Abstract

Current network control plane verification tools cannot scale to large networks, because of the complexity of jointly reasoning about the behaviors of all nodes in the network. In this paper we present a modular approach to control plane verification, whereby end-to-end network properties are verified via a set of purely local checks on individual nodes and edges. The approach targets the verification of safety properties for BGP configurations and provides guarantees in the face of both arbitrary external route announcements from neighbors and arbitrary node/link failures. We have proven the approach correct and also implemented it in a tool called LIGHTYEAR. Experimental results show that LIGHTYEAR scales dramatically better than prior control plane verifiers. Further, we have used LIGHTYEAR to verify three properties of the wide area network of a major cloud provider, containing hundreds of routers and tens of thousands of edges. To our knowledge no prior tool has been demonstrated to provide such guarantees at that scale. Finally, in addition to the scaling benefits, our modular approach to verification makes it easy to localize the causes of configuration errors and to support incremental re-verification as configurations are updated.

1 Introduction

Today, routing and forwarding in networks are controlled using low-level configuration on individual routers. Researchers have developed many techniques to analyze these configurations in order to verify that they meet a given specification of the intended end-to-end network behavior. For example, Minesweeper [4] models network behavior as SMT constraints, ARC [11] and Tiramisu [1] model network behavior as a graph, and Plankton [24] uses explicit-state model checking.

Despite their different approaches, these prior tools share one important limitation: they model and reason about network behavior monolithically. Specifically, they analyze the network and its configuration as a whole, exhaustively exploring all possible control-plane behaviors of the network that are induced by the complex interactions among all configuration directives and protocols. The requirement that entire networks be analyzed as a unit prevents these approaches from scaling to large networks, severely limiting their practical applicability.

In this paper, we present a modular approach to control plane verification. Like the prior control-plane verifiers, LIGHTYEAR takes as input a network’s configuration and a property to verify. However, LIGHTYEAR additionally requires the user to provide a set of local invariants that should hold on the BGP policies of individual nodes and edges in the network. LIGHTYEAR then automatically produces a set of local checks on individual nodes and edges that a) verify the user’s local invariants and b) ensure that these invariants imply the given end-to-end property. We focus on BGP since it is ubiquitous, and our approach targets a common class of safety properties, which intuitively ensure that “bad” routes never reach a particular node. For example, our approach can express and modularly ensure that routers never install routes to bogon addresses and that routes from one ISP are never advertised to another one.

We have formalized our approach to modular control plane verification, proved its correctness, and built a tool called LIGHTYEAR based on it. Our approach can be viewed as a general approach for control plane assume-guarantee reasoning—a technique that has previously been applied successfully to software verification [16,23] and to scale network data plane [14] verification to colossal cloud networks. While in principle a user can provide a different local invariant for each location (node or edge) in the network, clearly this is undesirable. Instead, we observe that in practice locations can typically be partitioned into three sets, with all locations in a set sharing the same local invariant. Intuitively, there are a small number of locations whose job is to establish an invariant (e.g., by tagging certain traffic with a community), many locations that maintain the invariant (e.g., by not stripping the community), and a small number of locations that use the invariant to enforce a desired property (e.g., dropping announcements that are tagged with the community). This reasoning naturally aligns with the common partitioning of
network nodes into roles (e.g., border and core routers) and is also analogous to modular reasoning in other settings, for example for software [13].

LIGHTYEAR’s approach offers several advantages over the prior work, as summarized in Table 1:

**Scalability** LIGHTYEAR performs a linear number of checks in the size (number of nodes and edges) of the network, and the complexity of each check depends only on the complexity of the configuration at individual nodes. Hence LIGHTYEAR scales roughly linearly with the network size. This contrasts with the prior approaches, which must reason about the joint behavior of all nodes’ policies. LIGHTYEAR’s local checks are also trivially parallelizable and enable incremental re-checking when a router’s configuration changes.

**Strong Guarantees** If all of LIGHTYEAR’s local checks are satisfied, then the specified network property is guaranteed to hold for all possible external route announcements from neighbors and for all possible node/link failures. Intuitively, the use of local checks enables this strong guarantee since each check makes minimal assumptions about the rest of the network. As shown in the first two rows of the table, of the prior work only Minesweeper [4] supports reasoning about both external route announcements and failures.

**Localization** When prior approaches identify incorrect network behavior, the resulting counterexample is a global snapshot of the routing and forwarding states of all routers and a packet that exhibits the violation in this state. The operator still has the difficult job of analyzing this counterexample to determine which router and policy is erroneous and how it is wrong. In contrast, a local-check violation in LIGHTYEAR directly indicates which network location is erroneous and what local invariant it violates.

To obtain these benefits, LIGHTYEAR makes two main tradeoffs, also shown in the table. First, LIGHTYEAR supports reasoning about a restricted, but common, class of network safety properties. Second, LIGHTYEAR’s modular approach requires extra effort for users to specify the intended local network invariants. However, networks are already designed in a modular and structured fashion, so in practice these invariants tend to be simple and few in number.

To evaluate LIGHTYEAR, we perform three sets of experiments. First, we compare the performance of LIGHTYEAR and Minesweeper on synthetically generated networks of various sizes. Minesweeper’s time increases drastically in the size of the network while LIGHTYEAR scales linearly. Second, we used LIGHTYEAR to verify three end-to-end safety properties for BGP in a large cloud provider’s wide-area network, which has hundreds of routers and tens of thousands of BGP edges. To our knowledge no prior tool that reasons about all possible external route announcements has been demonstrated at this scale. Third, we run tests on a university network to show how well LIGHTYEAR can localize violations.

In summary, we make the following contributions:

1. We describe a novel solution to scaling control plane verification by checking local invariants of individual routers.
2. We formalize our modular approach, based on a formal model of BGP routing, and prove correctness.
3. We instantiate our approach in the tool LIGHTYEAR.
4. We demonstrate LIGHTYEAR’s ability to scale to very large networks experimentally.

## 2 Approach Overview

In this section we illustrate how LIGHTYEAR works with the example shown in Figure 1. In the example network, each edge represents a connection between BGP speakers. The network contains three BGP routers: R1, R2, and R3. R1 and R2 each have an ISP as an external neighbor. R3 is connected to an external neighbor that is a customer. The network satisfies a standard no-transit property, as shown in the figure: routes originating from ISP1 should not be advertised to ISP2.

Existing control-plane verifiers [1, 4, 11, 24, 26] would verify this no-transit property by creating a representation of the possible data planes that can result from the entire network’s configuration and then searching this representation for a counterexample to the no-transit property. However, we observe that network configurations are highly structured and modular by design, with each node having its own responsibilities that combine to ensure desired global properties. In our running example, the no-transit property is ensured using a common approach based on communities and depends only on the following node-local behaviors of individual BGP route maps:

- (1) R1 tags routes from ISP1 with community 100:1;
- (2) R2 filters routes tagged with 100:1 when advertising to ISP2; and
- (3) no router strips community 100:1 from routes that it advertises. Prior tools are not aware of this modular structure and so cannot leverage it.

Figure 2 shows the architecture of LIGHTYEAR. Like prior control-plane verifiers, it takes as input the network configuration and an end-to-end property to verify. However, LIGHTYEAR additionally requires the user to provide network invariants that specify a condition for routes to satisfy at each location in the network — either installed at a particu-
lar node or sent along a particular edge. As we show below, these network invariants directly capture relevant information about the modular structure of the configurations. From these inputs LIGHTYEAR generates a set of local checks on individual nodes in the network and uses an SMT solver to verify each one. If all of these local checks succeed, then the end-to-end property is guaranteed to hold, for all possible external route announcements from neighbors and for all possible link and node failures in the network. Otherwise, LIGHTYEAR provides counterexamples for each failed local check.

In the rest of this section, we show how LIGHTYEAR modularly verifies the no-transit property for the network in figure 1; relevant information is summarized in Table 2.

**End-to-end Property** In LIGHTYEAR, the end-to-end property of interest is specified as a pair of a particular location in the network and a predicate on the routes reaching that location. As shown in the first line of the table, the no-transit property specifies that no route on the edge from R2 to ISP2 should originate at ISP1. To enable the expression of rich properties, LIGHTYEAR allows users to define *ghost attributes* that conceptually update message headers with additional fields. This is a common technique in software verification, where additional variables are introduced that do not affect the computation but allow for easier property specification [9]. In the table, `FromISP1(r)` is a boolean ghost variable that is defined by the user to be false in all originated routes, set to true by the import filter on R1 from ISP1, and left unchanged by all other filters.

**Network Invariants** While in principle the user could specify a different invariant for each network location, in practice locations can be partitioned into a small number of equivalence classes, each playing a different role in ensuring the end-to-end property. In our running example, there are three equivalence classes, which correspond exactly to the three node-local behaviors described earlier that ensure the no-transit property. Table 2 shows the three associated local invariants. First, no assumption is made about the routes coming from ISP1 to R1, so the associated predicate is `True`. Second, routes coming from R2 to ISP2 should not come from ISP1. Note that this invariant is identical to the end-to-end property, which is common but need not be the case. Third, all other locations in the network should satisfy the key correctness invariant: routes from ISP1 must be tagged with the community `100:1`. Notably, this three-part decomposition is analogous to the modular verification of software [13], which typically involves a *precondition* that is assumed to hold initially, a *postcondition* to be proven, and one or more *inductive invariants* that hold throughout each execution and are sufficient to imply the postcondition.

**Generated Checks** Given this information from the user, LIGHTYEAR automatically generates local checks to validate the given network invariants. Notably, each local check pertains to a single BGP filter of a single network router. Together these checks implement a form of *assume-guarantee reasoning* [16,23]: each location’s network invariant is proven under the assumption that the local invariant of its directly connected

Table 1: Comparison of prior verification tools with LIGHTYEAR.
locations hold. As we formalize later, together these checks imply that all of the local invariants of all locations in the network are respected.

The bottom of Table 2 shows the local checks that LIGHTYEAR automatically generates for our running example. The first check ensures that the export filter at R1 on the edge from ISP1 to R1 establishes the key invariant

\[ \text{FromISP1}(r) \Rightarrow 100:1 \in \text{Comm}(r) \]

Since that filter tags all routes with community 100:1, the check is easily provable by an SMT solver. The second check ensures that the key invariant is sufficient to ensure that routes from ISP1 are not exported on the edge from R2 to ISP2. Since the export filter at R2 on that edge drops all routes that are tagged with 100:1, the check passes. The third set of checks ensures that the key invariant is preserved by all other import and export filters in the network. Since these filters never strip community 100:1 from a route, the checks pass.\(^1\) Lastly (not shown in the figure), LIGHTYEAR generates a local check that the invariant on the edge from R2 to ISP2 implies the end-to-end property. This check is trivially since the two properties are identical.

In summary, LIGHTYEAR’s approach to control-plane verification leverages the modular structure that is already present in the network configurations. By requiring the user to make this structure explicit through a set of local invariants at each location, LIGHTYEAR soundly reduces checking an end-to-end network property to a set of checks that each pertain to a single BGP import or export filter. This approach has numerous benefits over the prior, monolithic approaches. First, our approach is highly scalable, since the number of checks is linear in the number of edges in the BGP network graph. Second, LIGHTYEAR’s modular checks provide an extremely strong guarantee, covering both all possible external route announcements from neighbors and all possible failure scenarios. Third, the modular approach naturally supports incremental verification when a node is updated: only the local checks pertaining to that node must be re-checked. Finally, modularity has large benefits for error localization and understanding: the failure of a local check directly pinpoints the erroneous import or export filter and the local invariant that it fails to satisfy.

Table 2: Using LIGHTYEAR to prove the no-transit property from figure 1. The user-provided global property and local invariants are shown in green. LIGHTYEAR-generated local verification checks are shown in blue.

\(^1\)There are also some analogous checks for originated routes, but they are omitted here for simplicity.

3 Formal Model of BGP

In this section we define a model of BGP in terms of traces and axioms on traces. This model is used in the next section to make LIGHTYEAR’s approach precise and to prove its correctness.

3.1 BGP Topologies and Policies

We model a network’s BGP configuration as consisting of two parts: a *topology* and a *policy*. A BGP network topology is a tuple of the form (ROUTERS, EXTERNALS, EDGES), where:

1. **ROUTERS** is the set of routers for which the user provides configurations.
2. **EXTERNALS** is the set of external routers. That is, there is no provided configuration, but each such router is an eBGP or iBGP peer with at least one router in ROUTERS.
3. **EDGES** is the set of directed edges corresponding to BGP peering sessions.

The network topology forms a graph with ROUTERS \cup EXTERNALS as the set of nodes and EDGES as the set of edges. We will use the notation \( A \rightarrow B \) to refer the directional edge \((A, B)\) in the topology.

A BGP route (or route advertisement) is modeled as a tuple (Prefix, ASPath, NextHop, LocalPref, MED, Comm) where:

1. NextHop, LocalPref, and MED are integer values
2. Prefix is a pair consisting of an IP address and a length, both of which are integer values.
3. ASPath and Comm are lists of integer values.

Let \( T \) denote the set of all traces. We will use \( \text{Comm}(r) \) to refer to the Comm field of the route \( r \), \( \text{Prefix}(r) \) to refer to the prefix of \( r \), and so on. Real BGP messages contain a few other attributes as well, which could be incorporated into this model in the future. \( \text{LIGHTYEAR} \) also allows routes to be extended with additional “ghost” attributes, such as the FromISP1 attribute from section 2; they are described in Section 4.5.

We model the BGP network policy as consisting of three functions, which can be derived from the BGP and route-map configurations of each router:

1. \( \text{Import} : \text{Edges} \times \text{Routes} \rightarrow \text{Routes} \cup \{\text{Reject}\} \)
2. \( \text{Export} : \text{Edges} \times \text{Routes} \rightarrow \text{Routes} \cup \{\text{Reject}\} \)
3. \( \text{Originate} : \text{Edges} \rightarrow \mathcal{P}(\text{Routes}) \)

For an edge \( A \rightarrow B \) and a route \( r \), \( \text{Import}(A \rightarrow B, r) \) either returns the route produced when applying the import filter at \( B \) to the route \( r \) sent from \( A \) or returns \text{Reject} if the import filter rejects the route. \( \text{Export}(A \rightarrow B, r) \) either returns the route produced when applying the export filter at \( A \) to the route \( r \) sent to \( B \) or returns \text{Reject} if the export filter rejects the route. \( \text{Originate}(A \rightarrow B) \) returns the set of routes that are originated at \( A \) and sent to \( B \).

### 3.2 BGP Traces

We model the semantics of BGP as a set of allowed traces. Our semantics is a variant of that from the Bagpipe tool [26], but simplified for our setting.

A trace is a sequence of events. In BGP, there are three types of events: \( \text{recv}, \text{slct}, \text{and} \text{frwd} \). For \( r \in \text{Routes} \), \( R \in \text{Routers} \), and \( N \in \text{EXTERNALS} \), and \( R \rightarrow N \in \text{Edges} \):

1. \( \text{recv}(N \rightarrow R, r) \) occurs when \( R \) receives route \( r \) from neighbor \( N \).
2. \( \text{slct}(R, r) \) occurs when \( R \) selects \( r \) as the best route for a destination and installs it.
3. \( \text{frwd}(R \rightarrow N, r) \) occurs when \( R \) forwards route \( r \) to the neighbor \( N \).

We denote the set of all traces as \( \text{Traces} \).

A valid trace is one that could occur for a given topology and policies, according to the BGP semantics. We formalize the notion of trace validity as a set \( \text{VALID} \subseteq \text{Traces} \) of traces that satisfy specific properties. However, our formalization deliberately over-approximates the set of such traces — we include some traces that are not actually legal according to the BGP semantics. Doing so has two advantages. First, over-approximation simplifies our formalism considerably yet is still sound for reasoning about safety properties, which is our focus. For example, our formalism does not need to model the route selection process at all, instead assuming that any received route can potentially be selected. Second, over-approximation allows us to reason about failures “for free,” as the set of traces that we consider valid includes all of those that could occur under any failure scenario (see Section 4.4).

We consider a trace \( A_1, A_2, \ldots, A_n \) to be valid, and hence part of the set \( \text{VALID} \), if it satisfies the following properties, for all \( 1 \leq k \leq n \):

1. If \( A_k = \text{recv}(N \rightarrow R, r) \), then either:
   
   (a) \( \text{N} \in \text{EXTERNALS} \), or
   (b) there exists \( j < k \) such that \( A_j = \text{frwd}(N \rightarrow R, r) \)
2. If \( A_k = \text{slct}(R, r) \), then there exists \( j < k, r' \in \text{Routes} \), and \( N \in \text{Routers} \cup \text{EXTERNALS} \) such that \( A_j = \text{recv}(N \rightarrow R, r') \) and \( r = \text{Import}(N \rightarrow R, r') \)
3. If \( A_k = \text{frwd}(R \rightarrow N, r) \), then either:
   
   (a) \( r \in \text{Originate}(R \rightarrow N) \), or
   (b) there exists \( j < k \) and \( r' \in \text{Routes} \) such that \( A_j = \text{slct}(R, r') \) and \( r = \text{Export}(R \rightarrow N, r') \)

Intuitively these properties require basic consistency among the events in a trace: a received route at \( R \) from \( N \) must be preceded by a forwarding of that route from \( N \) to \( R \) (unless \( N \) is external); a selected route must be the result of applying an import filter to a received route; and a forwarded route from \( R \) to \( N \) must either originate at \( R \) or be the result of applying the appropriate export filter to a selected route at \( R \).

### 4 LIGHTYEAR

\( \text{LIGHTYEAR} \) takes as input three things: the router configurations, a network property to be verified, and invariants for each location (node or edge) in the network. \( \text{LIGHTYEAR} \) then generates and performs a set of local checks on individual BGP filters in the network. If all checks succeed, that implies that the given network property holds. Otherwise, a counterexample is produced, which points the user to a specific location whose network invariant could not be proven.

This section makes \( \text{LIGHTYEAR} \)’s approach precise. We describe the tool’s three inputs, show the local checks that \( \text{LIGHTYEAR} \) generates from these inputs, and prove the correctness of the approach. Finally, we describe two important extensions to this formal model, respectively to reason about arbitrary network failures and to enable users to provide additional ghost route attributes.

#### 4.1 Inputs

\( \text{LIGHTYEAR} \)’s first input, the network configurations, is standard. As described previously, the configurations are used to build the BGP topology as well as the policy functions.

The second input is the network property. \( \text{LIGHTYEAR} \) focuses on a common class of safety properties, which requires that all route announcements that can reach a particular location satisfy certain constraints. Many network policies fall into this class of safety properties, for example bogon filtering; ensuring that a network only advertises routes to its own destinations; no-transit policies (see Section 2); and forms of isolation between nodes or groups of nodes. Such properties can also express complex constraints among BGP attributes, for example that prefixes in a specific range always have a particular local preference or MED value.
Formally, a network property is a pair \((\ell, P)\) where:
\[(\ell, P) \in (\text{Routers} \cup \text{Edges}) \times \mathcal{P}(\text{Routes})\]

\(\ell\) is a location, either a router or an edge, and \(P\) is a set of routes matching a particular constraint. In practice, users directly specify a logical constraint on route attributes that represents \(P\). For example, users might specify the location \((R1 \rightarrow R2)\) and a constraint \(1:1 \in \text{Comm}(r)\), specifying the property that routes sent on the edge \(R1 \rightarrow R2\) should always have the community \(1:1\).

Each network property \((\ell, P)\) corresponds to a property of all possible valid traces, as defined in the previous section—all routes that can reach location \(\ell\) must satisfy \(P\). Formally, a network satisfies a property \((\ell, P)\) if for all \(T \in \text{Valid}, r \in \text{Routes}, R, N \in \text{Routers}\):

- if \(\ell = R\) and \(\text{slct}(R, r) \in T\), then \(r \in P\)
- if \(\ell = R \rightarrow N\) and \(\text{frwd}(R \rightarrow N, r) \in T\), then \(r \in P\)

Finally, \(\text{LIGHTYEAR}\)'s third input is a set of network invariants, one per location in the given network. Formally, the network invariants are modeled as a set of pairs denoted \(I\):

\[I \subseteq (\text{Routers} \cup \text{Edges}) \times \mathcal{P}(\text{Routes})\]

Each element of the set has the form \((\ell, P)\), where \(\ell\) is a location and \(P\) is a set of routes, as in the network property defined above. The semantics of each pair is a property of traces, analogous to the semantics of network properties shown above.

We require that there exist exactly one pair in \(I\) per location in the given network, and we use the notation \(I_\ell\) to denote the set \(P\) of routes associated with location \(\ell\) in \(I\). We also require that \(I_{R \rightarrow N} = \text{Routes}\) for each edge \(R \rightarrow N\) where \(R \in \text{Externals}\). In other words, we make no assumption about routes coming from external neighbors but rather assume that any route may be advertised.

### 4.2 Local Checks

Given the network configuration, network property \((\ell, P)\), and network invariants \(I\), \(\text{LIGHTYEAR}\) generates the following local checks for each edge \(A \rightarrow B\) in the network topology:

1. **Import**: For all \(r, r' \in \text{Routes}\), if \(r = \text{Import}(A \rightarrow B, r')\) and \(r' \in I_{A \rightarrow B}\), then \(r \in I_B\).
2. **Export**: For all \(r, r' \in \text{Routes}\), if \(r = \text{Export}(A \rightarrow B, r')\) and \(r' \in I_A\), then \(r \in I_{A \rightarrow B}\).
3. **Originate**: For all \(r \in \text{Routes}\), if \(r \in \text{Originate}(A \rightarrow B)\), then \(r \in I_{A \rightarrow B}\).

If the router \(B\) is external then the import check is not performed, and similarly if the router \(A\) is external then the export and originate checks are not performed. In our implementation of \(\text{LIGHTYEAR}\), the local checks are performed by modeling import and export filters using SMT constraints and invoking an SMT solver to validate each check or provide a counterexample.

Finally, \(\text{LIGHTYEAR}\) checks that the network invariants \(I\) imply the network property \((\ell, P)\). This is done simply by requiring that \(I_\ell \subseteq P\), i.e., that the network invariant for \(\ell\) implies the network property \(P\). Again this check is performed with an SMT solver.

### 4.3 Correctness

In this section we prove that \(\text{LIGHTYEAR}'s modular approach to control-plane verification is correct.

First we state and prove the key lemma, which says that the local checks are sufficient to ensure that the network invariants \(I\) hold, for all valid traces.

**Lemma**: Given a BGP topology and policy as well as network invariants \(I\), let \(C\) be the set of Import, Export, and Originate checks that \(\text{LIGHTYEAR}\) generates. If all checks in \(C\) pass, then for all \(T \in \text{Valid}, r \in \text{Routes}, R, N \in \text{Routers}\):

- if \(\text{slct}(R, r) \in T\), then \(r \in I_R\)
- if \(\text{frwd}(R \rightarrow N, r) \in T\), then \(r \in I_{R \rightarrow N}\)
- if \(\text{recv}(R \rightarrow N, r) \in T\), then \(r \in I_{N \rightarrow R}\)

**Proof**: The proof is by induction on the length of the (partial) trace \(T\).

**Base case**: For a partial trace of length 0, there are no events, so the statement is vacuously true.

**Inductive case**: Suppose \(T = A_1, A_2, \ldots, A_{k+1}\). We assume by induction that the statement is true for \(A_1, A_2, \ldots, A_k\). We do a case analysis on the event \(A_{k+1}\):

- Case \(A_{k+1} = \text{recv}(N \rightarrow R, r)\), so we have to show that \(r \in I_{N \rightarrow R}\). By the trace validity axioms, \(|r| = 2\). For all traces with \(r \in \text{Routes}\), we know that the network invariants \(I\) hold.

  - There exists \(j < k + 1\) such that \(A_j = \text{frwd}(N \rightarrow R, r)\). Then by the inductive hypothesis we have that \(r \in I_{N \rightarrow R}\). By the import check in \(C\) for \(N \rightarrow R\), we can conclude that \(r \in I_{R \rightarrow N}\).

  Case \(A_{k+1} = \text{slct}(R, r)\), so we have that \(r \in I_{R \rightarrow N}\). From the trace validity axioms, we know that there exists \(j < k + 1\), \(r' \in \text{Routes}\), and \(N \in \text{Routers} \cup \text{Externals}\) such that \(A_j = \text{frwd}(N \rightarrow R, r')\) and \(r = \text{Import}(N \rightarrow R, r')\). From the inductive hypothesis, we know that \(r' \in I_{N \rightarrow R}\). Therefore by the import check in \(C\) for \(N \rightarrow R\), we can conclude that \(r \in I_{R \rightarrow N}\). By the trace validity axioms, either:

  - \(r \in \text{Originate}(N \rightarrow R)\). Then from the Originate check in \(C\) for \(N \rightarrow R\), we have that \(r \in I_{R \rightarrow N}\). Then from the Originate check in \(C\) for \(N \rightarrow R\), we can conclude that \(r \in I_{R \rightarrow N}\). Now we prove the correctness theorem for \(\text{LIGHTYEAR}\), which says that \(\text{LIGHTYEAR}'s checks are sufficient to ensure that the given network property holds, for all valid traces.

**Theorem**: Given a BGP topology and policy, a network property \((\ell, P)\), and network invariants \(I\), let \(C\) be the set of Import, Export, and Originate checks that \(\text{LIGHTYEAR}\) generates. If all checks in \(C\) pass and \(I_\ell \subseteq P\), then for all \(T \in \text{Valid}, r \in \text{Routes}, R, N \in \text{Routers}\):

- if \(\ell = R\) and \(\text{slct}(R, r) \in T\), then \(r \in P\)
• if $\ell = R \rightarrow N$ and $\text{frwd}(R \rightarrow N, r) \in T \lor \text{recv}(R \rightarrow N, r) \in T$, then $r \in P$.

Proof: There are two cases:
1. $\ell = R$ and $\text{slot}(R, r) \in T$. From the earlier lemma we have that $r \in I_\ell$, and since $I_\ell \subseteq P$ it follows that $r \in P$.
2. $\ell = R \rightarrow N$ and $\text{frwd}(R \rightarrow N, r) \in T \lor \text{recv}(R \rightarrow N, r) \in T$. Again from the earlier lemma we have that $r \in I_\ell$, and since $I_\ell \subseteq P$ it follows that $r \in P$.

4.4 Fault Tolerance

A significant benefit of LIGHTYEAR’s approach to control-plane verification is that it supports reasoning about failures “for free.” That is, if all of LIGHTYEAR’s checks pass, then the given network property is guaranteed to hold not only in the failure-free case but also in the presence of arbitrary node and link failures.

The fact that LIGHTYEAR soundly reasons about failures is a consequence of our over-approximate notion of trace validity (Section 3.2). Specifically, any trace that is feasible according to the given BGP topology and passes the import/export filters along the corresponding path is considered valid. Hence, every trace that can occur under any failure scenario is already considered valid. By our correctness theorem, all of these traces satisfy the property $(\ell, P)$.

One potential downside of using an over-approximate notion of trace validity is that it could cause LIGHTYEAR to incur false positives — signaling errors when none exist. Notably, trace validity does not take into account the BGP preference relation, but rather assumes that any received route could be installed at a router. However, our notion of validity is quite natural for the class of properties that LIGHTYEAR supports, namely those that ensure that certain “bad” events never occur. Indeed, when given correct invariants, LIGHTYEAR did not incur any false positives in our evaluation (Section 6).

4.5 Ghost Attributes

As described in Section 4.1, a property that LIGHTYEAR verifies is described as a set of routes that can reach a particular location. By default, that set can be described as a predicate on the attributes of a route $r$, for example $1:1 \in \text{Comm}(r)$. However, many natural properties cannot be described using solely route attributes. For example, in our no-transit example from Section 2 we would like to specify that the route $r$ does not originate at ISP1.

To increase LIGHTYEAR’s expressiveness, we allow users to define their own ghost attributes, which conceptually extend each route with additional fields. For example, the $\text{FromISP1}(r)$ ghost attribute from Section 2 is used to indicate whether $r$ originated from ISP1. A ghost attribute is defined by specifying the set of values that the attribute can take, along with updates to the Import, Export, and Originate functions that make up the given network’s policy (Section 3.1).

In the case of $\text{FromISP1}(r)$, the user would declare it as a boolean attribute and provide the following updates to the network policy functions (see Figure 1):

- the import filter on the edge ISP1 $\rightarrow$ R1 sets $\text{FromISP1}$ to true
- the import filter on the edge ISP2 $\rightarrow$ R2 sets $\text{FromISP1}$ to false
- all other import and export filters leave $\text{FromISP1}$ unchanged
- all originated routes have $\text{FromISP1}$ set to false

Many other natural network properties can be expressed using ghost attributes. For example, it is possible to define a WaypointR attribute that is true only for routes that have been processed by a particular router $R$. This can be done by specifying that filters on $R$ set WaypointR to true, origination as well as import filters from external neighbors at other routers set WaypointR to false, and filters between the routers in the network leave WaypointR unchanged.

Ghost attributes do not affect our description of LIGHTYEAR or proof of its correctness above at all, as they do not depend on the specific set of attributes that are in a route.

5 Implementation

LIGHTYEAR uses Batfish [10] to parse network configurations and determine the topology and policy. Since Batfish converts the configurations into a vendor-independent format, this allows LIGHTYEAR to handle configurations from numerous different vendors, such as Cisco and Juniper.

Properties and invariants are specified as Python functions mapping routers and edges to BGP route constraints. Our implementation allows users to define one boolean ghost variable, with Python functions to specify how route import, export, and origination should affect the variable’s value. Currently, we allow ghost variables to be transformed based on the location in the network, but not based on other route attributes. For example, users can specify that an import filter changes the value of a variable to true, but users cannot specify that the filter transforms the variable to true if the prefix is 10.0.0.0/8. This is not a fundamental limitation but simplifies our implementation and has been sufficient for our use cases.

The code for generating local checks from the user-provided invariants is written in Python. The local checks rely on the symbolic modeling of BGP policies [4]. Specifically, BGP route announcements are modeled as symbolic variables, and BGP route maps in the configurations are modeled as SMT constraints on these symbolic variables, and the Z3 SMT solver [7] is used to perform the local checks. Minesweeper’s symbolic analysis supports many common features of BGP route maps, like communities, local preference, and MEDs, as well as other configurable aspects of BGP like route origination. However, it does not support reasoning about AS-path filtering, which is necessary for one of our use cases. For that, we use an alternate backend for symbolic route analysis from Batfish that is based on binary decision diagrams (BDDs) [3].

Table 3: Comparison of runtimes between LIGHTYEAR and Minesweeper for synthetic networks of various sizes. X denotes a time that exceeds two hours. The time does not include time taken to parse configurations into the Batfish vendor-independent format.

There are many possible optimization opportunities to exploit in the future. For example, the local checks are easily parallelizable — separate processes can be created to perform checks from multiple routers at the same time. Another possibility is performing a single local check for policies duplicated in multiple routers. Despite lacking these sorts of optimizations, LIGHTYEAR was still able to scale to verify properties of the wide-area network of a major cloud provider, as we show in the next section.

6 Evaluation

In this section, we present three sets of experiments. First we compare the differences in scaling between LIGHTYEAR and Minesweeper [4] on synthetically generated networks of various sizes. We use Minesweeper since it is a state-of-the-art tool that is capable of checking the kinds of properties that we target, which require reasoning about all possible external route announcements. Second, we use LIGHTYEAR to verify three different properties of the wide-area network (WAN) of a major cloud provider, which has hundreds of routers and tens of thousands of edges. To our knowledge, LIGHTYEAR is the first tool that can scale to verify these kinds of properties on a network of that size. These experiments were performed on a system with 32GB of RAM and 8 cores, though no explicit parallelism was used. Third, we show how the output from LIGHTYEAR can aid in understanding and localizing errors in a university network.

6.1 Scaling Experiments

First we compared LIGHTYEAR and Minesweeper tools on synthetic test cases. We use a BGP full mesh where each router is connected to one external neighbor through eBGP and all other routers through iBGP. This leads to a total of \( N^2 \) edges in a network of size \( N \). The policy of the network was kept relatively simple, with each eBGP connection using only prefix and community filters. We checked a simple no-transit property similar to the example shown in figure 1. The number of routers, the number of edges, and the run times are shown in Table 3. Minesweeper does not terminate within two hours when run on a network of size 40, while LIGHTYEAR verifies a network of size 100 in 5.5 minutes.

Figure 3 provides more details on these results by comparing the number of SMT variables and assertions (i.e., constraints) generated by each tool, as well as the amount of time used to solve the SMT constraints compared to the total computation time. As the network size increases, Minesweeper requires several orders of magnitude more SMT variables and assertions than the maximum number required by LIGHTYEAR for any local check. As a result, SMT solving time dominates the run time of Minesweeper and is the limiting factor on its ability to scale, while for LIGHTYEAR the solving time is a relatively small portion of the total time.

We also ran scalability experiments on subsets of the cloud provider’s WAN network of various sizes. For each such subset we verified a property that external route announcements for bogon routes are disallowed (see the first use case in the next subsection). The results are shown in Table 4. The computation times are greater than for the synthetic networks of similar size, since the WAN configurations are more complex. Nonetheless, again LIGHTYEAR is scaling very well, verifying the property for a network of 100 routers in about 13 minutes, while Minesweeper times out after 2 hours. Further, as described below, LIGHTYEAR scales to verify the no-bogons property on the entire WAN in 240 minutes, while Minesweeper does not finish even after running for 24 hours.

6.2 Cloud WAN

In this section, we show that LIGHTYEAR can scale to verify a range of properties on the wide-area network (WAN) of a major cloud provider, containing hundreds of routers and tens of thousands of edges. To our knowledge no prior tool that verifies properties of all possible external announcements from neighbors has been demonstrated to scale to such a size. We describe three use cases in turn.

No Bogons: First, we verified that no router in the network installs a bogon route advertised from an external neighbor. Bogons refer to address spaces that are not used on the public internet and so should only be used internally. The property
to verify is as follows, for each node $R$ in the network:

$\{ R, \{ r \mid \text{FromPeer}(r) \implies \text{PREFIX}(r) \notin \text{BOGONS} \} \}$

Here, BOGONS is a set of bogon prefixes, and the FromPeer property is defined with a ghost variable that is set to true on all edges coming from external peers — external routers that have a different ASN from that of the cloud network. Note that the property still allows routers to receive routes to private addresses from iBGP and from eBGP sessions with other routers in the same network.

The WAN enforces the property above by having BGP filters at edge routers that drop announcements to bogon routes from external peers. This approach is easily verified to be correct by LIGHTYEAR, using the network invariants shown in Table 5a. In this case, the network invariants are identical to the network property, except that no assumptions are made on edges to and from external peers. LIGHTYEAR’s checks on the entire WAN network took a total of about 240 minutes, with the average check lasting only a fraction a second. We attempted to use Minesweeper to verify the no-bogons property for all possible external route announcements (but without considering failures), but it did not finish even after 24 hours.

Proper IP Reuse: In the second use case, we used LIGHTYEAR to verify that reused IPs are contained within a region. In the cloud network, some private IPv4 addresses are reused in different regions. Traffic sent to these private addresses must stay within the region. We verified this property for a single region. Specifically the property to verify is as follows, for each router $R$ that is not part of the region:

$\{ R, \{ r \mid \text{FromRegion}(r) \implies \text{PREFIX}(r) \notin \text{REUSEDIPS} \} \}$

Here FromRegion($r$) is a ghost variable that is set to true only on routes coming from external routers in the particular region, and REUSEDIPS is the set of prefixes that are reused.

The WAN enforces this property by tagging routes for reused IP addresses with a region-specific community $C$ when they are received from data centers. Routers in the same region then accept routes tagged with that community, while routers in other regions reject them. The network invariants that we provided to LIGHTYEAR to verify this approach are shown in Table 5b. One subtlety is that routes to reused IP addresses in the region must not only have the community $C$, but they also must not be tagged with the community of any other region. Otherwise, the routes could be accidentally accepted by those other regions. This property is enforced in the WAN by deleting all communities on routes coming from the data centers, before adding the community $C$. Unfortunately, neither the SMT modeling of routing from Minesweeper nor the

Figure 3: Comparison between LIGHTYEAR and Minesweeper on synthetic networks of various sizes.
Again, FromPeer is defined with a ghost variable that is set to true only on routes from certain peers. For this case, we did not check every peer but focused on the peers using a common policy, which comprise most of the eBGP connections.

This property is enforced by the WAN using AS-path filtering. Specifically, the configurations ensure that routes accepted from certain peers match specific AS-path regular expressions and prefixes, and the edges to other peers filter out those same routes. The network invariants used to verify this approach are shown in Table 5c. Here, VALIDPATHS is the set of AS paths that are allowed for routes coming from certain peers, represented as a regular expression. Similarly, VALIDPFXS is the set of prefixes that are allowed for routes coming from those peers. We ran this check primarily on the

(c) The end-to-end property and network invariants that are needed to verify no transit between peers. When checking, FromPeer here refers to a limited set of peers with common policies

Table 5: End-to-end properties and network invariants for three use cases in the WAN.

BDD modeling of routing from Batfish supports community deletion. Therefore, we instead verify a weaker version of the proper IP reuse property. Specifically, we make the assumption that external routes contain no communities, as shown in the last row of Table 5b, and LIGHTYEAR successfully verifies proper IP reuse under this assumption.

No Transit: In the third use case, we verified that BGP routes from peers are not exported to other peers. For edges from a router R to a peer P, the property to verify is as follows:

\[(R \to P, \{r \mid \neg\text{FromPeer}(r)\})\]

Again, FromPeer is defined with a ghost variable that is set to true only on routes from certain peers. For this case, we did not check every peer but focused on the peers using a common policy, which comprise most of the eBGP connections.
edge routers responsible for peering. LIGHTYEAR successfully verified the no-transit property.

Other Use Cases: As demonstrated above, LIGHTYEAR can verify complex policies on real-world configurations at scale. Many other common properties of wide-area networks fit within LIGHTYEAR’s expressiveness. For example, communities are commonly used to mark routes based on where they can be advertised or how they should be treated [8]. Some examples of these kinds of properties, which can be expressed and verified in our approach, are listed in Table 6.

### 6.3 University Network

Our experiences running LIGHTYEAR on the campus network of a large university show how the local counterexamples produced can aid in refining the network invariants and localizing errors. We used LIGHTYEAR to verify the property that only university-owned address blocks can be advertised to the ISPs. This property is shown at the top of Table 7. Our initial assumption was that this property only depends on prefix filtering done by the outbound filters on the border routers, so we provided the network invariants shown in the middle of the table. However, LIGHTYEAR produced counterexamples for the local checks on the edges from the border routers to the ISPs, since the outbound filters allow advertisements for other prefixes as long as they are tagged with the well-known blackhole community [19], which tells the ISPs to blackhole that traffic. However, by inspection we found that this mechanism was not being used currently — the blackhole community is not added to any announcements. Hence we were able to still prove the desired end-to-end property, using the refined set of invariants shown at the bottom of Table 7, where SCOMMS represents the set of blackhole communities.

To demonstrate our approach’s utility in error localization, we used LIGHTYEAR again after injecting three errors into the configurations: (1) adding a policy that attaches the blackhole community (2) changing a policy from removing communities to propagating them, and (3) changing the filter at the border router to allow a non-university address block. Each of these errors causes the local checks to fail for the edges using the erroneous routing policy. Further, the counterexample provided by LIGHTYEAR for each error provides the relevant information to understand the error, such as the prefix being advertised and whether communities are being added or propagated. For example, the first error causes the local check to fail because we cannot prove that Comm(r) ∩ SCOMMS = ∅ for all routes r that pass the filter, and the counterexample route includes the blackhole community.

### 7 Related Work

Control Plane Verification: The state-of-the-art approaches to network control-plane verification were summarized earlier in Table 1. Unlike LIGHTYEAR, these approaches are all monolithic — they require joint analysis of the configurations of all nodes in the network — which dramatically limits scalability. Most approaches therefore make tradeoffs in expressiveness, for example giving up the ability to reason about all possible BGP announcements from neighbors [1, 11, 24, 29]. In contrast, LIGHTYEAR’s modular approach only requires reasoning about individual BGP route maps in isolation and so is highly scalable. LIGHTYEAR also provides guarantees across all possible external announcements and all failures. The tradeoff is that LIGHTYEAR supports a more limited set of properties than prior approaches — safety properties that hold of all routes that can reach a particular location — and requires the user to specify local invariants.

Closest to our work is a recent technique for modular control-plane verification called Kirigami [25]. Like our work, the approach provides a form of assume-guarantee reasoning for the control plane using local invariants. However, Kirigami makes a different set of tradeoffs than LIGHTYEAR, leading to different strengths and weaknesses. Kirigami’s local invariants consist of information about the exact routes that will arrive on a particular edge. Because these invariants are fully concrete, Kirigami cannot reason about arbitrary route
announcements from neighbors, which is necessary for the properties that LIGHTYEAR targets, for example no-transit properties. Kirigami also does not reason about failures. On the other hand, Kirigami can verify safety properties that LIGHTYEAR cannot, for example verifying the exact number of hops that routes will take. Further, Kirigami is designed and implemented on top of a generic control-plane representation [12] and so is not restricted to checking BGP policies.

Another line of work has improved scalability of control-plane verification through forms of abstraction [5,6]. In these approaches, the full network is still analyzed monolithically, but irrelevant or redundant configuration information is abstracted away in order to simplify the analysis. Our work on modularity is orthogonal to this line of work and in the future could be potentially combined with it.

Data Plane Verification: Another class of network verification tools check properties of the forwarding state of the network, rather than of the network configurations [2,15,17,18,20,21,27]. These approaches also generally require joint reasoning about the entire network forwarding state as a whole. A recent exception is RCDC [14], which modularly verifies global reachability contracts in a data center via local checks. However, the approach is specific to the data center design and does not provide a general framework for decomposing global property checks into local checks. There has also been work on exploiting forms of abstraction, such as symmetries, to scale data-plane verification [22].

Modular Verification: Assume-guarantee reasoning [16,23] is the foundation for modular verification in other domains, including hardware and software verification. In this style, a global property is modularly by providing each system component with local invariants that it must satisfy, under the assumption that the other components satisfy their invariants. LIGHTYEAR directly applies this methodology in order to generate the local checks that each BGP policy must satisfy, and we have proven that our approach is sound.

Verification commonly requires the identification of inductive invariants, properties that hold over some unbounded space of system states. For example, reasoning about loops in traditional software requires the identification of a loop invariant that summarizes the behavior of the loop no matter how many times it is executed [13]. Though our approach does not specifically require such invariants, we have found that they arise naturally and enable the use of the same local invariant for almost all network locations. In particular, typically one or a small set of nodes establishes an inductive invariant (e.g., by attaching a community to certain routes), and then this invariant holds throughout the network as long as the other nodes “do no harm” (e.g., they never remove communities).
