Abstract

We consider the question of adaptive data analysis within the framework of convex optimization. We ask how many samples are needed in order to compute $\varepsilon$-accurate estimates of $O(1/\varepsilon^2)$ gradients queried by gradient descent, and we provide two intermediate answers to this question.

First, we show that for a general analyst (not necessarily gradient descent) $\Omega(1/\varepsilon^3)$ samples are required. This rules out the possibility of a foolproof mechanism. Our construction builds upon a new lower bound (that may be of interest of its own right) for an analyst that may ask several non-adaptive questions in a batch of fixed and known $T$ rounds of adaptivity and requires a fraction of true discoveries. We show that for such an analyst $\Omega(\sqrt{T}/\varepsilon^2)$ samples are necessary.

Second, we show that, under certain assumptions on the oracle, in an interaction with gradient descent $\tilde{\Omega}(1/\varepsilon^{2.5})$ samples are necessary. Our assumptions are that the oracle has only first order access and is post-hoc generalizing. First order access means that it can only compute the gradients of the sampled function at points queried by the algorithm. Our assumption of post-hoc generalization follows from existing lower bounds for statistical queries. More generally then, we provide a generic reduction from the standard setting of statistical queries to the problem of estimating gradients queried by gradient descent.

These results are in contrast with classical bounds that show that with $O(1/\varepsilon^2)$ samples one can optimize the population risk to accuracy of $O(\varepsilon)$ but, as it turns out, with spurious gradients.
1 Introduction

Adaptive data analysis is a recent mathematical framework [12] that aims to deal with modern issues of false discoveries [15, 16, 21]. These issues, potentially, occur when datasets are being reused in order to find statistically significant discoveries which, without proper care, may lead to overfitting due to adaptivity of the analysis to the data. Motivated by these issues, the framework of adaptive data analysis investigates a mathematical model that considers an analyst that interacts with a fixed dataset through access to an oracle or mechanism. In this framework, the analyst is assumed to be malicious and its objective is to find false discoveries i.e. queries for which the oracle fails to answer correctly. The oracle on the other hand, tries to maintain the validity of the answers. Through this formalism, investigators were able to provide new algorithms and methods that allow more principled use of the data [3, 11, 5, 10], as well as complementary work that provides limitations to what can be done with limited resources [23, 14, 22].

A very appealing example for adaptive data analysis, that has been noticed [13, 24], is that of stochastic convex optimization. In this setting we consider an optimizer, which can be regarded as the analyst, whose objective is to minimize a stochastic convex function, given access to finite noisy samples of the function. A standard approach to the problem is to consider an iterative process where the optimizer initializes at some point \( w_1 \) and then incrementally updates \( w_t \) using estimates of the gradient. For example, (full-batch) Gradient Descent performs an update step of the form:

\[
W_{t+1} = \Pi \left( W_t - \frac{\eta}{m} \sum_{i=1}^{m} \nabla f_i(w) \right),
\]

where \( f_i \) are i.i.d noisy instances of the function to be minimized and \( \Pi \) is a projection operator. This approach to stochastic convex optimization falls nicely into the framework of adaptive data analysis: At each iteration the optimizer (or analyst) asks the gradient of the population risk at \( w_t \), receives an estimation that is computed from a dataset and updates its state according to the answer. In Eq. (1), the estimates are provided by the naïve empirical mean.

Motivated by this example of adaptivity, in this work we revisit the framework of adaptive data analysis, and consider it from the lens of optimization. One motivation is to allow us to study the problem of adaptivity in a setting where the analyst has a well defined objective which is not necessarily to generate, maliciously, false discoveries. This affects much of the analysis, as the algorithms are fixed, as well as the number of needed queries and tolerance to noise.

Perhaps the first result that comes to mind in this context is that of SGD: In SGD the algorithm uses highly noisy estimates of the gradient. Instead of taking the empirical mean, we just sample one point (without replacement) as an estimate. On the one hand, it avoids the problem of adaptivity by using few examples per iteration. On the other hand, it does not even try to provide correct gradients. From the optimization point of view this algorithm achieves the optimal statistical rates [19].

But there are algorithms that don’t necessarily avoid adaptiveness and reuse the data to estimate the gradient. For example, full-batch GD as depicted in Eq. (1). How do they perform, and how does the problem of adaptivity affect them? Perhaps as expected, adaptivity does come with a certain cost. A recent construction by Amir et al. [2] shows that GD, with standard choice of hyperparameters (i.e. learning rate and no. of iterations) can minimize the empirical risk, and at the same time overfit and fail to generalize. A close examination of the construction shows that, already in the second step, the gradient starts to be biased and does not represent the true gradient of the loss function. In a subsequent work, [1], it was shown that this problem is inherent in the estimator. Namely, no method can accept the empirical gradients as estimates and optimize the problem with optimal rates. This is perhaps a good example to the shortcoming of naïve reusing of data.

There is a fix though. It leads to suboptimal rates in terms of computation but maintain optimal sample complexity rate. Specifically, Bassily et al. [3] showed that a smaller step size, and more iterations (quadratically more, in fact) would make the algorithm stable, and \( m = O(1/\epsilon^2) \) samples suffice for this iterative process to work. But, from the adaptive data analysis lens, this solution sort of shifts the responsibility from the estimation mechanism to the analyst. In particular, the gradients are still provided as is, it is the analyst that is being stabilized. Moreover, the analyst increased the number of queries. Namely, not only it did not improve the estimates, it actually enhanced its interaction with this inexact mechanism. Importantly, one
can show that the solution does not make the gradients any more accurate (see Theorem 2.2). Only the final output is being salvaged. The natural question, then, is whether we can think of another fix within the framework of adaptive data analysis. Thus, let us consider Gradient Descent as any algorithm that makes adaptive steps as in Eq. (1) but with any estimate of the gradient, not necessarily empirical mean. Then the question we would like to answer is:

What is the sample complexity of providing $O(1/\varepsilon^2)$, $\varepsilon$-accurate gradients of a 1-Lipschitz convex function to Gradient Descent with learning rate $\eta = O(\varepsilon)$?

We require $O(1/\varepsilon^2)$ gradients and $O(\varepsilon)$ learning rate as these are known to be necessary for optimization [20, 18] (and it is also easy to see that it is sufficient). We focus here on dimension-independent bounds as these are the optimal achievable rates. It is easy to see that $\tilde{O}(1/\varepsilon^3)$ is a naive, dimension independent bound that one could achieve (where the oracle uses $O(1/\varepsilon^2)$-fresh new samples at each iteration, hence by standard dimension independent concentration bounds [6]). Standard techniques of adaptive data analysis can also be used to achieve rates of $\tilde{O}(\sqrt{d}/\varepsilon^3)$ [4] but this is both dimension dependent and remains suboptimal for optimization purposes. The question above remains open, but we provide two intermediate answers, which we next describe:

Our first result is for general analysts and not for GD: We show that if an analyst is allowed to query gradients of a convex function then $\Omega(1/\varepsilon^3)$ samples are needed in order to provide $O(1/\varepsilon^2)$ $\varepsilon$-accurate answers. Our result here builds upon existing techniques and attacks [7, 9, 22], and we obtain a new lower bound (which may be of interest of its own right) to an analyst, in the standard statistical query setting, that queries many non-adaptive queries in sequential bulks of adaptive rounds (where the rounds of adaptivity are known, distinctively from [10]) and needs to obtain a fraction of true discoveries. We show that for such an analyst there exists a lower bound of $\Omega(\sqrt{dT}/\varepsilon^2)$ samples, where $T$ is the number of rounds of adaptivity and $\varepsilon$ is the accuracy. We then show a generic reduction to the setting of convex optimization. Though the analyst is not GD, this result does demonstrate that one cannot design a complete mechanism for any analyst with optimal rates. It does leave open, though, the possibility of designing incomplete oracles that interact with specific types of analysts (or algorithms) such as GD.

The second result is for GD. We provide a bound of $\tilde{O}(1/\varepsilon^{2.5})$, but under further assumptions: First, we assume the oracle is post-hoc generalizing [8, 23]. Roughly, post-hoc generalization means that the algorithm does not query points where the empirical loss and true loss differ. While this assumption may seem restrictive, we point out that we inherit it from existing known bounds in the standard statistical query setting. Specifically, we provide a generic reduction from statistical queries to the framework of GD. Then, we apply the lower bound of Ullman et al. [23] that assumes post-hoc generalization. But the reduction is generic, and guarantees, given a lower bound for statistical queries of the form $f(T, \varepsilon)$ where $T$ is the number of queries and $\varepsilon$ is the desired accuracy, a lower bound of the form $f(O(1/\varepsilon), O(\varepsilon))$ in the setting of convex optimization, under a first-order access assumption on the oracle which we discuss next.

The second assumption we make is what we term first-order-access. Here we assume that the oracle must compute the estimate only from the gradients at $\{w_1, \ldots, w_t\}$ and not, say, by using the global structure of the function (we mention that our result can easily be extended to allow any local, but at a small neighbourhood, information of the function). Note that, since the function must be fixed throughout the optimization process, and since the optimization algorithm is fixed, allowing the oracle global access to the function restricts us from using any type of randomness other than the randomness of the distribution. Hence, while slightly more delicate then the first assumption, here too we require this assumption since in the standard statistical query setting lower bounds are provided with respect to random analysts. Our reduction, then, can turn a more general oracle (without first-order access) into a procedure that can answer statistical queries against a deterministic analyst (in the sense that the distribution may be random, but the analyst’s strategy is fixed and known). This seems like an interesting question for future study.

It is interesting, then, to compare these results to recent adaptations of the standard model that restrict the analyst [24]. This is largely motivated by the reasoning that analysts are not necessarily adversarial. Our result, though, may hint (if one considers GD as a non malicious algorithm in this context) that the problem may be in the distribution of the data and not necessarily in the analyst. Namely, a general reduction from statistical queries to the framework of GD along our lines, will show that any lower bound can be described as constructing a malicious distribution which leads to overfitting together with a non-malicious analyst.
2 Background

2.1 Adaptive Data Analysis

We begin by revisiting the standard statistical queries setting of adaptive data analysis introduced by Dwork et al. [12]. In this model, we consider a subset $Q$ of statistical queries over a domain $X$. A statistical query is defined to be any function $q : X \rightarrow [-1, 1]$. We consider a sequential interaction between an analyst $A$ and a statistical queries oracle $O$ (or simply oracle) that continues for $T$ iterations and is depicted as follows:

At the beginning of the interaction the analyst $A$ chooses a distribution $D$ over $X$. The Oracle $O$ is provided with a finite collection of samples $S = \{x_1, \ldots, x_m\}$ drawn i.i.d from the distribution $D$. Then the interaction continues for $T$ sequential rounds: At round $t \geq 1$, $A$ provides a statistical query $q_t \in Q$, and the oracle $O$ returns an answer $a_t \in [-1, 1]$. The answer $a_t$ may depend on the dataset $S$ as well as on previous answers and queries $\{q_1, \ldots, q_t\}$. The query $q_t$ may depend on previous answers $\{a_1, \ldots, a_{t-1}\}$, as well as on the distribution $D$ (which is thought of as known to the analyst).

The goal of the oracle is to preserve accuracy, as next defined. And, here, we mostly care about the minimal size $m$ that is required by $O$ in order to succeed.

**Definition 2.1.** An oracle $O$ is $(\varepsilon, \gamma, \delta)$-accurate for $T$ adaptively chosen queries given $m$ samples in $X$ if for every analyst $A$ and distribution $D$, with probability at least $(1 - \delta)$ for $(1 - \gamma)T$ fraction of the queries output by $A$:

$$|a_t - q_t(D)| \leq \varepsilon.$$  

We will write, for brevity, $(\varepsilon, \delta)$-accurate instead of $(\varepsilon, 0, \delta)$-accurate. An additional requirement of post-hoc generalization [8], is also sometimes imposed:

**Definition 2.2.** An oracle $O$ is $(\varepsilon, \delta)$-post hoc generalizing for $T$ adaptive queries with $m$ samples if: given $m$ samples, for every analyst $A$, with probability at least $(1 - \delta)$: for all $t \in [T]$

$$\left| \frac{1}{m} \sum q_t(x_i) - q_t(D) \right| < \varepsilon.$$  

The following result bounds the sample complexity of a post-hoc generalizing oracle:

**Theorem 2.1** (Cor 3.2 [23]). There exists an analyst $A$, such that for every Oracle $O$, if $O$ is $(\varepsilon, 0.005)$ post hoc-generalizing and $(\varepsilon, 0.005)$-accurate, given $m$ samples, for $T$ adaptively chosen queries by $A$, then

$$m = \Omega(\sqrt{T}/\varepsilon^2).$$  

(2)

2.2 Stochastic Convex Optimization

We next review the setting of stochastic convex optimization. In this model we consider a function $f(w, x) : \mathbb{R}^d \times X \rightarrow \mathbb{R}$, which is convex and $O(1)$-Lipschitz in the parameter $w$, for every $x \in X$. We also consider a distribution $D$ over $X$ and we denote by $F$ the population risk:

$$F(w) = \mathbb{E}_{x \sim D} [f(w, x)].$$

The objective of an optimization algorithm $A$ (or analyst) is to calculate $w^*$ such that:

$$F(w^*) \leq \min_{\|w\| \leq 1} F(w) + \varepsilon.$$  

In order to achieve this goal, we also assume an interaction with what we’ll call here exact-first-order oracle, $O_{f, \nabla f}(w, x)$, for the function $f$ that, given $w$ and $x$ returns

$$O_{f, \nabla f}(w, x) = (O_f(w, x), O_{\nabla f}(w, x)) := (f(w, x), \nabla f(w, x)).$$
full-batch Gradient Descent Arguably, one of the most well studied algorithms in this context is that of Gradient Descent. Here we assume a very simple update rule: At first, the algorithm initializes at \( w_1 = 0 \). Then, at each iteration \( t \) the algorithm updates

\[
w_{t+1} = \Pi \left[ w_t - \frac{\eta}{m} \sum_{i=1}^{m} \nabla f(w_t, x_i) \right],
\]

where \( \Pi \) is a projection on the unit ball. Considering the objective of minimizing the population risk, the following result bounds the iteration complexity required for a full batch gradient descent:

**Theorem (3).** Let \( D \) be an unknown distribution, over \( \mathcal{X} \) and suppose that \( f(w, x) \) is \( O(1) \) Lipschitz and convex with respect to \( w \in \mathbb{R}^d \). Let \( S = \{x_1, \ldots, x_m\} \) be a sample drawn i.i.d from distribution \( D \), and consider the update rule in Eq. (3) with a first order oracle \( \mathcal{O}_{\nabla f} \). Then for \( w_S = \frac{1}{T} \sum_{t=1}^{T} w_t \)

\[
E_{S \sim D^m}[F(w_S)] \leq \min_{\|w^*\| \leq 1} F(w^*) + O \left( \sqrt{\frac{m}{T}} + \frac{1}{T} \sum_{t=1}^{T} \frac{\eta T}{m} \right).
\]

In particular, a choice of \( T = O(m^2) \), \( \eta = 1/m^{3/2} \) leads to an error of \( O(1/\sqrt{m}) \) which is statistically optimal. As discussed, Amir et al. [2] provided a matching lower bound for GD.

One could also ask whether the empirical mean of the gradients also generalizes. Namely, is the empirical mean of the gradients close to their true expectations? A close examination of the construction used by Amir et al. [2] shows that, without special care, the empirical estimate of the gradient, fails to provide accurate gradients, even if we choose the learning rate and number of iteration to minimize Eq. (4).

We provide a proof sketch in Appendix A.

**Theorem 2.2.** Suppose we run GD over an i.i.d sample, with learning rate \( \eta > 0 \). There exists a distribution over \( \mathcal{X} \) and an \( O(1) \) convex Lipschitz function. Such that if \( S \) is a sample drawn i.i.d from the distribution \( D \) of size \( m \) and \( w_t \) is defined as in Eq. (3) then for \( t = 2 \), with probability \( 1/2 \) over \( w_2 \):

\[
\left\| \mathbb{E}_{S \sim D^m} \left[ \frac{1}{m} \sum_{i=1}^{m} \nabla f(w_2, x_i) \right] - \nabla F(w_2) \right\| = \Omega(1).
\]

As discussed, there is in fact a simpler example to the fact that optimizing the objective doesn’t require accurate gradients which is SGD. It is known that when \( T = m \) and \( \eta = 1/\sqrt{T} \), the analyst optimizes the objective to the same accuracy of \( O(1/\sqrt{m}) \). Remarkably, this requires even less iterations and the gradient doesn’t even presume to be accurate. Nevertheless, the analysis here rely on the fact that the gradient is an unbiased estimate, where adaptivity is avoided since we use a fresh example at every round.

It is also worth mentioning that recently Koren et al. [17] showed that, in adaptive data analysis terminology, SGD is an example to a non post-hoc generalizing algorithm in the following sense: It can be shown that the output parameter \( w_S \) provided by SGD may minimize the population loss, but there is a constant gap between the empirical and population loss at \( w_S \).

## 3 Problem setup

We next describe our setting. We consider the problem of adaptiveness within the context of stochastic convex optimization. We consider an interaction between an analyst \( A \) and a first-order optimization oracle, \( O_F \). At the beginning of the interaction the analyst chooses a function \( f \) and a distribution \( D \). Then a sample \( S = \{x_1, \ldots, x_m\} \) is drawn and provided to the oracle. The interaction then proceeds for \( T \) rounds, where at round \( t \in [T] \) the analyst queries for a point \( w_t \), and the oracle returns \( O_F(w_t) \in \mathbb{R}^d \). The query points \( w_1, \ldots, w_T \) may depend on the distribution \( D \) and the oracle answer \( O_F(w_t) \) may depend on the sample \( S \), the function \( f \), as well as on the sequence of previously seen \( w_1, \ldots, w_{t-1} \).

\(^1\)Having the analyst choose the distribution is a little bit unnatural in this setting, as generally the analyst wants to optimize the risk. However, since our focus is not to produce optimization algorithms but to analyze them, this will not be a restriction.
Gradient Descent. Let us now describe the algorithm GD, with learning rate \( \eta > 0 \), within our framework. For every \( \eta > 0 \) we let GD with learning rate \( \eta \) be defined by the following update at each iteration \( t \geq 1 \) (setting \( w_1 = 0 \)):

\[
w_t = \Pi(w_t - \eta \nabla \mathcal{O}_f(w_t)),
\]

where \( \Pi \) is the projection operator over the \( \ell_2 \)-unit ball. Notice that, if \( \mathcal{O}_f \) has an access to an exact first order oracle for \( f \), \( \mathcal{O}_\nabla f \), and returns the empirical mean at each iteration then we obtain full-batch GD as described in Eq. (1). Before we continue, we notice that good generalization of \( \mathcal{O}_f \) is sufficient for optimization. Indeed, the following result is an easy adaptation of the classical optimization bound for GD:

**Theorem 3.1.** Let \( D \) be an unknown distribution over \( \mathcal{X} \) and suppose that \( f(w, x) \) is \( O(1) \)-Lipschitz and convex with respect to \( w \in \mathbb{R}^d \). Let \( S = \{x_1, \ldots, x_m\} \) be a sample drawn i.i.d from distribution \( D \), and consider the update rule in Eq. (5). Assume that for every iteration \( \mathcal{O}_f \) satisfies

\[
|\mathcal{O}_f(w_t) - \nabla F(w_t)| \leq \varepsilon,
\]

Then for \( w_S = \frac{1}{T} \sum_{t=1}^T w_t \)

\[
E_{S \sim D}[F(w_S)] \leq \min_{\|w^*\| \leq 1} F(w^*) + O\left( \eta + \frac{1}{\eta T} + \varepsilon \right).
\]

The above rate is optimal, which leads to the natural question, what is the sample needed by an oracle that returns \( O(1/\varepsilon^2) \) \( \varepsilon \)-accurate gradients for GD with learning rate \( O(\varepsilon) \). Such an oracle improves over full-batch GD which requires \( \Theta(1/\varepsilon^4) \) iterations to achieve error of \( O(\varepsilon) \). The performance of such an oracle should also be compared with SGD that can achieve a comparable bound on the number of iterations and requires the optimal sample size of \( m = O(1/\varepsilon^2) \).

Next, we provide natural extensions to the definition of adaptive oracles to the setting of stochastic optimization.

**Definition 3.1.** A first order oracle \( \mathcal{O}_f \) is \((\varepsilon, \gamma, \delta)\)-accurate against algorithm \( A \) for \( T \) iterations, given \( m \) samples, if \( \mathcal{O}_f \) is provided with \( m \) samples and with probability at least \((1 - \delta)\) for \((1 - \gamma)T\) fractions of the \( t \in [T] \):

\[
\|\mathcal{O}_f(w_t) - \nabla F(w_t)\| \leq \varepsilon.
\]

If \( \mathcal{O} \) is \((\varepsilon, \gamma, \delta)\)-accurate against any algorithm \( A \) we say it is \((\varepsilon, \gamma, \delta)\)-accurate.

We will write in short \((\varepsilon, \delta)\)-accurate for \((\varepsilon, 0, \delta)\)-accurate.

**Definition 3.2.** A first-order oracle \( \mathcal{O}_f \) is \((\varepsilon, \delta)\)-post hoc generalizing against algorithm \( A \) for \( T \) iterations, given \( m \) samples if with probability at least \((1 - \delta)\): for every \( t \in [T] \)

\[
\|\nabla F(w_t) - \frac{1}{m} \sum_{i=1}^m \nabla f(w_t, x_i)\| \leq \varepsilon.
\]

If \( \mathcal{O} \) is \((\varepsilon, \delta)\)-post hoc generalizing against any algorithm \( A \) we simply say it is \((\varepsilon, \delta)\)-post hoc generalizing.

First order local access. We next introduce the following assumption on the oracle:

**Definition 3.3.** A first order first-order-access (FOA)-oracle \( \mathcal{O}_f \) is a procedure that, given access to an exact-first-order oracle \( \mathcal{O}_{\nabla f} \) to the function \( f \), and access to a sample \( S \) of size \( m \), returns for every point \( w_t \) a gradient estimate \( \mathcal{O}_f(w_t) \) that may depend only on

\[
\{\mathcal{O}_{\nabla f}(w_{t'}, x_i)\}_{x_i \in S},
\]

for every \( t' \leq t \).

Equivalently, we may think of an FOA oracle as a procedure that does not have access to \( f \), instead, at each iteration \( t \) receives as input the parameter \( w_t \) as well as a function

\[
\tilde{\rho}_t : \mathcal{X} \rightarrow \mathbb{R} \times \mathbb{R}^d,
\]

such that \( \tilde{\rho}_t(x) = (f(w_t, x), \nabla f(w_t, x)) \) for every \( x \).
4 Main Results

We are now ready to state our main results. Our first result state that, for a general analyst, the oracle cannot generalize for $T = O(1/\varepsilon^2)$ estimated gradients, unless it is provided with $m = \Omega(1/\varepsilon^3)$ examples. The proof is provided in Section 5.2.1

Theorem 4.1. There exists constants $\gamma, \delta > 0$ and a randomized analyst $A$ the chooses a determined 1-Lipschitz function $f$, defined over sufficiently large $d$, such if $OF$ is a first-order oracle that is $(\varepsilon, \gamma, \delta)$-accurate against $A$ for $T$ iterations, then $m = \Omega\left(\frac{\varepsilon^3}{\gamma^2}\right)$. In particular, any oracle $OF$ that is $(\varepsilon, \gamma, \delta)$-accurate for $T = O(1/\varepsilon^2)$ iterations must observe $m = \Omega\left(1/\varepsilon^3\right)$ examples.

Making no assumption on the analyst may seem non-realistic, especially to assume it is malicious and attempts to achieve false gradients. Nevertheless there is value in producing oracles that are foolproof. The above theorem shows that such security guarantees are impossible with the standard sample complexity.

The next natural thing that we might want to consider is an oracle that is principled under certain assumptions on the optimization algorithm. We might even hope to design an incomplete oracle that can interact with specific optimization algorithms and halt when certain assumptions are broken. The next result demonstrate that limitations from general statistical queries can be translated into limitations for (FOA) oracles that interact with gradient descent. The proof is provided in Section 6.3.

Theorem 4.2. For sufficiently large $d$, suppose that there exists a FOA oracle, $OF$, that is $(\varepsilon, \delta)$-accurate that receives $m$ samples and answers $T$ adaptive queries against Gradient Descent with learning rate $\eta = O(\varepsilon)$. Then there exists a $(O(\varepsilon), O(\delta))$-accurate statistical queries oracle, $O$, that receives $m$ samples and answers $\Omega\left(\min\{T, 1/\eta\}\right)$ adaptive queries.

Moreover, if $OF$ is $(\varepsilon, \delta)$-post-hoc generalizing then $O$ is $(O(\varepsilon), O(\delta))$-post-hoc generalizing.

Together with Theorem 2.1 we obtain the following corollary

Corollary 4.3. For sufficiently large $d$, let $OF$ be an $(\varepsilon, \delta)$-accurate and post-hoc generalizing FOA that receives $m$ samples and answers $T > \Omega(1/\varepsilon)$ adaptive queries against Gradient Descent with learning rate $\eta = O(\varepsilon)$. Then $m = \Omega\left(1/\varepsilon^{2.5}\right)$.

We stress again, that, in contrast with these results, an optimization algorithm can correctly minimize the true loss using no more than $\tilde{O}(1/\varepsilon^2)$ iterations and $\tilde{O}(1/\varepsilon^2)$ examples [17].

5 Lower bounds against malicious analysts

In this section we set out to prove Theorem 4.1 and provide a lower bound to general oracles against adversarial analysts. In section Section 5.2 we show how to turn a generic lower bound for statistical queries to a lower bound in convex optimization. However, to the best of the author’s knowledge, there is no (unconditional) known lower bound that shows that $m = \Omega(\sqrt{T}/\varepsilon^2)$ examples are necessary to answer $T$ queries. So we actually rely on a slightly stronger reduction than from the standard setting of statistical queries. We rely, then, on the fact that querying a single gradient carries more information than a single statistical query, in fact $d$ more. However, these may not be chosen adaptively, and the errors are spreaded.

The setting from which we provide the reduction is as follows: We consider an analyst that at each iteration $t$ can ask $k$ non-adaptive queries. This is reminiscent to a similar problem that was studied by Dwork et al. [12] but, there it is unknown what are the rounds of adaptivity. Here we consider a significantly simpler problem where the rounds of adaptivity are known in advance and we show, using ideas from [7] (that constructs a similar lower bound but in the setting of privacy), that for certain $k = \Omega(1/\varepsilon^2), \Omega(\sqrt{T}/\varepsilon^2)$ samples are needed to ensure a large enough fraction of the answers are correct. Then, as discussed, we provide a generic reduction to convex optimization. We now turn to describe the setting of adaptive non-adaptive queries and state our main lower bound for this setting.

5.1 Adaptive-non-Adaptive queries

In this section we take a little detour from our basic setting and return to the setting of statistical queries.
5.1.1 Setup

We will consider now a natural generalization of the standard setting of adaptive data analysis where, we allow the analyst to query at each round \(k\) queries simultaneously. In this setting, as before, we have a family of queries \(Q\) as well as an analyst \(A\) and oracle \(O\) which interact for \(T\) rounds. Distinctively from before, at round \(t\) we assume \(A\) asks \(k\)-statistical queries \(q_t = \{q_{t,1}, \ldots, q_{t,k}\} \subseteq Q^k\), and \(O\) returns an answer vector \(a_t = (a_{t,1}, \ldots, a_{t,k})\). The answer vector \(a_t\) may depend on the sample \(S\) and on previously published queries \(q_1, \ldots, q_t\). Similarly the query vector may depend on previous answer vectors \(a_1, \ldots, a_{t-1}\) and the distribution \(D\).

**Definition 5.1.** Similar to Definition 2.1, we say that \(O\) is \((\varepsilon, \gamma_T, \gamma_k, \delta)\)-accurate for \(T\) adaptively chosen queries, given \(m\) samples, if the oracle samples at most \(m\) samples and with probability \(1 - \delta\) we have for \((1 - \gamma_T)\) fraction of the rounds, for \((1 - \gamma_k)\) of the queries:

\[
|O(q_{t,i}) - q_{t,i}(D)| \leq \varepsilon.
\]

We next set out to prove the following lower bound:

**Theorem 5.1.** For \(k = \Omega(1/\varepsilon^{2.01})\), there exists a finite family of queries \(|Q|\), constants \(\gamma_T, \gamma_k, \delta\), such that no oracle \(O\) is \((\varepsilon, \gamma_T, \gamma_k, \delta)\) accurate for \(k\)-non adaptive \(T\) adaptively chosen queries given \(m\) samples unless \(m = \Omega(\sqrt{T}/\varepsilon^2)\)

Before we begin with the proof, we provide several preliminary results that we build upon.

5.1.2 Technical Preliminaries

The proof of Theorem 5.1 relies on two types of attacks that were introduced by Steinke and Ullman [22], De [9] as well as a method to combine them which has also appeared in [7]. Our first type of attack is a standard reconstruction attack, we follow the definition of Bun et al. [7):

**Definition 5.2** (Reconstruction Attack). For a dataset \(S = \{x_1, \ldots, x_m\}\), we will say that \(S\) enables an \(\varepsilon'\)-reconstruction attack from \((\varepsilon, \gamma)\)-accurate answers to the family of statistical queries \(Q\) if: There exists a function

\[
B : \mathbb{R}^{|Q|} \rightarrow [0, 1]^m,
\]

such that for every vector \(v \in [0, 1]^m\) and every answer sequence \(a = (a_q)_{q \in Q} \in [0, 1]^Q\): If for at least \(1 - \gamma\) fraction of the queries \(q \in Q\) holds:

\[
|a_q - \frac{1}{m} \sum_{i=1}^m q(x_i)v(i)| < \varepsilon,
\]

then for \(b = B(a)\):

\[
\frac{1}{m} \sum_{i=1}^m |b(i) - v(i)| < \varepsilon'.
\]

The following result is due to De [9], we state it as in [7]:

**Theorem 5.2.** Let \(k \geq 1/\varepsilon^{2.01}\), and assume \(\varepsilon\) is sufficiently small. There exists a constant \(\gamma_0\) (independent of \(\varepsilon\) and \(k^2\)) such that for every \(\varepsilon'\), there exists a dataset \(S = (\{0, 1\}^k)^n\) with \(|S| = \Omega(1/\varepsilon^2)\) such that \(S\) enables an \(\varepsilon'\)-reconstruction attack from \((\varepsilon, \gamma_0)\)-accurate answers to a family of queries \(Q\) of size \(k\).

The second attack that we rely on provides an information theoretic lower bound of \(\Omega(\sqrt{k})\) to answer adaptive statistical queries:

**Theorem 5.3** (Thm 3.10 [22]). For all \(\gamma < 1/2\), there is a function \(T(m, \gamma) \in \Omega(m^2/(1/2 - \gamma)^4)\), such that there is no oracle \(O\) that is \((0.99, \gamma, 1/2)\)-accurate for \(T(m, \gamma)\) adaptively chosen queries, given \(m\) samples in \(\{0, 1\}^d\), where \(d \geq T(m, \gamma)\).

\(^2\)note that in [7] \(k\) is used to describe \(k\)-way marginals, where we state here the theorem for \(k = 1\) in [7] notation
We will require a dual restatement of Theorem 5.3, which essentially follows the same proof together with standard minmax theorem:

**Theorem 5.4.** There exists a randomized analyst $A$ such that for any oracle $O$ that interacts with $A$ for $T(m, \gamma)$ rounds having $m$ samples, then with probability at least $1/2$ for at least $\gamma T$ of the rounds:

$$|a_t - q_t(D)| > 0.01.$$  

**Proof Sketch.** The proof is essentially the proof of Theorem 5.3 as depicted by Steinke and Ullman [22]. We only need to argue that in the construction of Steinke and Ullman [22] the adversarial analysts that are being constructed are from a finite set and hence use standard minmax duality. To see that the analysts in the original proof are supported on a finite set, first observe that the analyst chooses (randomly) a uniform distribution over a sequence of pairs $(1, v_1), (2, v_2), \ldots, (N, v_N)$ where $N = T(m, \gamma)$ and each $v_i$ depicts a secret key (where for the information-theoretic lower bound we choose a one-time pad encryption and then $v_i \in \{\pm 1\}^N$). Hence the set of feasible distributions is of size $2^N$, and $N = O(T(m, \gamma))$. Next, we note that at each iteration, the analyst rounds the answer for $O$, $a_t$ and chooses as a query, $q_t$ which is parameterized by a vector in $\{-1, 0, 1\}^N$. Hence, the query at round $t$ depends on $t$ vectors in $\{-1, 0, 1\}^N$ and $\{\text{sgn}(a_1), \ldots, \text{sgn}(a_t)\}$ hence overall there is a finite set of states to which the analyst can transition at each iteration, so overall there is only a finite amount of analysts on which the distribution is supported. ■

### 5.2 Proof of Theorem 5.1

Let $k \geq 1/\varepsilon^2.01$, and set $Q_\varepsilon$ be a set of queries over a dataset $S_x$ and $\gamma_0$ a parameter that enables an $\varepsilon'$-reconstruction attack from $(\varepsilon, \gamma_0)$-accurate answers to $Q_\varepsilon$ as guaranteed in Theorem 5.2. Without loss of generality we assume $\gamma_0 < 1/2$, and $\varepsilon'$ is chosen such that:

$$\varepsilon' < \frac{0.01}{3 \cdot 2^k}.$$  

Now we let $d = \mid S_x \mid = O(1/\varepsilon^2)$.

Suppose $Q$ is a family of queries, and given a sequence of $d$ analysts $(A_1, \ldots, A_d)$ in the standard model (i.e. each analyst asks a single question), we define an analyst that asks $k$ queries $A$ as follows:

First, when the analysts choose distributions $D_1, \ldots, D_d$ over $X$, the analyst $A$ defines a distribution $D$ over $S_x \times X$ that chooses first randomly and uniformly $i \in [d]$ and returns $(s_i, x)$ where $x \sim D_i$.

The interplay with the oracle proceeds as follows: At each iteration $t$, we assume by induction that each analyst, $A_1, \ldots, A_d$, provides a query $q_{t,1}, \ldots, q_{t,d}$. The analyst $A$ constructs for each query $q \in Q_\varepsilon$ the query

$$q'((s_i, x)) = q(s_i)q_{t,i}(x),$$

and asks these $k$ non-adaptive queries.

Then, given the answer vector $\{a_{q'}\}$, we provide analyst $A_t$ with the answer $a_{t,i}$, where

$$a_t = B(a_{q'}),$$

and $B$ defines the reconstruction attack in Theorem 5.2. The analysts then provide the queries $q_{t+1,1}, \ldots, q_{t+1,k}$ and the analyst $\bar{A}$ continues to the next round until round $T$.

Our analyst then depends on the $d$ analysts. We choose them to be $d$ i.i.d copies of the analyst in Theorem 5.4 and we let $\bar{A}$ be the analyst induced by such $A_1, \ldots, A_d$.

Notice that when we fix $A_1, \ldots, A_{i-1}, A_{i+1}, \ldots, A_d$, through this analyst $\bar{A}$ we induce an oracle, that we denote by $O_i$ that interacts with analyst $A_i$. To be more specific, we consider a randomized analyst $O_i$ who operates as follows: $O_i$ draws $A_1, \ldots, A_{i-1}, A_{i+1}, \ldots, A_d$, as well as samples $s^{(1)}, \ldots, s^{(m)}$. For each sample $s^{(j)} \neq s_i$ the oracle gets a sample ($x \sim D_{s^{(i)}}$). Then given $m_i$ samples $\{x_1, \ldots, x_m\}$ from $D_i$, where $m_i$ is the number of times $s_i$ was drawn, the oracle adds to the sample the sample points $\{(s_i, x_j)\}_{j=1}^{m}$ and interact with $A_i$ where at each round $\bar{A}$ transmit the question, $O$ answers, and $\bar{A}$ transmit the answer back, as described above. In this interaction the number of samples is random, but notice that if $T \geq T(m_i, 1/4)$, where

$$T(m, 1/4) = O(m^2),$$

8
is defined in Theorem 5.4, then with probability at least 1/2 for $T/4$ of the rounds, by Theorem 5.4
\[
\|a_{t,i} - q_{t,i}(D_i)\| > 0.01.
\]

This also entails that for every $i$:
\[
\mathbb{E}_{\Lambda_i, Q_i} \left( \frac{1}{T} \sum_{t=1}^{T} |a_{t,i} - q_{t,i}(D_i)| \right) > \frac{0.01}{2^5} \mathbb{P}(T \geq T(m_i, 1/4)). \tag{6}
\]

Now assume $O$ is $(\varepsilon, \varepsilon', \gamma_0, \varepsilon')$-accurate for $T = T(4m/3d, 1/4)$ rounds, and consider $A$ as defined above. Then with probability $1 - \varepsilon'$: for $(1 - \varepsilon')$-fractions of the rounds, for $(1 - \gamma_0)$-fraction of the queries $q'$:
\[
\left| a_{q'} - \frac{1}{k} \sum_{i=1}^{k} q(x_i)q_i(D_i) \right| = |a_q - q'(D)| < \varepsilon.
\]

Which entails by reconstruction attack, for the same fraction of rounds:
\[
\frac{1}{k} \sum_{i=1}^{k} |a_{t,i} - q_{t,i}(D_i)| \leq \varepsilon'.
\]

Taken together we have
\[
\mathbb{E} \left[ \frac{1}{T} \sum_{t=1}^{T} |a_{t,i} - q_{t,i}(D_i)| \right] \leq 3\varepsilon' \leq \frac{0.01}{2^6}. \tag{7}
\]

On the other hand, notice that for any analyst, with probability $1/4$, $O_i$ is provided with less than $4m/3d$ samples from the distribution $D_i$

So by choice $T \geq T(4m/3d, 1/4) = O(m^2\varepsilon^4)$, and by Eq. (6), we have:
\[
\mathbb{E}_{\Lambda, Q} \left( \frac{1}{T} \sum_{t=1}^{T} \sum_{i=1}^{k} |a_{t,i} - q_{t,i}| \right) = \frac{1}{k} \sum_{i=1}^{k} \mathbb{E}_{\Lambda_i, Q_i} \left( \frac{1}{T} \sum_{t=1}^{T} |a_{t,i} - q_{t,i}| \right) > \frac{0.01}{2^5}.
\]

contradicting Eq. (7).

5.2.1 Proof of Theorem 4.1

We are now ready to prove Theorem 4.1. Given a family of queries $|Q| \leq d$ index the coordinates of $\mathbb{R}^d$ by the elements of $Q$. Namely, we think of $\mathbb{R}^d$ as $\mathbb{R}^Q$ where each vector $w \in \mathbb{R}^Q$ is thought of as a function $w : Q \to \mathbb{R}$.

We define a convex function in $\mathbb{R}^Q$:
\[
f(w, x) = \sum_{q \in Q} \frac{q(x) + 1}{4} w^2(q). \tag{8}
\]

Note that, since $|q(x)| \leq 1$, the above function is always convex and 1-Lipschitz for any choice of queries and $x$. Let $O_F$ be a first order $(\varepsilon, \gamma_T, \delta)$-accurate oracle, and let us consider the setting of an analyst that requires $k$ non adaptive queries for $T$ rounds. Let $A$ be an analyst that asks $k$ non adaptive, $T$ adaptive queries, and consider an oracle $O$ that performs as follows: Given queries $q_{t,1}, \ldots, q_{t,k}$, the oracle $O$ transmit to the oracle $O_F$ the point:
\[
w_t = \frac{1}{\sqrt{k}} \sum_{i=1}^{k} e_{q_{t,i}},
\]

where $e_q$ is the vector in $\mathbb{R}^Q$ that is $e_q(q) = 1$, and $e_q(q') = 0$ when $q' \neq q$. In turn, the oracle receives the answer vector $O_F(w_t) = g_t$ and returns the answers $a_{t,i} = 2\sqrt{k}g_t(q_{t,i}) - 1$

Now suppose that with probability $(1 - \delta)$ for $\gamma_T$ fraction of the rounds:
\[
\|g_t - \nabla F(w_t)\| \leq \varepsilon,
\]
then:
\[
\frac{1}{k} \sum \left( \frac{a_{t,i} - q_{t,i}(D)}{2} \right)^2 = \sum \left( \frac{a_{t,i} + 1}{2k} - \frac{q_{t,i}(D) + 1}{2k} \right)^2 \leq \|g_t - \nabla F(w_t)\|^2 \leq \varepsilon^2.
\]

Then by Markov’s inequality for any \(\gamma_k\), for \(\gamma k\) fraction of the queries we have:
\[
|a_{t,i} - q_{t,i}(D)| \leq \frac{2\varepsilon}{\sqrt{\gamma k}}.
\]

Which means \(O\) is an \((\frac{2\varepsilon}{\sqrt{\gamma k}}, \gamma_T, \gamma k, \delta)\)-accurate oracle that answers \(k\) non adaptive \(T\) adaptive queries. By Theorem 5.1, for small enough \(\varepsilon\), with correct choice of \(\gamma_k, \gamma_T\) and \(\delta\):
\[
m = \Omega \left( \sqrt{T/\varepsilon^2} \right).
\]

6 Gradient Descent

In this section we set out to prove Theorem 4.2. In contrast to previous result, here we fix the analyst and assume that it performs predefined update steps. This puts several complications into the lower bound as we cannot actively make it “adversarial”, at least not in the standard way. Nevertheless our construction builds on a similar idea as the proof before. The idea here is to think of the function as a “state” machine, where each coordinate represents a query that may be asked. The analyst, given answers to the queries, moves to the next query. The complication though, is that here the dynamic is predefined and we need to design our function carefully so that GD will induce the correct transition between states.

The idea is captured in what is our main technical workhorse which is the notion of a GD simulation, which we build in Section 6.4. GD simulations will be used to provide a reduction from a special class of analysts termed Boolean analysts, which are depicted in Section 6.1. Then we use a simple reduction from general analysts (see Lemma 6.1) to obtain a reduction from general analysts to our setting.

We begin with a brief overview of the construction. After that, in Section 6.2 we depict the technical notion of GD simulation. We then explain, in Section 6.3, how to deduce Theorem 4.2 from the existence of a GD simulation. Finally, in Section 6.4 we provide a construction of a GD simulation, which concludes the proof.

6.1 Brief overview

As discussed, the heart of our construction is the notion of a GD simulation. The idea is quite straightforward. Given an analyst \(A\) we want to construct a convex function \(f_A\) that is convex and such that the trajectory of the function provides the answers to our question. We’ve done something similar in the construction of Eq. (8). There too, we constructed a convex function that the gradient of \(w_t\) at a certain coordinate provides an answer to a given query. The issue though is that there we could ask to query any coordinate we wanted. Here we need to make sure that the dynamic of GD moves us from query \(q_t\) to query \(q_{t+1}\).

Thus, the first requirement that we want from our function \(f_A\) is that by looking at the outputs: \(O(w_1), \ldots, O(w_{t-1})\) we can identify the answer to query \(q_t\). For one non-adaptive query this is straightforward. Indeed, consider the linear function
\[
f_q(w, x) = q(x) \cdot w(1).
\]

Then, the gradient \(\nabla F_q(w) = \mathbb{E}_{x \sim D}[q(x)]e_1\). So we can identify the answer to the first query.

Simulating an adaptive analysis with 2 questions As a next step, let us construct a GD simulation that works as follows: At step \(t\) the simulation will provide answer to query \(q_1\), and if \(q_1(x) > b_1\) for some threshold \(b_1\), then the simulation transitions to a state that identifies the answer to a query \(q^+\) and else moves to a state that identifies \(q^-\) (to simplify, we will assume that the answer is never \(q = b_1\)). This is still far from a general strategy of an analyst, but at the end of this overview we will discuss how we can reduce the general problem to a problem of a similar form.
Also, for the exposition we don’t want to consider the oracle’s strategy, hence assume that at each iteration the oracle returns the true gradient and we will show how the trajectory simulates the adaptive query interaction:

\[ f_{q,q^+,q^-} = \max \left\{ w(1) + \eta - \frac{1-q(x)}{3}w(2) - \frac{1+q(x)}{3}w(3)w(4), w(3) + q^+(x)w(5) \right\}. \]

Our function is described as the maximum of three linear functions hence it is convex. Now let us follow the trajectory for the first two steps. At the first step, note that the first term maximizes the term. Recall that the gradient of a function \( f = \max\{g_1, \ldots, g_k\} \), is given by \( \nabla f = \arg \max_{i \in [k]} \nabla g_i \) hence we have that for \( w_1 = 0 \), for every \( x \):

\[ \nabla f_{q,q^+,q^-}(0, x) = e_1 - \frac{1-q(x)}{3}e_2 - \frac{1+q(x)}{3}e_3. \]

hence:

\[ w_2 = w_1 - \eta \nabla \mathbb{E}_{x \sim D}[f_{q,q^+,q^-}(0, x)] = -\eta e_1 + \frac{1-q(D)}{3} \eta e_2 + \frac{1+q(D)}{3} \eta e_3. \]

Now, note that the first term is no longer maximized by \( w_2 \) for any \( x \), as we moved against the gradient and now it smaller. On the other hand, if \( q(D) < 0 \) the second term is maximized, and else the last. Assume the first: then

\[ \mathbb{E}_{x \sim D} \nabla f(w_2, x) = e_2 + q^+(D)e_4, \]

Note that the gradient at \( w_2 \) tells us exactly whether \( q(D) > 0 \) or \( q(D) < 0 \). In particular, if \( \mathcal{O}(w_2)_2 > 1/2 \), then we know the \( q(D) > 0 \). Any oracle that returns an approximate answer will also identify the answer. Using a recursive process, along these lines, we then can construct a convex function that moves from one query to another using gradient descent.

In general, the state of an analyst does not depend, necessarily, on some threshold value as in our case above. However, as the next reduction shows, if we are willing to suffer a \( \log 1/\varepsilon \) factor increase in the number of queries, we can turn a general analyst to an analyst whose decision indeed depend on some threshold as depicted here:

**Boolean Analysts** We will call an analyst Boolean if it provides to the oracle a query \( q_t : \mathcal{X} \to [-1, 1] \) and its state at time \( t \) depends only on \( \{\text{sgn}(a_1), \text{sgn}(a_2), \ldots, \text{sgn}(a_{t-1})\} \). A more general setup could allow at each iteration a query \( q_t \) and a threshold \( b_t \) and the state may depend only on \( \text{sgn}(a_1 - b_1), \ldots, \text{sgn}(a_{t-1} - b_{t-1}) \). However, up to rescaling it can be seen that the two types of analysts are equivalent.

For such a boolean analyst, we define an oracle to be \( (\varepsilon, \delta) \)-accurate for \( T \) adaptive queries against a Boolean analyst, if given \( m \) samples for every Boolean analyst \( A \) with probability at least \( (1 - \delta) \) for all \( t \in [T] \) if \( a_t = 1 \) then

\[ q_t(D) > -\varepsilon, \]

and if \( a_t = -1 \)

\[ q_t(D) < \varepsilon. \]

Similarly, an oracle \( \mathcal{O} \) is \( (\varepsilon, \delta) \)-post hoc generalizing for \( T \) adaptive queries against a Boolean analyst, if given \( m \) samples for every Boolean analyst \( A \) with probability at least \( (1 - \delta) \) for all \( t \in [T] \) if \( q(D) > 0 \) then

\[ \frac{1}{m} \sum q_t(x_t) > -\varepsilon, \]

and if \( q(D) < 0 \)

\[ \frac{1}{m} \sum q_t(x_t) < \varepsilon. \]

The following statement is easy to see:

**Lemma 6.1.** Suppose that there exists an oracle \( \mathcal{O}_1 \) that is \( (\varepsilon, \delta) \)-post hoc generalizing \( (\varepsilon, \delta) \)-accurate oracle against any Boolean analyst that answers \( T \) queries with \( m \) samples. Then there exists a \( (4\varepsilon, \delta) \)-post hoc generalizing \( (4\varepsilon, \delta) \)-accurate oracle, \( \mathcal{O}_2 \), that answers any analyst (not necessarily Boolean) \( \Omega \left( \frac{T}{\log 1/\varepsilon} \right) \) queries with \( m \) samples.
General first order local access oracles  We so far assume a truthful Oracle, that provides the true answer. We now need to deal with an oracle whose decision is both based on finite data and is strategic, in the sense that it can manipulate the simulation above with his answers.

Note that in order to construct the simulation we designed a function whose dependent on all possible states of the analyst \( A \). In particular, an all powerful oracle can basically look at the design of the function and get to know the exact strategy. That includes random bits as the function needs to be determined and chosen at the beginning of the game. That is why, as long as existing lower bounds for statistical queries rely on randomized analysts, for this strategy to work, we need to somehow prohibit from the oracle to identify the random bits. Note that the reverse is also true. Without some restrictions on the oracle, the construction against Gradient Descent becomes a pure strategy (modulus the choice of the distribution of the data).

We thus assume that the oracle has only access through the local gradients at points visited which restricts him from identifying the whole strategy of the analyst. In turn, we need to make sure, in our construction, that such internal bits are indeed not transmitted through the gradients. We therefore add in our notion of GD simulation a further restriction called correctness of gradients: In addition to requiring that answers can be extracted from the gradients, we also require that the gradients of the instance functions can be completely derived from the current state. This ensures us that an FOA Oracle may be operated solely on already published information, hence its decision cannot be dependent on internal bits which are independent of the current state. We now move on to introduce the notion of GD simulation, which explains exactly these requirements:

6.2 GD simulation of adaptive data analysis

A GD simulation (with learning rate \( \eta \) and initialization \( s \)), consists of

1. A simulating function which is a function \( f(A; w, x) \) that accepts a deterministic Boolean analyst and \( \in \mathbb{R}^d \)

2. A strictly increasing mapping \( T : [T_1] \to [T_2], \ T(1) > 1 \). The simulation is said to answer \( T_1 \) queries and to perform \( T_2 \) iterations, and \( T \) is called the iteration complexity.

3. A sequence \( \bar{\kappa} = \{\kappa_t\}_{t=1}^{T_1} \) of \( T_1 \) functions which are termed answering mechanisms:

\[
\kappa_t : (\mathbb{R}^d)^{T(t)} \to [0,1],
\]

4. A sequence \( \bar{\rho} = \{\rho_t\}_{t=1}^{T_2} \) of \( T_2 \) functions which are termed gradient access functions:

\[
\rho_t : \mathcal{Q} \times (\mathbb{R}^d)^t \times \mathcal{A} \to \mathbb{R}^d \times \mathbb{R}^d,
\]

where \( T(t') < t \).

A GD simulation interacts with a deterministic simulated oracle \( \mathcal{O} \). The interaction continues for \( T_2 \) rounds in the following manner: At the beginning of the interaction, the oracle receives a vector \( w_1 = s \) which is termed the initialization of the simulation. Then, we define two sequences iteratively: the trajectory of the simulation \( w_1, \ldots, w_{T_2} \), which is defined inductively where \( w_1 = s \), and

\[
w_t = \Pi (w_{t-1} - \eta \mathcal{O}(t-1)).
\]

Second we define the answering sequence, which is updated whenever \( t = T(t') \) for some \( t' \):

\[
a_{t'} = \kappa_{t'}(\mathcal{O}(w_1), \ldots, \mathcal{O}(w_t)).
\]

Next, at each round \( t \), suppose we have the answering sequence \( a_1, \ldots, a_{t'} \). Then, the oracle receives, as input, the \( t \)-th gradient access function, considered as a function of the argument \( x \), defined as follows:

\[
\bar{\rho}_t(x) = \rho_t(q_{t'+1}, \mathcal{O}(1), \ldots, \mathcal{O}(t), x),
\]

where \( q_{t'+1} \) is the \( t' + 1 \)-th query asked by analyst \( A \), given the answering sequence \( a_1, \ldots, a_{t'} \) (if \( t' = 0 \), i.e. \( T(1) > t \), then, \( q_{t'+1} = q_1 \)). In turn, \( \mathcal{O} \) outputs \( \mathcal{O}(t + 1) \in \mathbb{R}^d \).
The GD simulation is said to be \((\varepsilon_1, \varepsilon_2, \delta)-\text{GD} \) accurate against \(O\) if for every distribution \(D\), the following occurs w.p. \((1 - \delta)\), for every \(t_0 \leq T_1\):

If, for analyst \(A\):

\[
\|O(t) - \mathbb{E}_{x \sim D}[\nabla f(A; w, x)]\| \leq \varepsilon_1.
\] (9)

for every \(t < t_0\) Then:

- (Correct gradients at \(t_0\)) For every \(x \in \mathcal{X}\):

\[
\hat{\rho}_{t_0}(x) = (f(A; w_{t_0}, x), \nabla f(A; w_{t_0}, x)),
\] (10)

- (Accurate answers) If Eq. (9), in addition, holds for \(t = t_0\), and \(T(t) = t_0\) then \(a_i = 1\) implies \(q_i(D) > -\varepsilon_2\), and \(a_i = -1\) implies \(q_i(D) < \varepsilon_2\), where \(q_i\) is the \(i\)-th query provided by \(A\) when provided with answer sequence \(a_1, \ldots, a_{i-1}\).

If a GD simulation is \((\varepsilon_1, \varepsilon_2, \delta)\)-accurate against any oracle, we simply say it is \((\varepsilon_1, \varepsilon_2, \delta)\)-accurate.

It can be seen that a GD simulation together with an FOA Oracle imply an oracle that answers statistical queries (we provide the proof in Section 6.5)

**Lemma 6.2.** Suppose that there exists \((2\varepsilon_1, \varepsilon_2, \delta)\)-accurate GD simulation with \(\eta > 0\), and a \(1\)-Lipschitz simulating function, that answers \(T_1\) queries and perform \(T_2\) iterations. Suppose also, that there exists an oracle that is a \((\varepsilon, \delta)\)-accurate FOA oracle, \(O_F\), that receives \(m\) samples and answers \(T_1\) adaptive queries against Gradient Descent with learning rate \(\eta > 0\).

Then there exists an \((\varepsilon_2, 2\delta)\)-accurate oracle, \(O\), that receives \(m\) samples and answers \(T_1\) adaptive queries against any Boolean analysts. Moreover, if \(O_F\) is \((\varepsilon, \delta)\)-post-hoc generalizing then \(O\) is \((2\varepsilon_2, 2\delta)\)-post-hoc generalizing.

Next, in Section 6.4 we provide a construction of a GD simulation. Specifically, we prove the following:

**Lemma 6.3.** For sufficiently small \(\varepsilon, \eta > 0\), and \(\delta > 0\). Assume \(\eta < \sqrt{\varepsilon/48}\), and \(T < \min\{1/4\eta, 1/24\varepsilon\}\). For sufficiently large \(d\), there exists a \((\varepsilon, O(\varepsilon), \delta)\)-accurate GD simulation with a learning rate \(\eta > 0\) and \(1\)-Lipschitz simulating function that answers \(T\) queries and performs \(2T\) iterations.

### 6.3 Proof of Theorem 4.2

Suppose \(\eta = O(\varepsilon)\), and set \(T' = \min\{1/4\eta, 1/24\varepsilon\} = \Omega(1/\varepsilon)\). We then use Lemma 6.3 and conclude from Lemmas 6.1 and 6.2 that if there exists an oracle that is \((\varepsilon, \delta)\)-accurate FOA and \((\varepsilon, \delta)\)-post-hoc generalizing oracle that receives \(m\) samples and answer \(T'\) questions, then there exists an \((O(\varepsilon), O(\delta))\)-accurate post-hoc generalizing oracle that receives \(m\) samples and answers \(T'/2\) questions against any Boolean analyst and answers \(\Omega(T'/\log 1/\varepsilon) = \Omega(1/\varepsilon \log 1/\varepsilon)\) against any analyst.

### 6.4 Proof of Lemma 6.3

#### 6.4.1 The Construction

We start the proof by first providing the construction. We let \(T(t) = 2t\), and proceed to construct \(f, \hat{\rho}\), and \(\hat{\kappa}\).

**Defining \(f\):** We begin by defining for every \(T\), a convex 4-Lipschitz function recursively, where each \(f_T\), is defined over \(\mathbb{R}^{4 \cdot 2^T - 5}\). Our final choice for the proof will be \(f := f_T\) (after some permutation).

We start with \(f_1\), which is defined over \(\mathbb{R}^5\) to be:

\[
f_1(A; w, x) = \max \left( h_1(q_1, w, x), h_2(w), \frac{3}{4} \eta \right),
\]
where \( q_1 \) is the first query outputted by \( A \), and:

\[
\begin{align*}
    h_1(q; w, x) &= w(1) - \frac{(1 + q(x))}{16} w(2) - \frac{(1 - q(x))}{16} w(3), \\
    h_2(w) &= \max\{(2 + \xi_2)w(2) + w(3) - w(4), (2 + \xi_3)w(3) + w(2) - w(5)\}.
\end{align*}
\]

Where \( \xi_2, \xi_3 \sim U[0, \eta]^2 \) are chosen uniformly at random.

To define the rest of the sequence, we will notate the following three projection functions:

\[
\begin{align*}
    \Pi_{\pm}^{(t)}(w) &= (w(4), w(6), w(8), \ldots, w(4 \cdot 2^{t-1} - 4)) \\
    \Pi^{(t)}(w) &= (w(5), w(7), w(9), \ldots, w(4 \cdot 2^{t-1} - 3)) \\
    \Pi_0^{(t)}(w) &= (w(1), w(2), w(3), w(4), w(5)).
\end{align*}
\]

To avoid cumbersome notations we will omit the dependence of the matrices \( \Pi_{\pm}^{(t)} \) on \( t \) when this can be derived from the dimension of the input. Then, \( f_t \) is defined as follows: draw, independently, a function \( f_1 \) and a function \( f_{t-1} \) and define:

\[
    f_t(A; w, x) = \max \{ f_1(A; \Pi_0 w, x), f_{t-1}(A^+; \Pi_+ w, x), f_{t-1}(A^-; \Pi_- w, x) \}.
\]

where \( A^+ \) denotes the analyst obtained from \( A \) if we provide it with answer \( a_1 = 1 \) to \( q_1 \) and \( A^- \) denote the analyst obtained by providing \( a_1 = -1 \).

One can show by induction that each \( f_t \) is indeed convex. This follows easily from the fact that maximum of convex functions is convex and that \( h_1 \) is convex, in fact linear, and also \( h_2 \) (which is again maximum over two linear functions). Next, recall that for a function \( g = \max\{g_1, g_2, \ldots, g_m\} \) the subgradient at \( w \) is given by \( \text{conv}(\nabla g_i : g_i(w) = g(w)) \), hence by induction we prove that for every analyst \( A \):

\[
    \|\nabla f_t(A; w, x)\| \leq \max\{\|\nabla h_1\|, \|\nabla h_2\|, \|\nabla f_{t-1}\|, \|\nabla f_{t-1}\|\} \leq \max_w \|\nabla h_2(w)\| \leq 4.
\]

**Defining \( \kappa \):** For the answering mechanisms we define for every \( t \) a sequence \( \tilde{\kappa}^{(t)} = \{\kappa_i^{(t)}\}_{i=1}^t \) of \( t \) functions from \( \mathbb{R}^{4t-3} \) to \( [0, 1] \), defined as follows. For every \( t \):

\[
    \kappa_1^{(t)}(g_1, g_2) = \begin{cases} 
        1, & \Pi_0 g_2(4) < -\frac{1}{2}, \\
        -1, & \text{else}
    \end{cases}
\]

and

\[
    \kappa_i^{(t)}(g_1, g_2, \ldots, g_{2t}) = \begin{cases} 
        \kappa_{i-1}^{(t-1)}(\Pi_+ g_3, \ldots, \Pi_+ g_{2t-2}), & \kappa_{i-1}^{(t-1)}(\Pi_+ g_3, \ldots, \Pi_+ g_{2t-2}) \neq 1 \\
        \kappa_{i-1}^{(t-1)}(\Pi_- g_3, \ldots, \Pi_- g_{2t-2}), & \text{else}
    \end{cases}
\]

**Defining \( \rho \):** Next, we define for every \( t \) a sequence \( \tilde{\rho}^{(t)} = \{\rho_i^{(t)}\}_{i=1}^{2t} \) of \( 2t \) gradient access functions from \( \mathbb{R}^{4t-3} \) to \( [0, 1] \), defined as follows:

First define \( \tilde{\rho}_1^{(t)}, \tilde{\rho}_2^{(t)} \):

\[
    \tilde{\rho}_1^{(t)}(q, w, x) = (h_1(q, \Pi_0 w, x), \Pi_0^{-T} \nabla h_1(q, \Pi_0 w, x)), \quad \tilde{\rho}_2^{(t)}(q, \Pi_0 w, x) = (h_2(\Pi_0 w), \Pi_0^{-T} \nabla h_2(\Pi_0 w)).
\]

\( \tilde{\rho}_3^{(t)}, \ldots, \tilde{\rho}_{2t}^{(t)} \) are defined inductively as follows:

\[
    \rho_j^{(t)}(q, c_1, \ldots, c_{i-2}, w, x) = \begin{cases} 
        \Pi_+^{j} \rho_{j-1}^{(t-1)}(q, c_2, \ldots, c_{i-2}, \Pi_+ w, x), & c_1 = 1 \\
        \Pi_-^{j} \rho_{j-2}^{(t-1)}(q, c_2, \ldots, c_{i-2}, \Pi_- w, x), & c_1 = -1
    \end{cases}
\]

Finally, we let

\[
    \tilde{\rho}_i^{(t)} = \rho_i^{(t)}(q, a_1, \ldots, a_{i-2}, w, x).
\]

Note that the answering sequence as well as \( w_t \) are determined by \( O(1), \ldots, O(j) \), (through \( \kappa_i \)), hence \( \tilde{\rho} \) is well defined.
Defining a random embedding  The final object we will need is a random embedding that will “hide” the analyst in the function $f$. We will later use this embedding and compose it with $f$, however for the proof it will be easier to think of the transformation as operating over $O$. Specifically, let $d = 4 \cdot 2^T - 3$ and define:

$$
\Sigma_T : \mathbb{R}^{4 \cdot 2^T - 3} \to \mathbb{R}^d,
$$

be a random embedding that simply permutes the coordinates (i.e. $\Sigma_T$ embeds $\mathbb{R}^{4 \cdot 2^T - 3}$ in $\mathbb{R}^d$ by padding with zeros and then applying a random permutation), where all coordinates are randomly permuted except

$$
\Sigma_T e_i^{4 \cdot 2^T - 3} = e_i^d,
$$

where we denote by $e_i^k$ the $i$-th standard basis vector in $\mathbb{R}^k$. We will call such an embedding a random hiding with known first coordinate.

Then, given a simulated Oracle $O : \mathbb{R}^d \to \mathbb{R}^d$, we define a projected oracle $O_{\Sigma} : \mathbb{R}^{4 \cdot 2^T - 3}$ that operates:

$$
O_{\Sigma}(t) = \Sigma^T O(t),
$$

and given a gradient access function $\tilde{\rho}_t(x)$, the oracle $O_{\Sigma}$ update the state of $O$ by providing $\tilde{\rho}_t \Sigma(x) = \Sigma \rho_t(x)$.

Continuing with the proof  For the proof we will prove by induction the following Lemma:

**Lemma 6.4.** Fix $\varepsilon < 1/48$, assume $\eta < \sqrt{\varepsilon}/48$, and $T < \min\{1/4\eta, 1/24\varepsilon\}$. Also, let $d \geq 4 \cdot 2^T + \frac{4 \cdot 2^T + 320}{\eta \varepsilon}$. Suppose $\bar{v} \in \mathbb{R}^d$ is a vector where $\|\bar{v}\| \leq 2\eta \varepsilon$. and that

$$
\Sigma : \mathbb{R}^{4 \cdot 2^T - 3} \to \mathbb{R}^d,
$$

is a random hiding with known first coordinate (as in Eq. (12)). Then with probability $1 - 2T\delta$ (w.r.t the random embedding $\Sigma$):

The GD simulation $(f_T(A, w_t, x), \tilde{\rho}^{(T)}, \tilde{\kappa}^{(T)})$ is $(\varepsilon, 99\varepsilon, 1)$-accurate for the initialization point $w_1 = \eta \epsilon_1 + \Sigma^T \bar{v}$ and answers $T$ queries with $2T$ iterations against the Oracle $O_{\Sigma}$.

For this, we show that the GD simulation $(f \circ \Sigma, \tilde{\rho}_{\Sigma}, \tilde{\kappa}_{\Sigma})$ with initialization $\Sigma w_1 = e_1^d$, is accurate against $O$, where:

$$
f \circ \Sigma = f(A, \Sigma^T w_t, x), \quad \tilde{\rho}_{\Sigma} = \Sigma \rho_{\Sigma}(x), \quad \tilde{\kappa}_{\Sigma}(O(1), \ldots, O(t)) = \kappa_t(O_{\Sigma}(1), \ldots, O_{\Sigma}(t)).
$$

Therefore by setting $\delta = \delta/T$, $s = \eta \epsilon_1$ in $\mathbb{R}^d$, we obtain a $(\varepsilon, O(\varepsilon), \delta)$-accurate simulation against an arbitrary simulated oracle $O$. Note that we can rescale $f$ to obtain a 1-Lipschitz function and still remain with $(\varepsilon, O(\varepsilon), \delta)$-accurate simulation (up to new constant factors).

To see that $(f \circ \Sigma, \tilde{\rho}_{\Sigma}, \tilde{\kappa}_{\Sigma})$ is accurate, we note that by our choice of parameters $T \leq 1/4\eta$, $\|w_t\| = \|\eta\|$, and thus we have for every $w_t$, $\|w_t\| \leq 2\eta + \eta T \leq 1/16 + 1/4 \leq 1$. Therefore, applying GD over the sequence never set outside of the unit ball. We can assume, then, that the update steps produced by GD does not perform projections and we have that the update step, in terms of $w_t$ is given by:

$$
w_{t+1} = w_t - \eta O(t).
$$

We also have that if $w_1, \ldots, w_T$ is the trajectory sequence of the GD simulation $(f, \rho, \kappa)$ against $O_{\Sigma}$, by the definition of $O_{\Sigma}$ and a similar argument as before we have that again projections don’t occur and:

$$
w_{t+1} = w_t - \eta O_{\Sigma}(t) = w_t - \Sigma^T O(t),
$$

Hence we have that $w_{t+1} = \Sigma^T w_t$. Moreover if $O$ satisfies Eq. (9) then:

$$
\|O_{\Sigma}(t) - \nabla f(A, w'_t, x)\| = \|\Sigma^T O(t) - \Sigma^T \nabla f(A, \Sigma^T w_t, x)\| \leq \|O(t) - \nabla f(A, \Sigma^T w_t, x)\| \leq \varepsilon_1,
$$

and we obtain $O(99\varepsilon)$-accuracy of the answers and correctness of the gradients by standard chain rule.

**Proof of Lemma 6.4.** We prove the statement by induction. Again, we recall that by our choice of parameters $T \leq 1/4\eta$, $\|w_t\| \leq \eta + 2\eta \varepsilon$, and we have for every $w_t$, $\|w_t\| \leq 2\eta + \eta T \leq 1/16 + 1/4 \leq 1$. Therefore, applying GD over the sequence never sets outside of the unit ball, and the update steps produced by GD is given by:

$$
w_{t+1} = w_t - \eta O_{\Sigma}(t). \quad \tag{13}$$
The base case $T = 1$. For the base case, we assume that
\[
\|O_2(1) - \mathbb{E}_{x \sim D} [\nabla f_1(A; w_1, x)]\| \leq \varepsilon, \tag{14}
\]
and we need to verify the correctness of gradients and accuracy of answers for $t_0 = \{1, 2\}$.

First, notice that at initialization $w_1 = \eta e_1 + \Sigma^T v$, and $\|v\| \leq 2\eta\varepsilon$. For $j \geq i$, let us denote by $\Pi_{i:j}$ a projection over coordinates $i$ to $j$, then note that for $i \geq 2$, since $\Pi_{i,j} \Sigma^T$ is chosen randomly then
\[
\mathbb{E}[\|\Pi_{2,5} \Sigma^T v\|^2] \leq \sum_{i=2}^{5} \mathbb{E}[\|e_i^T \Sigma^T v\|^2] = \sum_{i=2}^{5} \frac{1}{d} \sum_{j=2}^{d} (v(j))^2 \leq \frac{10\varepsilon}{d} \leq \frac{\varepsilon \eta^6}{32}\delta \leq \eta^4\delta. \tag{15}
\]

By Markov’s inequality, we have that with probability at least $(1 - \delta)$ we have that
\[
\|\Pi_{2,5} \Sigma^T v\| \leq \eta^2.
\]

If this happens, as $h_2$ is 4-Lipschitz, $h_2(0) = 0$ and $h_2$ depends only on the 2 to 5 coordinates, then
\[
|h_2(w)| \leq 4\eta^2 \leq \frac{1}{2}\eta.
\]

On the other hand, because $h_1$ is 2-Lipschitz, one can also observe that
\[
\begin{align*}
h_1(q_1, w_1, x) &\geq h_1(q_1, \eta e_1, x) - 2\|w_1 - \eta e_1\| \\
&= h_1(q_1, \eta e_1, x) - 2\|\Sigma^T v\| \\
&\geq \eta - 2\eta\varepsilon \\
&> \frac{3}{4}\eta.
\end{align*}
\]

Hence,
\[
f_1(A; w_1, x) = h_1(q, w_1, x), \quad \text{and} \quad \nabla f_1(A; w_1, x) = \nabla h_1(q, w_1, x). \tag{16}
\]

Together with Eq. (11), this shows that Eq. (10) holds for $t_0 = 1$. Thus, if $t_0 = 1$ the conditions are met (the second condition trivially follows since $T > 1$.) We only need to take care of the case $t_0 = 2$.

For $t_0 = 2$ note that by assumption
\[
\begin{align*}
\eta\varepsilon &\geq \eta \cdot \|O_2(1) - \mathbb{E}_{x \sim D} [\nabla f(A; w_1, x)]\| \\
&= \left\|w_2 - \left(w_1 - \eta \mathbb{E}_{x \sim D} [\nabla f(A; w_1, x)]\right)\right\| \\
&= \left\|w_2 - (\eta e_1 + \Sigma^T v) + \eta \mathbb{E}_{x \sim D} (\nabla h_1(q, w_1, x))\right\| \\
&= \left\|w_2 - \eta e_1 - \Sigma^T v + \eta \mathbb{E}_{x \sim D} [e_1 - \frac{1 + q(x)}{16} e_2 - \frac{1 - q(x)}{16} e_3]\right\| \\
&= \left\|w_2 - (\frac{1 + q(D)}{16} \eta e_2 - \frac{1 - q(D)}{16} \eta e_3)\right\| - 2\eta\varepsilon \\
&= \|w_2 - \bar{w}_2\| - 2\eta\varepsilon.
\end{align*}
\]

where we denote $\bar{w}_2 = \frac{1 + q(D)}{16} \eta e_2 + \frac{1 - q(D)}{16} \eta e_3$. Hence,
\[
\|w_2 - \bar{w}_2\| \leq 3\eta\varepsilon \tag{17}
\]

16
Now, by 4-Lipschitzness of $h_2$:

\[
h_2(w_2) \geq h_2(\bar{w}_2) - 4\|w_2 - \bar{w}_2\|
\]

\[
\geq \max\{(2 + \xi_2)(1 + q(D)) + (1 - q(D)), \{(2 + \xi_3)(1 - q(D)) + (1 + q(D))\}\} \eta - 12\eta \varepsilon
\]

\[
\geq \max\{3 + (1 + \xi_2)q(D), 3 - (1 + \xi_3)q(D)\}\eta - 12\eta \varepsilon
\]

\[
\geq 3\eta - 12\eta \varepsilon
\]

\[
\geq \frac{3}{4}\eta.
\]

On the other hand,

\[
h_1(q, w_2, x) \leq h_1(q, \bar{w}_2, x) + 12\eta \varepsilon \leq \left|\frac{1 + q(x)}{16}\right| \eta + \left|\frac{1 - q(x)}{16}\right| \eta + 12\eta \varepsilon \leq \frac{\eta}{32} + \frac{\eta}{4} < \frac{\eta}{2}
\]

We obtain then that for $t_0 = 2$:

\[
f_1(A; w_2, x) = h_2(q, w_2, x), \quad \text{and} \quad \nabla f_1(A; w_2, x) = \nabla h_2(q, w_2, x).
\]

Which, again by Eq. (11), proves correctness of gradients at $t_0 = 2$. We now need to show that the answer is accurate, contingent on Eq. (14) holding for $t_0 = 2$. Now we’ve already shown that

\[
\mathbb{E}_{x \sim D}[\nabla f_1(A; w_2, x)] = \mathbb{E}_{x \sim D}[\nabla h_2(w)] = \nabla h_2(w_2),
\]

Now, $h_2$ is random, and note that $w_2$ is independent of the random bits of $h_2$ as it is determined by the oracle $O$, $w_1$ and $\rho_1$, all are independent of $\xi_2, 3$. The randomness ensures that with probability 1, the two terms are not equal, and the subgradient at $w_2$ is well defined. Next, notice that for $g_2 = O_2(2) = \nabla h_2(w_2) + O(\varepsilon)$, by assumption. We have, then, $g_2(4) < -1/2$ if and only if the first term is greater. Suppose, then, that the first term is greater.

Denote $\|\Pi_{4:5}(w_2 - \bar{w}_2)\| = \xi$. Then by the definition of $h_2$:

\[
(2 + \xi_2)w_2(2) + w_2(3) - w(4) > (2 + \xi_3)w_2(3) + w_2(2) - w(5).
\]

By rearranging terms and noting that $\xi_2, 3 \sim U[0, \eta^3]$ we have that:

\[
w_2(2) > w_2(3) - 2\eta^3 + w(4) - w(5).
\]

which implies since $|w_2(2) - \bar{w}_2(2)| \leq 3\eta \varepsilon$, similarly $w_2(3)$, and $|w(4)|, |w(5)| \leq \xi$:

\[
\frac{\eta(1 + q_1(D))}{16} > \frac{\eta(1 - q_1(D))}{16} - 2\eta^3 - 6\eta \varepsilon - 2\xi.
\]

Rearranging terms:

\[
q_1(D) > -16\eta^2 - 48\varepsilon - \frac{2\xi}{\eta} > -49\varepsilon - \frac{2\xi}{\eta},
\]

where last inequality follows from $\eta < \sqrt{\varepsilon}/48$. A similar calculation show that the reversed inequality holds if the inequality is reversed. We now only need to show that with probably at least $1 - \delta \xi < 2\eta \varepsilon$, this is similar to the way we bounded $\|\Pi_2.5v\|$. In particular note that

\[
\|\Pi_{4:5}\xi\| = \|\Pi_{4:5}\Sigma^T v + \eta \Pi_{4:5}O_2(2)\| \leq \eta^2 + \eta\|\Pi_{4:5}\Sigma^T O(2)\| \leq \eta \varepsilon + \eta\|\Pi_{4:5}\Sigma^T O(2)\|,
\]

where the last inequality is true since $\eta^2 < \varepsilon$. Next, if we set $v_2 = O(2)$, then $v_2$ is dependent on $\rho_1, w_1$ and $w_2$, conditioning on these vectors we know that $\Pi_{4:5}\Sigma^T$ is a random embedding and permutation in $\mathbb{R}^{d-3}$, and, by choice of $d$, we have that

\[
\|\Pi_{4:5}\Sigma^Tv_2\|^2 = \sum_{i=4}^{5}(\xi_i^T \Sigma^Tv_2)^2 \leq \frac{2}{d-3} \sum_{i=4}^{5} v_2(i)^2 \leq \frac{2\varepsilon}{d-3} \leq \frac{2\eta^3\delta^2}{4\cdot 2^4} \leq \varepsilon^2 \delta,
\]

where, again, the last inequality follows from $\eta^2 < \varepsilon$. By Markov inequality we obtain the desired bound on $\xi$, which concludes the base case.
The induction step: We now move on to the induction step. Suppose we proved the statement for \( T - 1 \), and we want to prove it for \( T \). We begin with the observation that, similar to the argument that bounds \( \|\Pi_{2:5}v\| \), we have that since \( d > \frac{42^T}{\eta^6} \):

\[
\mathbb{E}[\|\Pi_+ \Sigma^T v\|^2] \leq \eta^6 \delta.
\]

One can also observe, for the same reason,

\[
\mathbb{E}[\|\Pi_+ \Sigma^T \mathcal{O}(1)\|^2] \leq \eta^6 \delta,
\]

Hence with probability \((1 - 2\delta)\):

\[
\max \left\{ \|\Pi_+ \Sigma^T \mathcal{O}(1)\|, \|\Pi_+ \Sigma^T v\| \right\} \leq \eta^3 \leq \frac{\eta \epsilon}{32}.
\]  

(19)

We assume that this event happened. It is then easy to see that for \( i = \{1, 2\} \) we have that

\[
f_T(A, w_i, x) = \max \{ f_1(A, \Pi_0 w_i, x), f_{T-1}(A^+, \Pi_+ w_i, x), f_{T-1}(A^-, \Pi_- w_i, x) \} = f_1(A, \Pi_0 w_i, x).
\]  

(20)

As such the calculations of the first two iterates are the same as in the base case and we have that for \( t_0 = \{1, 2\} \), the conditions are met.

For the cases \( t_0 \geq 3 \), we begin with the observation that, given \( \Sigma \Pi_0 \), the embedding \( \Sigma \Pi_+ \) is still a random embedding in \( \mathbb{R}^{d-5} \), with the exception that the embedding of \( \Sigma e_4 \) is determined by \( \Sigma \Pi_0 \) but since all other coordinates are orthogonal to the range \( \Pi_0 \), we have that all other coordinates in the subspace are randomly embedded and permuted in \( \mathbb{R}^{d-5} \). A similar argument holds for \( \Sigma \Pi_- \) and thus, we can treat \( \Sigma \Pi_+ \) and \( \Sigma \Pi_- \) as random hidings where the first coordinate is known to dimension \( d > \frac{42^T}{\eta^6} - 5 > \frac{32^T - 1}{\eta^6} \).

We now claim that for \( t \geq 3 \) we have that, if

\[
\| \mathcal{O}_\Sigma(t') - \mathbb{E}_{x \sim D}[\nabla f_T(A, w, x)] \| \leq \epsilon, \quad t' = 1, \ldots, t,
\]  

then:

\[
f_T(A, w_t, x) = \begin{cases} f_{T-1}(A, \Pi_+ w_t, x) & a_1 = 1 \\ f_{T-1}(A, \Pi_- w_t, x) & a_1 = -1 \end{cases}
\]  

(22)

Let us consider the case \( a_1 = 1 \) (the other case is equivalent). We’ve already shown that if \( a_1 = 1 \) then

\[
\nabla f_T(A; w_2, x) = \nabla f_1(A; \Pi_0 w_2, x) = \nabla h_2(w_2) = (2 + \xi_2)e_2 + \epsilon_3 - \epsilon_4,
\]

Hence, let

\[
\bar{w}_3 = \bar{w}_2 - \eta \nabla h_2(w_2) = \left( \frac{1 + q_1(D)}{16} - 2 - \xi_2 \right) \eta e_2 + \left( \frac{1 - q_1(D)}{16} - 1 \right) \eta \epsilon_3 + \eta \epsilon_4
\]

since

\[
\| \bar{w}_3 - w_3 \| \leq \| \bar{w}_2 - w_2 \| + \eta \| \mathcal{O}_\Sigma(2) - \mathbb{E}[\nabla f(A, w, x)] \| \leq 4\epsilon,
\]

we conclude that we can write

\[
w_3 = \eta \epsilon_4 + \eta w_3,
\]

where \( -3\eta - 4\epsilon \leq v_3(2) \leq 0, -\eta - 4\eta \epsilon \leq v_3(3) \leq 0, \) and \( v_3(1) \leq 4\epsilon \).

By definition of \( h_1, h_2 \) we have then:

\[
h_1(q_1, w_3, x) \leq v_3(1) + \frac{1}{8} \| v_3(2) \| + \frac{1}{8} \| v_3(3) \| \leq 4\epsilon + \frac{3 + 4\epsilon}{8} \eta + \frac{1 + 4\epsilon}{8} \eta \leq \frac{1}{2} \eta + 5\epsilon,
\]  

(23)

and,

\[
h_2(w_3) \leq 0.
\]  

(24)
Taken together since $\frac{1}{4}\eta + 5\eta \varepsilon < \frac{3}{4}\eta$:

$$f_T(A, w_3, x) = f_{T-1}(A^+, \Pi_+ w_3, x),$$

where we use here the (easy to see) fact that for all $w f_{T-1}(A^+, w, x) > \frac{3}{4}\eta$.

Now we prove by induction that for all $t > 3$ we have that the equality remains. This can be seen by the fact that the gradient is almost completely orthogonal to the coordinates on which the other terms depend on except $w(4)$, but $f_{T-1}(A, \Pi_+ w_t, x)$ is decreasing in $w(4)$, hence we conclude that $\Pi_0 \nabla f_{T-1}(A, \Pi_+ w_t, x) \geq 0$, which means that $\Pi_0 w_t$ can increase at each iteration by at most $\eta \varepsilon$. So we have that:

$$\|\Pi_0 w_t - \Pi_0 w_3\| \leq \eta \varepsilon T,$$

and by 4-Lipschitzness of these terms as well as Eqs. (23) and (24)

$$\max\{h_1(q_1, \Pi_0 w_t, x), h_2(\Pi_0 w_t)\} \leq 4\eta T + \max\{h_1(q_1, \Pi_0 w_3, x), h_2(\Pi_0 w_3)\} \leq \frac{1}{2}\eta + 5\eta \varepsilon (T + 1) \leq \frac{3}{4}\eta,$$

where the last inequality follows from $\varepsilon \leq 1/24, T \leq 1/(24\varepsilon)$.

Now we can use the induction hypothesis. First, notice that if Eq. (21) is met, then by our assumption and contraction of a projection operator we have for $t' = 1, \ldots, t$:

$$||O_{\Sigma^+} (t') - \mathbb{E}_{x \sim D} [\nabla f_{T-1}(A^+, \Pi_+ w_{t'}, x)]|| = ||\Pi_+ O_{\Sigma} (t') - \mathbb{E}_{x \sim D} [\Pi_+ \Pi_+^T \nabla f_{T-1}(A^+, \Pi_+ w_{t'}, x)]||$$

$$\leq ||O_{\Sigma} (t') - \mathbb{E}_{x \sim D} [\Pi_+^T \nabla f_{T-1}(A^+, \Pi_+ w_{t'}, x)]||$$

$$\leq ||O_{\Sigma} (t') - \mathbb{E}_{x \sim D} [\nabla f_T(A^+, \Pi_+ w_{t'}, x)]||$$

$$\leq \varepsilon, \ldots$$

(28)

Also, we have that the sequence $\Pi_+ w_3, \ldots, \Pi_+ w_T$ initializes at

$$\Pi_+ w_3 = \Pi_+ \bar{w}_3 + \Pi_+ w_3 - \Pi_+ \bar{w}_3 = \eta \epsilon_4 + \Sigma^T v,$$

where

$$||v|| = ||\Sigma \Pi_+ \bar{w}_3 - \Sigma \Pi_+ w_3||$$

$$= ||\Pi_+ \bar{w}_3 - \Pi_+ w_3||$$

$$\leq ||\Pi_+ \bar{w}_2 - \Pi_+ w_2|| + \eta ||\Sigma_2 (2) - \mathbb{E}_{x \sim D} [\nabla f(A, w_2, x)]||$$

$$\leq ||\Pi_+ w_2|| + \eta \varepsilon$$

$$= ||\Pi_+ \Sigma^T T v|| + ||\Pi_+ \Sigma_2 (1)|| + \eta \varepsilon$$

$$\leq 2\eta^3 + \eta \varepsilon$$

$$\leq 2\eta \varepsilon.$$

Also, note that the gradient access functions provided to $O_{\Sigma}$ are of the form $\Pi_+ \rho_j^{(T-1)}(t, x)$, and finally, note that:

$$\kappa_i^{(T)}(O_{\Sigma}(1), \ldots, O_{\Sigma}(T)) = \kappa_i^{(T-1)}(\Pi_+ O_{\Sigma}(w_1'), \ldots, \Pi_+ O_{\Sigma}(w_T'))$$

$$= \kappa_i^{(T-1)}(O_{\Sigma}^{+}(w_1'), \ldots, O_{\Sigma}^{+}(w_T')).$$

So to summarize, the sequence $\Pi_+ w_3, \ldots, \Pi_+ w_T$ and $a_2, \ldots, a_T$ is the trajectory sequence and answering sequence of the GD simulation of $f_{T-1}, \kappa^{(T-1)}, \rho^{(T-1)}$, against the oracle $O_{\Sigma^+}$.

If Eq. (25) is met then, we obtain by the guarantees of correctness of gradients and accurate answers and the sequence $a_2, \ldots, a_T$ is indeed correct and by the chain rule we also obtain correctness of gradients. With probability $1 - 2\delta(T - 1)$. Applying union bound we obtain the desired result. ■
6.5 Proof of Lemma 6.2

Without loss of generality we may assume that the simulation initializes at \( w_1 = 0 \). Given an FOA Oracle \( \mathcal{O}_F \), we define a simulated oracle \( \mathcal{O} \) that works as follows: at step \( t \) provide \( \mathcal{O}_F \) with \( \hat{\rho}_t(x) \), and \( w_t \), and output \( \mathcal{O}(t) = \mathcal{O}_F(w_t) \). Notice that \( w_t \) is defined by \( \mathcal{O}(1), \ldots, \mathcal{O}(t-1) \) hence the above procedure is well defined.

The statistical query oracle works as follows:

- Receive query \( q_t \) from analyst \( A \).
- For \( t = 1, \ldots, T \)
  - For \( s = T(t-1) + 1, \ldots, T(t) \) (where we define \( T(0) = 1 \))
    * Provide the gradient access function \( \hat{\rho}_s(x) \) to \( \mathcal{O}_F \).
    * Set \( w_{s+1} = w_s - \eta \mathcal{O}_F(w_s) \).
  - Calculate the answer \( a_t = \kappa_t(\mathcal{O}(w_1), \ldots, \mathcal{O}(w_{T(t)})) \)
  - Provide \( A \) with the answer \( a_t \) and receive \( q_{t+1} \).

Next, for the proof let us fix the random bits of the simulation, the analyst and oracles. And we assume that \( w_1', \ldots, w_T' \) is the sequence generated by the recursive relation

\[
w_1' = 0, \quad w_{t+1}' = \Pi(w_t' - \eta \nabla \mathcal{O}_F(w_t')), \]

where \( \mathcal{O}_F \) at each iteration is provided with a function \( \hat{\rho}_t(x) = (f(A, w_t', x), \nabla f(A, w_t', x)) \). Now Suppose that the internal random bits of \( \mathcal{O}_F \) are such that for all \( t \leq T_2 \):

\[
\| \mathcal{O}_F(w_t') - \mathbb{E}_{x \sim D}[\nabla f(A; w_t', x)] \| \leq \varepsilon_1.
\]

This event happens with probability \( 1 - 2\delta \), and we throughout assume that it occurred.

Under this assumption, we can show by induction that \( w_t' = w_t \), hence

\[
\mathcal{O}(t) = \mathcal{O}(w_t) = \mathcal{O}(w_t'),
\]

which implies:

\[
\| \mathcal{O}(t) - \mathbb{E}_{x \sim D}[f(A; w_t, x)] \| \leq \varepsilon_1.
\]

Hence, by correctness of the gradients: \( \hat{\rho}_t = \hat{\rho}_t \), and we have that \( w_{t+1}' = w_{t+1} \).

Also, through the same reasoning applied to Eq. (29), and using triangular inequality:

\[
\| \mathcal{O}(t) - \frac{1}{m} \sum_{i=1}^{m} [\nabla f(A; w_t, x_i)] \| \leq 2\varepsilon_1.
\]

Both results imply, by the property of a GD simulation, that the sequence of answers is \( \varepsilon_2 \) accurate w.r.t the population and \( 2\varepsilon_2 \) accurate w.r.t the empirical distribution which can be seen to entail \((\varepsilon_2, \delta_1)\)-accuracy and \((2\varepsilon_2, \delta_1)\)-post-hoc generalization as in Definitions 3.1 and 3.2.

A Proof sketch for Theorem 2.2

The construction is a simplification of the construction in [2]. For every $x \in \{0,1\}^d$ we define

$$f(w, x) = \frac{1}{2} \sqrt{\sum_i x(i) \max\{0, w(i)\}^2 + \gamma_v v_x \cdot w},$$

where

$$v_x(i) = \begin{cases} \frac{1}{m} & x(i) = 0 \\ -1 & x(i) = 1 \end{cases}.$$

and $\gamma < m/20$ is sufficiently small so that the function $f$ is 1-Lipschitz.

We define the distribution on $x$ so that every $x(i)$ are i.i.d Bernoulli variables. Initializing at $w_1 = 0$ we have that $\nabla f(w_1, x) = \gamma v_x$, and

$$w_2 = w_1 - \eta \frac{m}{m} \sum_j v_{x_j},$$

Notice that $w_2(i) > 0$ if and only if $x_j(i) = 0$ for all $j = 1, \ldots, m$, hence:

$$\left\| \mathbb{E} \left[ \frac{1}{m} \sum_{i=1}^m \nabla f(w_2, x_i) w_2 \right] \right\| = \left\| \frac{1}{m} \sum_{j=1}^m v_{x_j} \right\| \leq \gamma m \leq 1/20.$$

On the other hand, suppose $w_2$ is such that there are coordinates such that $x_j(i) = 0$ for all $j = 1, \ldots, m$, then:

$$\|\nabla F(w_2)\| \geq \mathbb{E}_{x \sim D} \left[ \sum_{i:w(i)>0} \frac{w(i)}{\sqrt{\sum_{i:w(i)>0} w(i)^2}} v_i \right] - \gamma m \geq 1 - \gamma m \geq 19/20.$$

Note that if $d$ is sufficiently large then, indeed, with probability $1/2$ there will be some coordinate $i$, where $x_j(i) = 0$ for all $j$.
