, which
is tailored for M5 dataset. On the basis of FFORMA framework (Montero-Manso et al. 2020), Kang et al. (2021) used the diversity of forecasting models as the only feature. Accounting for the diversity of the forecasts not only improved the forecast accuracy but also simplified the modelling process and reduced computational complexity.

The potential of time series features and the diversity of the forecasts has not been investigated when producing forecast combinations for intermittent demand. In our work, we extract a set of time series features tailored for intermittent demand and calculate the diversity based on a pool of intermittent demand forecasting models. To this end, an intermittent demand forecast combination framework can be constructed by using eXtreme Gradient Boosting (XGBoost) (Chen and Guestrin 2016), which we present in Section 3.

3. Forecast combination for intermittent demand

3.1. Time series features for intermittent demand

We consider nine comprehensible time series features for intermittent demand forecasting, which are listed in Table 1. The selected features are based on previous studies in Kourentzes and Petropoulos (2016), and Christ et al. (2018), O’Hara-Wild, Hyndman, and Wang (2021). We describe them as follows.

- \( F_1, F_2 \): The average Inter-Demand Interval (IDI) and squared Coefficient of Variation (CV\(^2\)) are the two most popular attributes to describe demand patterns, which are used in the SBC classification scheme for intermittent demand (Synthetos, Boylan, and Croston 2005; Kostenko and Hyndman 2006).
- \( F_3 \): Entropy-based measures have been applied to quantify the regularity and unpredictability of time-series data (Kang, Hyndman, and Smith-Miles 2017; Theodorou et al. 2021). We use the approximate entropy in this paper, which can be computed by the \texttt{TSEntropies} (Tomcala 2018) package in R. A relatively small value of \( F_3 \) indicates that the demand series includes more regularity and is more forecastable.
- \( F_4, F_5 \): The two features describe the ratios of some specific data. The percentages of zero values and the values away from the mean in \( F_4 \) and \( F_5 \) are simple tools to further measure the intermittency and volatility respectively.
- \( F_6 \): This feature provides the coefficient of a linear least-squares regression, which

<td>$[0, 1]$</td>
</tr>
</tbody>
</table>

measures the linear trend of the variances from a series of chunks. The length of chunks is a parameter in $F_6$, which determines how many demand values are in each chunk. For monthly data in following experiments, we set the parameter to be 12.

- $F_7$: Given two quantiles, $F_7$ reflects consecutive changes of the fixed corridor. The quantiles of concern in this paper are 40%-quantile and 100%-quantile.

- $F_8$, $F_9$: In the field of intermittent demand, except for the intermittency and volatility, the risk of obsolescence is another factor to bring difficulty to forecasting (Teunter, Syntetos, and Babai 2011; Babai et al. 2019). The last two features capture the recent demand pattern. $F_8$ and $F_9$ focus on the sum of squares of the last chunk and the recent zero demand, respectively. The number of chunks in $F_8$ is an unknown parameter, which is set to be 4 in this paper.

Based on the nine time series features tailored for intermittent demand, we put forward a feature-based forecast combination approach, the Feature-based Intermittent DEmand forecasting (FIDE).

3.2. Diversity for intermittent demand

In this paper, we extend Kang et al. (2021)’s work and propose an intermittent demand forecasting combination method based on their diversity, the DIVersity based Intermittent DEmand forecasting (DIVIDE). The scaled diversity between any two forecasting methods is defined as:

where $H$ is the forecast horizon, $\hat{y}_{ih}$ is the $h$-th step forecast generated from the $i$-th forecasting model, and $\{y_t, t = 1, 2, \ldots, T\}$ is a series of observed values.

The main merits of applying the diversity to intermittent demand forecasting are twofold. The first aspect is simplicity, as the calculation only depends on forecasting values, with no need to compute a separate set of features. The second is general applicability. The diversity can be obtained straightforwardly from intermittent demand forecasts and comprehended easily by forecasters, regardless of the inventory management problem. Nevertheless, time series features need to be customized based on the specific application scenarios.

### 3.3. Generalized forecast combination framework

To be able to produce forecasts combinations for intermittent demand, we first need to define a suitable pool of forecasting methods. The pool includes traditional forecasting models, which are Naive, seasonal Naive (sNaive), Simple Exponential Smoothing (SES), Moving Averages (MA), AutoRegressive Integrated Moving Average (ARIMA), Exponential Smoothing (ETS), and intermittent demand forecasting methods, which are Croston’s method (CRO), optimized Croston’s method (optCro), SBA, TSB, ADIDA, IMAPA. Implementations for these methods exist in the `forecast` and `tsintermittent` packages in R.

Then, given a forecast error metric, the optimization objective for the FIDE and DIVIDE is

$$
\text{arg min}_{w_F} \sum_{n=1}^{N} \sum_{i=1}^{M} w(F_n)_i \times error_{n,i},
$$

$$
\text{arg min}_{w_D} \sum_{n=1}^{N} \sum_{i=1}^{M} w(D_n)_i \times error_{n,i},
$$

(4) (5)
where $F_n$ is the feature vector, and $D_n$ is the diversity vector of the $n$-th time series. $error_{n,i}$ is the forecast error of the $i$-th model for the $n$-th time series. A simple form of the error is the traditional absolute or squared error measure. To meet the actual application needs, we can also use a comprehensive error by adding some other measures that can reflect inventory problems, such as stockout. A series of error metrics for intermittent demand forecasting are discussed in the next subsection. The optimal combination weights $w_F$ and $w_D$ can be estimated by mapping the features or the diversity to the errors based on the \texttt{M4metalearning} package by Montero-Manso et al. (2020).

In the training phase, we generate forecasts based on the intermittent demand forecasting pool of methods and calculate errors required in the objective function. In FIDE, we compute the features tailored for intermittent demand and learn the relationship between the features and combination weights based on XGBoost algorithm. In DIVIDE, the intermittent demand forecasting combination model can be obtained based on the diversity of different forecast methods. In the forecasting phase, we calculate the features of the new time series and the diversity of the respective forecasts, and get the combination weights through the pre-trained XGBoost model for FIDE and DIVIDE respectively. Finally, we average point forecasts from different methods in the pool based on the optimal weights to achieve the combined forecast results. The flowchart of the proposed framework is presented in Figure 1.

The advantages of the proposed framework are as follows: (1) a diverse forecasting pool, consisting of intermittent demand forecasting methods and traditional time series forecasting models; (2) a customizable objective function depending on actual inventory management requirements; (3) the selection of comprehensible time series features especially for intermittent demand; and (4) the use of the diversity of the forecasts. The above advantages allow us to propose a generalized intermittent demand forecasting combination framework by considering both features and the diversity to learn from other time series and estimate optimal combination weights.

### 3.4. Evaluation metrics for intermittent forecasting

In previous studies, various forecasting evaluation metrics have been used for intermittent demand. The chosen metric of forecast errors may influence the ranked performance of the forecasting methods. Silver et al. (1998) pointed out that no single
metric was universally best. Since the groundbreaking intermittent demand method by Croston (1972) was proposed, a large number of scholars began to examine the forecasting performance of Croston (1972)’s method and its variants by comparing them with traditional time series methods. Syntetos and Boylan (2005) evaluated the simple Moving Average (MA), single Exponential Smoothing (ES), Croston method (Croston 1972) and a modified Croston method (Syntetos and Boylan 2001) based on 3000 Stock Keeping Units (SKUs). They used Mean Error (ME), scaled Mean Error (sME), Relative Geometric Root Mean Squared Error (RGRMSE) and Percentage Better (PBt) to evaluate the forecasting results. Syntetos and Boylan (2006) continued their work by focusing on the stock control performance and used two percentage accuracy measures, PBt and Average Percentage Regret (APR).

Teunter and Duncan (2009) pointed that some traditional error measures, such as Mean Absolute Deviation (MAD), Mean Square Error (MSE) and RGRMSE, were not suitable for intermittent demand forecasting, because they preferred zero forecasts. Therefore, Teunter and Duncan (2009) tried to measure service and inventory levels under the order-up-to policy and showed that Croston-type approaches outper-
formed others (MA, ES, and bootstrapping) based on the Royal Air Force (RAF) dataset. Wallström and Segerstedt (2010) discussed a series of forecasting error measurements especially for intermittent demand and split them into two categories, traditional (accuracy) and bias error measurements. As traditional measures, Wallström and Segerstedt (2010) considered MSE, MAD, symmetric Mean Absolute Percentage Error (sMAPE). As bias error measures, they examined the Cumulated Forecast Error (CFE), Number Of Shortages (NOS), and Periods In Stock (PIS). Further, they suggested that complementary measures should be considered based on Principal Components Analysis (PCA).

Given that traditional error metrics favor distorted forecasts, bias measures need to be also considered when evaluating forecasts for intermittent demands. Kourentzes (2014) proposed two novel cost functions to parameter optimization for intermittent demand methods, the Mean Squared Rate (MSR) and the Mean Absolute Rate (MAR) errors. He evaluated parameter and model selection results based on two accuracy metrics. The first is the Mean Absolute Scaled Error (MASE), which was suggested to be the standard measure for the data with different scales and zero values (Hyndman and Koehler 2006). The second is the scaled Absolute Periods In Stock (sAPIS), which is a scale-independent variant of PIS. Petropoulos and Kourentzes (2015) tracked five measurements to assess the performance of different intermittent demand approaches, including sME, scaled Mean Absolute Error (sMAE), scaled Mean Squared Error (sMSE), scaled Mean Periods In Stock (sMPIS), and scaled Mean Absolute Periods In Stock (sMAPIS). We sum up the aforementioned research in Table 2.

There is still no consensus regarding the most appropriate measure to evaluate intermittent demand forecasts. In our analysis, we consider the two categories of error metrics (Wallström and Segerstedt 2010) and adopt some scaled measures. Let $y_t$ be the demand and $\hat{y}_t$ be the demand forecast at time $t$ for each time series. Four traditional error measures are presented in Table 3. Minimizing these error measures results in the proposed methods to prefer zero forecasts and leads to under-stocking. Thus, we also consider three bias error measures as shown in Table 4. To achieve a balance in improving forecast accuracy and reducing shortage, we add a penalty for NOS into the optimization objective function and propose a novel form of $error_{ni}$:

$$error_{ni} = MASE_{ni} + \alpha \cdot NOS_{ni},$$

where $\alpha$ is a tuning parameter.

where the penalty factor $\alpha$ is non-negative and can be adjusted according to actual inventory cost and shortage cost.

4. Simulation studies

4.1. Simulated data

In our work, we adopt the SBC classification scheme for demand patterns (Syntetos, Boylan, and Croston 2005; Kostenko and Hyndman 2006) based on two attributes: IDI and CV$^2$. Petropoulos et al. (2014) investigated four possible determinants (IDI, CV$^2$, the number of observations and forecasting horizon) of forecasting accuracy through

Simulations on intermittent data. They found that with the increase of IDI and CV², the accuracy of all the investigated forecasting models decreased. Additionally, the number of observations had small influence and the forecasting horizon had almost no effect on forecasting performance in Petropoulos et al. (2014)’s research.

Therefore, in this paper, we generate the simulated data based on the three factors (IDI, CV² and the number of observations). Each factor is varied around four levels as shown in Table 5. The forecast horizon is set to be 12 periods for each time series. Considering 64 \((4^3)\) combinations and 1,000 series at each level, we generate in total 64,000 simulated time series in the following experiment. The production of simulated data with the required characteristics can be made using the `tsintermittent` (Kourentzes and Petropoulos 2016) R package. Figure 2 demonstrates the distribution of the simulated data, which covers all the four categories in the SBC classification scheme. To this end, we can compare the performance of aforementioned forecast combination methods based on the intermittent demand data from different categories.

### 4.2. Forecasting results

In the following experiment, we investigate the forecasting performance of combination methods for intermittent demand. For each simulated time series, the last 12 obser-
The heat map of hexagon matrix for the simulated data. The data density is denoted by the color depth. The x-axis and y-axis show the logarithmic transform of IDI and CV\(^2\) respectively. Rad lines indicate the boundaries of different categories. Class 1 is the time series with low intermittence and high variability, Class 2 is that with high intermittence and high variability, Class 3 is that with low intermittence and low variability, and Class 4 is that with high intermittence and low variability.

Observations constitute the forecasting period. We consider simple combinations (SA, Median), an error-based combination (Optimal), performance-based combinations (BG1, BG4), Lasso-based combinations and combinations by learning (FFORMA, FIDE, DVIDE). We only preserve BG1 and BG4 in Newbold and Granger (1974) because the two methods with simple algorithms have been proved to be more successful than others in previous studies. The forecasting accuracy in this experiment is measured by two scaled absolute errors, MASE and sMAE. The gains associated with reducing the bias are generally considered to be more beneficial for inventory-related decisions compared to the decrease of squared errors in literature (Kourentzes, Barrow, and Petropoulos 2019; Sanders and Graman 2009).

For local combination methods, we perform a rolling origin evaluation to generate 12 out-of-sample forecasts, and the obtained forecast errors are used to calculate combination weights for Optimal, BG1 and BG4 methods. In particular, the estimation of combination weights requires some conditions, such that the covariance matrix is non-singular and the training data can be standardized. To this end, we exclude some series in the second and fourth categories with high intermittence, which contain a lot of continuous zero demands in the tail of training period. For global combination
methods, the model training setup in this paper is consistent with FFORMA. We suggest referring to Montero-Manso et al. (2020)’s work for details.

Table 6 presents the forecasting accuracy of different methods based on the simulated data. We observe that the best individual methods are IMAPA and SBA, which are proposed especially for intermittent demand forecasting. Additionally, IMAPA performs the best in most cases. The traditional combination methods (SA, Median, Optimal, BG1, BG4) perform worse than the corresponding best individual models. However, the Lasso method, which considers a logarithmic transform before regression, significantly improves the forecasting accuracy. Indeed, this simple combination method yields the best MASE and sMAE for the time series with low intermittence and high variability in Class 1.

The proposed methods based on intermittent demand features and the diversity consistently outperform the best individual models. FIDE shows obvious superiority compared with the 42 traditional time series features in FFORMA. Furthermore, DIVIDE offers the best forecasting results overall. Especially for the data from Class 2 and 4 with high intermittence, the benefits from the proposed methods compared with FFORMA are more significant. Therefore, the simulation results in Table 6 provide good evidence for the importance of intermittent demand features and the diversity in estimating combination weights.

Figure 3 presents the distributions of combination weights based on our FIDE and DIVIDE methods respectively. The boxplots in the left and right panels show similar patterns. This indicates that intermittent demand features and diversity are two types of effective inputs for the forecast combination model to learn and estimate optimal weights. For the time series from different classifications, the weights’ distributions of individual models show obvious variation. However, Class 2 and 4 with high intermittence have similar distributions, and the same is true of Class 1 and 3 with low intermittence. Therefore, the intermittence is a crucial factor affecting the intermittent demand forecasting performance.

5. Empirical evaluation

5.1. Real dataset

The RAF dataset used for the empirical evaluation has been previously investigated in the literature (Kourentzes and Athanasopoulos 2021; Petropoulos and Kourentzes 2015; Teunter and Duncan 2009). It contains 5000 monthly time series, with 84 observations each. Figure 4 describes the distribution of the dataset, which has the same x-axis and y-axis as Figure 2. We can observe that the time series exhibit high intermittence and only relate to Class 2 and 4 based on SBC scheme (Kostenko and Hyndman 2006).

In the following experiment, we produce 12-step-ahead point forecasts. To this end, the first 72 periods constitute the in-sample set to train the forecast combination model for the proposed methods. The following 12 periods are treated as the out-of-sample set, which is used to evaluate the forecasting performance of different combination methods.

A series of forecasting error measurements for intermittent demand have been reviewed in Section 3.4. We consider both traditional errors and bias errors to give a comprehensive description of point forecasting performance. For traditional errors, we
calculate two absolute errors $s_{MAE}$ and $MASE$, a squared error $s_{MSE}$, and a cumulated error $s_{MAPIS}$. For bias errors, we compute two relative errors $s_{ME}$ and $s_{MPIS}$, and a shortage-based error $NOS$, which is always nonnegative.

5.2. Forecasting performance

Firstly, we use traditional forecast errors in the optimal objective function as shown in Table 3. We compare our methods with individual models, SA, Median and FFORMA, and the results are presented in Table 7. Other combination methods in Table 6 are omitted here, being inferior to the simple combination based on the RAF dataset. For each column, the optimal objectives in FFORMA and the proposed methods depend on the relevant error measures. We observe that:

- According to $s_{MAE}$ and $MASE$, the best individual model is Naive. This is due to that a zero forecast is optimal for the majority of out-of-sample periods that exhibit high intermittence. However, Naive yields the worst performance based on $s_{MAPIS}$, which indicates the adverse impact of under-stocks. Therefore, we need to consider complementary metrics to evaluate forecast accuracy.
- The DIVIDE method achieves the best forecast accuracy based on $s_{MAE}$, $MASE$ and $s_{MAPIS}$. However, it is worse than the best individual model based on $s_{MSE}$, as the weighted average loss function in the proposed framework is not suitable
Table 7  Forecasting performance of different methods. For each error measure (column), the smallest value is marked in bold. The last column is the average rank of all methods based on the four metrics.

for quadratic errors, due to the sensitivity of sMSE in the presence of outliers and high variability.

• Combinations based on the diversity and intermittent demand features consistently outperform FFORMA based on traditional time series features for all four measures. In the field of intermittent demand forecasting, the time series features designed for fast-moving data are not appropriate to describe intermittent data. Our chosen time series features for intermittent demand appear to be more appropriate to tackle this challenge. Furthermore, diversity, that only relates to predicted values, is a simple and robust choice for feature-based forecast combinations with improved forecasting accuracy.

5.3. Inventory analysis

The proposed methods good appealing forecasting accuracy by minimizing traditional errors. However, the optimal objective based on traditional errors closely tracks the median of the distribution of intermittent demand, which is often zero. Therefore, FIDE and DIVIDE will inevitably lead to under-stocking. As low absolute errors and reducing shortage can not be reached simultaneously, we modify the objective function with a novel error in Equation (6). To reflect the inventory and shortage clearly, we introduce two bias measures sME and sMPIS. The sME reports the point forecast bias. Its positive values refer to stock-outs. The sMPIS is enhanced by the dimension
of time via cumulative summation. Positive values imply that the stock is left over, which is opposite of sME.

Figure 5 presents the forecasting performance of MASE, NOS, sMPIs and sME with different penalty factors in the objective function of our methods. We use MASE as a representative measure of forecast accuracy and NOS, sMPIs and sME to estimate the inventory status. The penalty factor ranges from 0 to 0.5. The objective function is only based on MASE when the penalty factor is 0. As shown in Figure 5, with the increase of penalty factor, the under-stocking decreases gradually, but the absolute error MASE increase. FIDE and DIVIDE have similar patterns in Figure 5 and the range of evaluation measures varies across other methods. Therefore, our proposed methods are flexible and can achieve a balance of reducing shortage and improving forecast accuracy. Furthermore, the rate of change in DIVIDE is greater than that of FIDE, which indicates that the diversity is more effective than time series features in intermittent demand forecast combination. The exact choice of a penalty factor depends on the application context, and forecast managers can adjust the parameter depending on inventory management goals.

6. Discussion

Forecast combinations have been proven to improve forecast accuracy in recent years. In this paper, we focus on a specific forecasting field, intermittent demand, which is almost widespread in spare parts and inventory management. To the best of our knowledge, our study is the first to analyze forecast combination methods systematically in the field of intermittent demand forecasting. Most importantly, we are the first to apply time series features explicitly related to intermittent demand data and the diversity for estimating combination weights for intermittent demand forecasts. Our proposed approaches offer superior forecasting accuracy performance compared to individual methods for intermittent demand forecasting as well as existing combination schemes. The good performance of our approaches is verified both through a simulation study and a large-scale empirical evaluation.

Nine time series features customized for intermittent demand are used in the proposed framework, which are selected based on their interpretability, the convenience of computation and the dispersion degree of distributions. Based on the experiments
Figure 5  Forecasting performance of MASE, NOS, sMPIs and sME with different penalty factors in the objective function of our methods. The red and blue solid lines denote proposed DIVIDE and FIDE respectively, which consider the penalty of under-stocking in the objective function. The forecasting errors of other methods are fixed and indicated by dotted lines for comparison.
in this paper, $F_9$ is the most important feature in training the forecast combination model and $F_8$ ranks the second. $F_8$ and $F_9$ extract characteristics of recent demand. Therefore, the pattern of recent data is crucial to determine the optimal forecast combination for intermittent demand.

Except for the results shown in Section 4 and 5, we investigate the effect of two factors on the proposed framework: intermittent demand classes and methods in the combination pool. Given the SBC classification scheme (Syntetos, Boylan, and Croston 2005; Kostenko and Hyndman 2006), we implement the proposed framework by training the forecast combination model for each class individually versus training for the whole data set. The forecasting results show no significant difference between the two settings.

The quality of forecast combination has been demonstrated to depend on the individual forecasts as well as the diversity between forecasts (Lemke and Gabrys 2010; Kourentzes, Barrow, and Petropoulos 2019; Kang et al. 2021). Therefore, defining an appropriate forecasting pool is one of the most crucial steps in forecast combination exercises. We study the effect of three pooling algorithms based on the proposed framework, which are forecast islands proposed by Kourentzes, Barrow, and Petropoulos (2019), a screened method from Lichtendahl Jr and Winkler (2020), and a Lasso-based method by Diebold and Shin (2019). Through a series of experiments, we find that none of the pooling methods significantly improves forecasting performance. The proposed framework automatically appropriately reduces the weights of some methods to very small values, which can be regarded as a generalized pooling method customized for each time series. Therefore, unless the pool of forecasting methods is too large that would render the computation process very time-consuming, we found that there is no need to add modelling complexity by implementing explicit pooling approaches on top of our proposed framework.

The good performance of our proposed framework is attributed to: (1) defining a forecasting pool suitable for intermittent demand, which consists of several intermittent demand forecasting methods and traditional time series forecasting methods; (2) applying diversity and time-series features to determine the optimal combination weights automatically; (3) customizing the objective function based on the inventory management plan in practice. Based on the results presented in this paper, DIVIDE that uses diversity outperforms FIDE that is based on time-series features. The process
of extracting the diversity is independent of historical data, making more attractive for intermittent demand forecasting where the training set is limited especially with regards to positive demand values.

7. Conclusion

This paper focused on forecast combinations for intermittent demand. We reviewed a series of forecasting methods and evaluation measures, and investigated the performance of some existing forecast combination methods for intermittent demand. We proposed time-series features and diversity to improve the performance of intermittent demand forecasting combinations and propose a generalized framework, which can automatically determine the optimal combination weights. We conducted a simulation exercise and an empirical investigation based on real-life data to analyze the forecast accuracy and gain insights related to the inventory performance of different combination approaches.

The results of simulation study showed that simple combination and local weighted combination methods do not perform better than the best individual method for intermittent data. The proposed forecast combination framework notably outperforms others, which confirms the value of the diversity and time-series features in the context of intermittent demand forecasting. In the empirical evaluation, we utilized both traditional errors and bias-related errors to describe the performance of point forecasts comprehensively. Based a modified objective function, the proposed FIDE and DIVIDE approaches offer flexibility between forecast accuracy and the reduction of shortages.

However, we recognise the lack of explicit inventory performance metrics in the current study. Petropoulos, Wang, and Disney (2019) combined financial, operational, and service metrics to form a holistic measure for inventory control objectives. Ducharme, Agard, and Trépanier (2021) focused on stock-out events and proposed a novel metric called Next Time Under Safety Stock. Such utility measures are important to achieve a direct link with inventory holding costs and service levels in operation management. Future research should focus on further analyzing the performance of our proposed framework to this direction. Another limitation of this paper is the lack of estimating the uncertainty of the intermittent demand forecasts, either in terms of quantiles or
probability distributions. Nevertheless, these are important for determining optimal safety stock levels in supply chain management (Traperó, Cardós, and Kourentzes 2019). Therefore, another avenue for further work could be to extend our approach to probability forecast combinations for intermittent demand.
